In the first to third postnatal years (**3**.120) the two halves join at their symphysis from below upwards; separation near the alveolar margin may persist into the second year. The body elongates, especially behind the mental foramen, providing space for three additional teeth (pp. 1317–1318). During the first and second years, as a chin develops, the mental foramen alters direction from anterior to posterosuperior, and then almost horizontally posterior, as in adults (Warwick 1950), accommodating a changing direction of the emerging mental nerve. The proximal zone of the conical condylar cartilage persists as an epiphysial plate. Its proliferation contributes to vertical increase in the ramus and to general mandibular growth which is essentially *downwards and forwards*. With its antimere it also adapts the intercondylar distance to the widening cranial base. The condylar cartilage is covered on its articular aspect by self-perpetuating fibrous tissue, deep to which a proliferating intermediate zone is responsible for ramal growth (and thus displacement of the whole mandible). Beneath this are hypertrophic chondrocytes and then bone (Blackwood 1959). As depth of the body increases, alveolar growth makes room for roots of teeth, the subalveolar region becoming thicker and deeper. After eruption of permanent teeth (**3**.120D,E) the mandibular canal is a little above the mylohyoid line, and the mental foramen occupies its adult position. As the mandible increases in size, bone is added at posterior borders of ramus and coronoid process, absorption occuring at their anterior borders. This remodelling is continuous until adult size is reached, allowing alveolar parts to accommodate permanent molar teeth (Enlow & Harris 1964). Organ culture of condylar cartilage in rats shows no growth potential, but in vivo all mandibular growth cartilages respond to mechanical forces (Petrovic 1972).

In adults (**3**.120E) alveolar and subalveolar regions are about equal in depth, the mental foramen midway between upper and lower borders; the mandibular canal nearly parallels the mylohyoid line. The *angle* between the lower border of body and a plane touching the posterior surface of condyle above, and ramus below, diminishes as ramal height increases with age; but X-ray photographs at different ages (Brodie 1941) show that its *(gonial) contour* remains unaltered.

In old age (3.120F) the bone is reduced in size as teeth are lost and the alveolar region absorbed; the mandibular canal and mental foramen are nearer the superior border. Both may even disappear, exposing the inferior alveolar nerve (Gabriel 1958). The ramus becomes oblique, the angle about 140°, and the neck inclined backwards (Fawcett et al 1924). Absorption affects chiefly the thinner alveolar wall (lingual or labial) and, after completion, a linear *alveolar ridge* is left at the superior border of the mandible (and inferior border of the maxilla). In the mandible the labial wall is thinner in incisor and canine regions, the lingual wall in the molar. The mandibular alveolar ridge hence is within the line of teeth in the former but outside it in molar regions, forming a curve wider posteriorly than that of the line of the teeth, but intersecting it near the premolars. In the maxilla, however, the labial wall is everywhere thinner and after absorption its maxillary alveolar ridge is entirely within the line of teeth.

3.120 The mandible at different periods of life.

The Hyoid Bone

The U-shaped or *hyoid* bone (3.121A,B) is suspended from the tips of the (bilateral) styloid processes by the stylohyoid ligaments. It has a body, two greater and two lesser cornua. **The body** is irregular, elongated and quadrilateral. Its *anterior surface* is convex, facing anterosuperiorly, and is crossed by a transverse ridge with a slight downward convexity; often a vertical median ridge bisects the body; the upper part of this vertical ridge is usually present, the lower part is rare. The *posterior surface* is smooth, concave, faces postero-inferiorly, and is separated from the epiglottis by the thyrohyoid membrane and loose areolar tissue, with a bursa between bone and membrane. In early life the **greater cornua** are connected to the body by cartilage, but after middle age they are usually united by bone. They project back (curving dorsolaterally) from the lateral ends of the body; horizontally flattened, they taper posteriorly, each ending in a tubercle. When the throat is gripped between finger and thumb above the thyroid cartilage, the greater cornua can be identified and the bone can be moved from side to side.

The lesser cornua are two small, conical projections at the junctions of the body and greater cornua, connected basally to the body by fibrous tissue and occasionally to the greater cornua by synovial joints, which occasionally become ankylosed (vide infra).

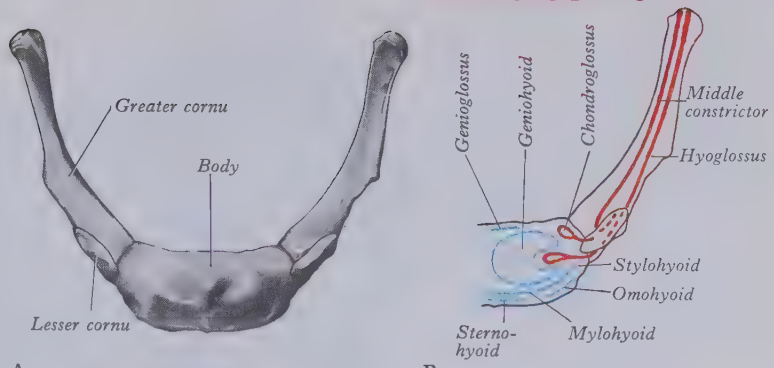
Attached to most of the body's *anterior surface* is geniohyoid, above and below the transverse ridge; but the medial part of hyoglossus invades the lateral geniohyoid area (3.121B). The lower anterior surface gives attachment to mylohyoid, above the sternohyoid medially and omohyoid laterally. To the rounded *superior border* the lowest fibres of the genioglossi, the hyo-epiglottic ligament and (most posteriorly) the thyrohyoid membrane are attached; to the *inferior border* are attached sternohyoid medially and omohyoid laterally, sometimes with the medial fibres of thyrohyoid and levator glandulae thyroideae, when present. The oblique postero-inferior surface was mentioned above.

To the *upper surface of each greater cornu* the middle pharyngeal constrictor and, more laterally (superficially), hyoglossus, are attached along its whole length. Near the junction of cornu with body the stylohyoid muscle is attached, lateral to hyoglossus, and a little posterior to this, the fibrous loop for the digastric tendon. To the *medial border* is attached the thyrohyoid membrane, to the *lateral border* anteriorly the thyrohyoid. The oblique *inferior surface* is separated from the thyrohyoid membrane by fibro-areolar tissue.

At the *posterior* and *lateral aspects of lesser cornua* are the attachments of the middle pharyngeal constrictors. To their apices are attached the stylohyoid ligaments, often partly ossified, and to the medial aspects of their bases, the chondroglossi.

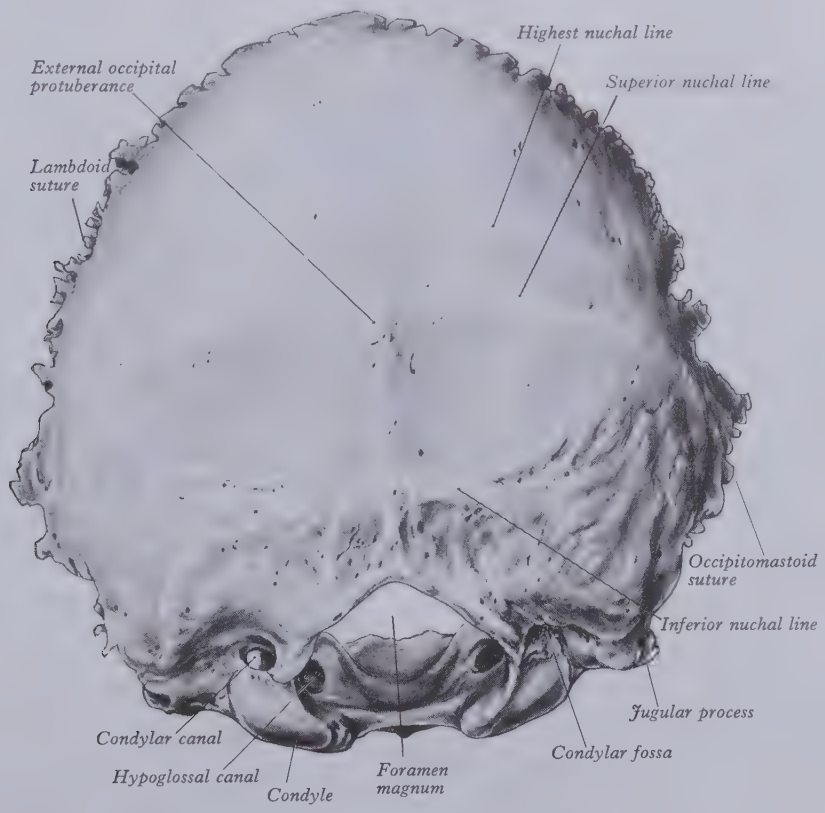
Ossification. The hyoid bone is evolved from cartilages of second and third visceral arches, the lesser cornua from second, the greater from the third and the body from fused ventral ends of both (p. 172). Chondrification begins in the fifth fetal week in these elements, completed in the third and fourth months. Ossification proceeds from six centres—a pair for the body, one for each cornu—commencing in the greater cornua towards the end of intrauterine life, in the body shortly before or after birth, and in lesser cornua around puberty. The greater cornual apices remain cartilaginous until the third decade and epiphyses may occur here. They fuse with the body. Synovial joints between the greater and lesser cornua may be obliterated by ossification in later decades.

The Occipital Bone



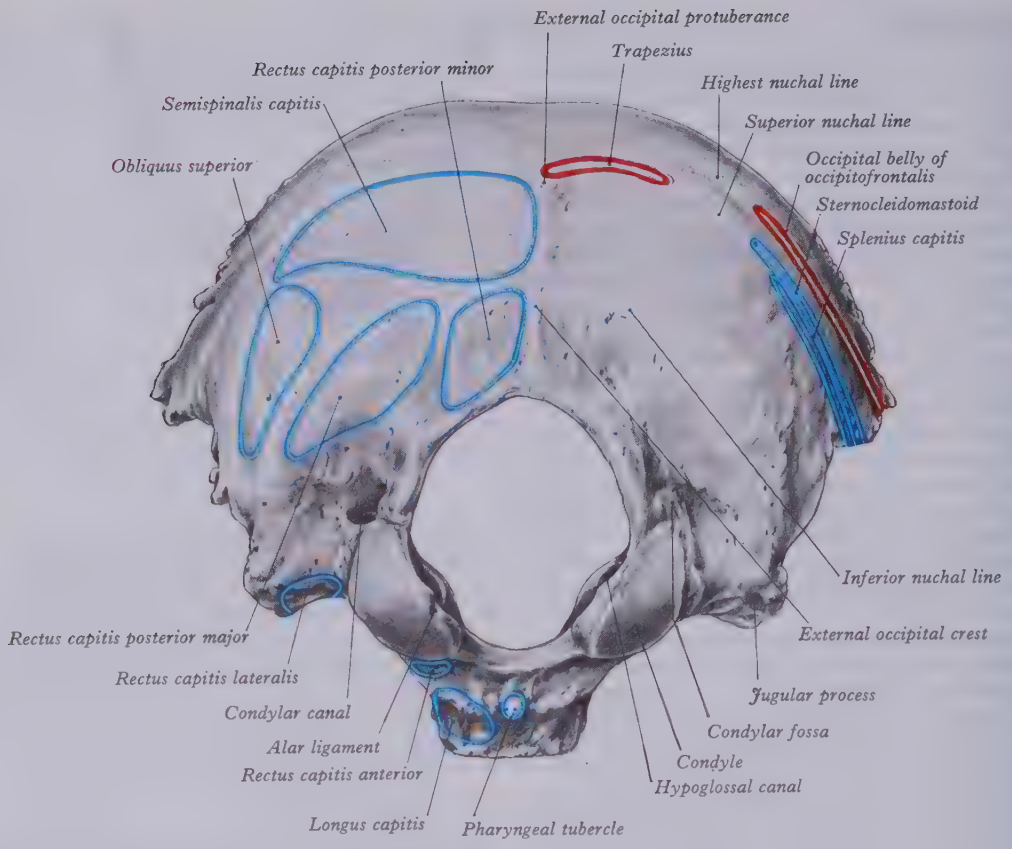
The occipital bone (3.122–124), forming much of the cranium's back and base, is trapezoid and internally concave. It encloses 'basally' the *foramen magnum*; the expanded plate posterosuperior to this is the *squama (squamous part)*, the massive quadrilateral part anterior to it being the *basilar part (basi-occipital)*; on each side of the foramen is a *lateral part (exoccipital)*.

The squama is convex externally and concave internally. The *external surface* presents, midway between summit and foramen magnum, the *external occipital protuberance*. On each side two curved lines extend laterally from this; the upper, faintly marked and often almost imperceptible, is the *highest nuchal line* to which the epicranial aponeurosis is attached; the lower is the *superior nuchal line*. The surface above the highest nuchal lines is smooth and covered by the occipital part of occipitofrontalis; below this it is rough and irregular for attachment of muscles. From the external occipital protuberance the median *external occipital crest*, often faint, descends to the foramen magnum and is an attachment of the ligamentum nuchae; on each side an *inferior nuchal line* spreads laterally from the crest's midpoint. Areas of muscular attachment are shown in 3.100,104,123. The posterior atlanto-occipital membrane is attached posterolaterally just outside the foramen magnum's margin.



The squama's *internal surface* is divided into four deep fossae by an irregular *internal occipital protuberance* and by ridged sagittal and horizontal extensions from it. The two superior fossae are triangular and adapted to the cerebral occipital poles, the inferior are quadrilateral and shaped to accommodate the cerebellar hemispheres. A wide groove, with raised banks, ascends from the protuberance to the squama's superior angle—the *superior sagittal sulcus*. The posterior part of the falx cerebri is attached to its margins. A prominent *internal occipital crest* descends from the protuberance, for attachment of the falx cerebelli, and bifurcates near the foramen magnum; the occipital sinus, sometimes double, lies in this attachment. At the crest's lower end a small *vermian fossa* may exist, occupied by part of the inferior cerebellar vermis. On each side a wide *sulcus for the transverse sinus* extends laterally from the protuberance; to the margins of these sulci the tentorium cerebelli is attached. The right sulcus is usually larger, passing into the sulcus for the superior sagittal sinus, but the left may be larger or both almost equal in size. The position of this *confluence of sinuses* is indicated by a depression on one side of the protuberance.

The *superior angle* at the squama's summit meets the occipital angles of the parietal bones, the position of the fetal *posterior fontanelle*. The *lateral angles* of the squama, marked internally by ends of the transverse sulci, project between parietal and temporal bones. The *lambdoid borders* extend from superior to lateral angles, serrated for articulation with the occipital borders of the parietals at the *lambdoid suture*. The *mastoid borders* extend from lateral angles to jugular processes, articulating with the mastoid parts of temporal bone. A variety of ossicles may occur at or near the lambda (p. 386 and Srivastava 1977), e.g. the 'interparietal' (Inca bone or ossicle of Goethe).



The occipital's basilar part extends anterosuperiorly from the foramen magnum, fusing with the sphenoid in adults. In

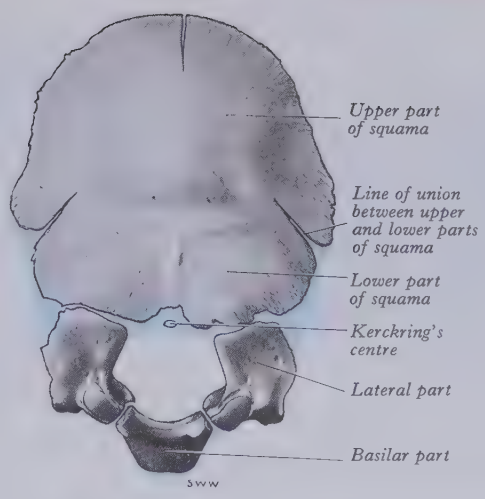
 3.124 The occipital bone: internal aspect.

young skulls a rough and uneven surface is joined to the body of the sphenoid by a growth cartilage. By the twenty-fifth year this plate has ossified and occipital and sphenoid bones are fused.

The inferior surface of the basi-occipital, about 1 cm anterior to foramen magnum, bears a small *pharyngeal tubercle* for attachment of the fibrous pharyngeal raphe. Longus capitis is attached anterolateral to the tubercle and rectus capitis anterior to a small depression immediately anterior to the occipital condyle which, on occasion, may be replaced by a small *precondylar tubercle*, of low incidence, but relatively frequent in Mexican and Burmese crania (p. 396). To the anterior margin of the foramen the anterior atlanto-occipital membrane is attached.

The *superior basi-occipital surface* is a broad groove, part of the *clivus*, which ascends anteriorly from foramen magnum; above it are the medulla oblongata and lower pons. Near the foramen the membrana tectoria and axial apical ligament are attached to the clivus. On its lateral margins are *sulci of the inferior petrosal sinuses*, below which the lateral margins articulate with petrous temporal bones.



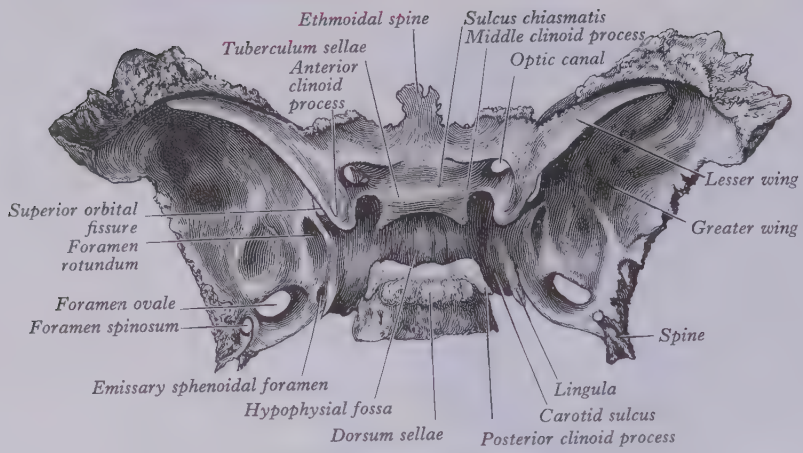
The lateral (condylar) parts of the occipital bone flank the foramen magnum; on their *inferior surfaces* are *occipital condyles* for articulation with superior atlantal facets. They are oval or reniform, their long axes converging anteromedially. Their anterior ends invade the basi-occipital, level with the foramen's centre. The articular surfaces, wholly convex, face inferolaterally; they are occasionally constricted and a condyle may be in two parts (p. 396). The atlantal superior articular facets are also frequently constricted and occasionally 'double' (Singh 1965). Medial to each facet a tubercle gives attachment to an alar ligament. Anteriorly above each condyle is a *hypoglossal canal*, which starts internally a little above the anterolateral part of the foramen magnum and continues anterolaterally. It may be partly or wholly divided by a spicule of bone and transmits the hypoglossal nerve and a meningeal branch of the ascending pharyngeal artery. A *condylar fossa*, behind each condyle, fits the posterior margin of the superior atlantal facet in full extension; its floor is sometimes perforated by a *condylar canal* for a sigmoid emissary vein. The *jugular process*, jutting laterally from the posterior half of each condyle, is a quadrilateral plate, indented in front by a *jugular* notch, the posterior part of the jugular foramen. This notch is sometimes partly divided by a small *intrajugular process*, projecting anterolaterally. The jugular process' inferior surface is roughened by attachment of rectus capitis lateralis; a *paramastoid process* sometimes projects down and may even articulate with the atlantal transverse process. Laterally the jugular process has a rough quadrilateral or triangular area joined to the jugular surface of the temporal bone by a growth plate of cartilage, which begins to ossify at about 25 years. For variations of jugular foramen, processes, etc., consult Solter & Paljan (1973). Though rare or absent in many populations, a paramastoid process was recorded in 44% of 149 male and 31% of 137 female American Indians (Finnegan 1972).

On the superior condylar surface an oval *jugular tubercle* overlies the hypoglossal canal, its posterior part often bearing a shallow furrow for the glossopharyngeal, vagus and accessory nerves. On the jugular process' superior surface a deep groove, curving anteromedially around a hook-shaped process, ends at the jugular notch; it contains the end of the sigmoid sinus. Near the groove's medial end the condylar canal opens into the posterior cranial fossa.

The *foramen magnum* is described on page 359.

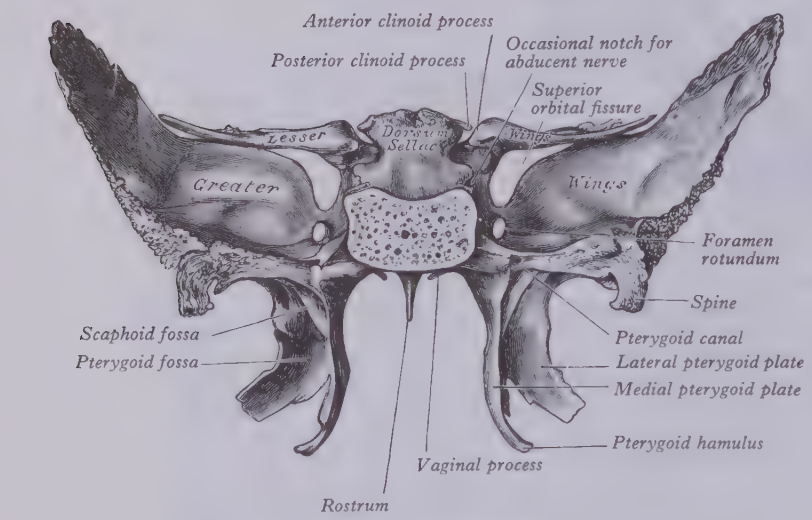
Structure. The occipital, in common with many parts of other cranial bones, consists of two compact lamellae, *outer* and *inner plates*, enclosing trabecular bone or *diploë*; the bone is thick at ridges, protuberances and condyles, and in the anterior basi-occipital; in lower parts of cerebellar fossae, however, it is thin, semitransparent and devoid of diploë. As noted, the intertrabecular spaces (cancelli) of the diploë are occupied by haemopoietic red bone marrow (p. 360), the latter being drained by radicles of the wide diploic veins (p. 798), of which the occipital diploic vein is usually the largest.

Ossification (3.125). A common but *oversimplified* account of occipital ossification states that above the highest nuchal lines the squama is developed in a fibrous membrane and ossified from two centres, one on each side from about the second fetal month; this part may remain separate as the *interparietal bone*; the rest is preformed in cartilage. Below the highest nuchal lines, the squama ossifies from two centres, appearing in about the seventh week and soon uniting. These two regions of the squama unite in the third postnatal month but the line of union is recognizable at birth.



3.125 The occipital bone of a newborn child: external surface. Parts of the chondrocranium still unossified are shown in blue.

An occasional centre appears in the posterior margin of the foramen magnum in about the sixteenth week (Kerckring); it unites with the rest of the squama before birth. From a survey of literature and examination of 620 human skulls for anomalies of the occipital squama, however, Srivastava (1977) has proposed a more complex developmental history. He regards the *membranous (dermal)* part above the nuchal lines as compounded of *interparietal* and *preinterparietal* parts, the interparietal consisting of *two lateral plates* and a *central piece*. The intramembranous centres proposed for these are a pair for each lateral plate and two for the central piece of the interparietal, additionally a pair of centres for the pre-interparietal. Pal et al (1984) have recently criticized the views of Srivastava (1977); they consider the so-called pre-interparietal elements as probably sutural; but it has to be stated that much uncertainty persists regarding the status of these accessory ossicles. Fusion may fail, partly or completely, between any of these elements. To the *cartilaginous supraoccipital* Srivastava allots five endochondral centres, a pair each for right and left *lateral segments* and one for the *central segment* (the latter may correspond to Kerckring's centre). Each lateral (condylar or exoccipital) part ossifies from one centre, appearing during the eighth prenatal week. The basi-occipital is ossified from one centre appearing about the sixth week. Near the second year's end the squama unites with condylar parts and by the sixth year the bone is one entity. Between the eighteenth and twenty-fifth years the occipital and sphenoid bones unite. Metrical study of the occipital bone (Olivier 1975) suggests that squamous and basilar parts have independent parameters of growth, and that sexual differences are chiefly evident in condylar regions. Routal et al (1984) have described sexual dimorphism, chiefly difference in size, in the foramen magnum.



The Sphenoid Bone

The sphenoid bone (3.126–131) is in the base of the skull, 'wedged' (as its name implies) between the frontal and temporal and occipital bones. It has a central body, paired greater and lesser wings spreading laterally from it and two pterygoid processes, descending from junctions of the body and greater wings.

The body is cuboidal; it contains two large air sinuses, separated by a septum. The *cerebral* or *superior surface* (3.111,126) articulates in front with the ethmoidal cribriform

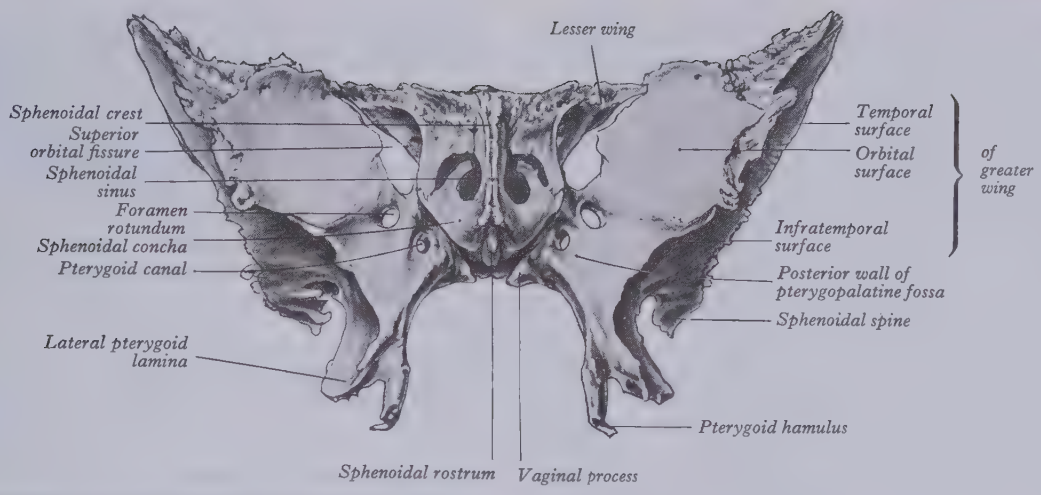
3.126 The sphenoid bone: superior aspect.

3.127 The sphenoid bone: posterior aspect.

plates; anteriorly it is the smooth *jugum sphenoidale*, related to gyri recti and olfactory tracts. The jugum is bounded behind by the anterior border of the *sulcus chiasmatis*, leading laterally to the *optic canals*. Posterior to this is the *tuberculum sellae*, behind which the deeply concave *sella turcica* contains the hypophysis cerebri in the *hypophysial fossa*. The sella's anterior edge is completed laterally by two *middle clinoid processes* (**3**.126), posteriorly by a square *dorsum sellae*, the superior angles of which bear variable *posterior clinoid processes*, for attachment of tentorium cerebelli. On each side, below the dorsum sellae, a small *petrosal process* articulates with the apex of the petrous temporal bone. (For variations in sella turcica see Kinman 1977, Lang 1977.) Posterior to the dorsum sellae the sphenoid body slopes directly into basi-occipital bone in adults, together forming the *clivus*. The latter's sphenoidal part lies beneath the upper pons.

The body's *lateral surfaces* are united both with the greater wings and the medial pterygoid plates. Above the root of each wing a broad *carotid sulcus*, curved like a tilde or 'swung dash' (~), it accommodates the internal carotid artery and cavernous sinus and a series of closely related nerves. It is deepest posteriorly, overhung medially by the petrosal process and has a sharp lateral margin, the *lingula*, which continues back over the posterior opening of the pterygoid canal.

On the *anterior surface* (**3**.128) a median triangular, structurally bilaminar *sphenoidal crest* forms a small part of the nasal septum; its anterior border joins the ethmoid's perpendicular plate; on each side of it opens a *sphenoidal sinus*. The sphenoidal sinuses (p. 1179), two large, irregular cavities in the body, are separated by a usually asymmetrical septum. Varying in form and size, each sinus is partially divided by bony laminae. A lateral recess may extend into the greater wing and lingula (Cope 1917) and may even invade the basi-occipital bone almost to the foramen magnum. Trans-sphenoidal surgical approach to the hypophysis cerebri has prompted classification into types: *conchal*—a small sinus separated from the sella turcica by about 10 mm of trabecular bone; *presellar*—a sinus not extended dorsally to the tuberculum sellae; and *sellar*—the sinus extended, as described above, at variable distances beyond the tuberculum (Hammer & Rådberg 1961, Kinman 1977, Lang 1977). In the articulated state they are closed antero-inferiorly by the *sphenoidal conchae* (p. 376), leaving openings by which each communicates with its spheno-ethmoidal recess. Each half anterior surface of the body consists of: (*a*) a superolateral depressed area joined to the ethmoid labyrinth, completing the posterior ethmoidal sinuses; its lateral margin articulates with the ethmoid's orbital plate above and palatine's orbital process below; (*b*) an inferomedial, smooth, triangular area, forming the posterior nasal roof; near its superior angle is the orifice of a sphenoidal sinus.



The body's *inferior surface* bears a median triangular *sphenoidal rostrum*, embraced above by the diverging lower margins of the crest, its narrow ventral end fitting into a fissure between the anterior parts of the vomerine alae. Posterior ends of the sphenoidal conchae flank the rostrum, articulating with vomerine alae. On each side of the posterior part of the rostrum, behind the sphenoidal concha's apex (vide infra), a thin *vaginal process* projects medially from the base of the medial pterygoid plate (**3**.128).

The greater wings, strong processes, curve broadly superolaterally from the body. Posteriorly each is triangular, fitting the angle between petrous and squamous parts of the temporal bone (**3**.103B,C) at a sphenosquamosal suture. The *cerebral surface* (**3**.126) is an anterior part of the middle cranial fossa. Deeply concave, its undulating surface is adapted to the anterior gyri of the temporal lobe. Anteromedial is the *foramen rotundum* for the maxillary nerve, posterolateral to this the *foramen ovale* for the mandibular nerve, accessory meningeal artery and sometimes the lesser petrosal nerve, which may have a special *canaliculus innominatus* medial to the foramen spinosum. A small *emissary sphenoidal foramen* exists on one or both sides in 40% of skulls; it opens below, lateral to the scaphoid fossa, and transmits a small vein from the cavernous sinus. Anteromedial to the sphenoidal spine the *foramen spinosum* transmits the middle meningeal artery and meningeal branch of the mandibular nerve.

The *lateral surface* (**3**.103A) is vertically convex and divided by a transverse *infratemporal crest* into temporal (upper) and infratemporal (lower) surfaces; to the upper surface the temporalis is attached; the lower is directed downwards and, with the infratemporal crest, it is the attachment of upper fibres of the lateral pterygoid. It presents the *foramen ovale* and *foramen spinosum* and posteriorly the *spine of the sphenoid* (p. 355)—a small, sometimes pointed process, projecting downwards; its medial side shows a faint antero-inferior groove for the chorda tympani and also appears in the lateral wall of the sulcus for the auditory tube (p. 1226). To its tip is attached the sphenomandibular ligament. Medial to the anterior end of the infratemporal crest a triangular process is part of the lateral pterygoid's attachment; a ridge, descending medially from this to the front of the lateral pterygoid plate, is a posterior boundary of the pterygomaxillary fissure.

The quadrilateral *orbital surface* (**3**.128) faces anteromedially as a posterior part of the lateral orbital wall. Its serrated upper edge articulates with the frontal's orbital plate, its serrated lateral margin with the zygomatic bone. Its smooth inferior border is the posterolateral edge of the inferior orbital fissure. Its sharp medial margin is the inferolateral edge of the superior orbital fissure; on it a small tubercle affords partial attachment of the common annular ocular tendon (p. 1208). Below the superior fissure's medial end a grooved area forms the posterior wall of the pterygopalatine fossa, pierced by the foramen rotundum.

The irregular *margin of the greater wing* (**3**,127), from sphenoid body to spine, is in its medial half an anterior limit of the *foramen lacerum* and displays the posterior aperture of the pterygoid canal. Its lateral half articulates with the petrous temporal bone at a *sphenopetrosal synchrondrosis*. Inferior to this the *sulcus tubae*

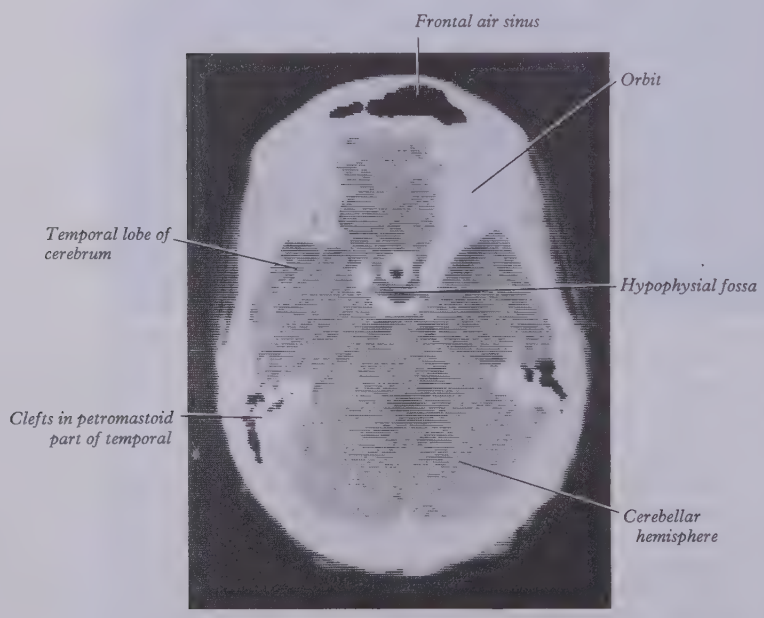
3.129 High resolution projection microradiograph of the sphenoid bone (anteroposterior projection). Note in particular the sphenoidal body and its contained sinuses, the architecture of the greater and lesser wings, and pterygoid processes and the disposition of the optic canal, superior orbital fissure, foramen rotundum and pterygoid canal. (Contributed by C Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

contains the cartilaginous auditory tube. Anterior to the sphenoidal spine the concave *squamosal margin* is serrated (bevelled internally below, externally above) for articulation with the temporal squama. The tip of the greater wing, bevelled internally, articulates with the parietal's sphenoidal angle at the *pterion*. Medial to this, a triangular rough area articulates with the frontal bone, its medial angle continuous with the inferior boundary of the superior orbital fissure, its anterior angle by a serrated articulation with the zygomatic bone.

The lesser wings are triangular, pointed plates protruding laterally from the anterosuperior regions of the body (**3**.126,127). The *superior surface* of each is smooth and related to the cerebral frontal lobe. The *inferior surface* is a posterior part of the orbital roof and upper boundary of the *superior orbital fissure*; it overhangs the middle cranial fossa. The *posterior border* projects into the lateral cerebral fissure; its medial end is the *anterior clinoid process*, for attachment of the anterior end of the free tentorial border. The anterior and middle clinoid processes are sometimes



united to form a *caroticoclinoid foramen*. The lesser wing is connected to the body by an anterior root, thin and flat, and a posterior, thick and triangular root; between them the *optic canal* contains the optic nerve and ophthalmic artery. Growth of the posterior root is closely associated with variations in the canal (Kier 1966), whose cranial opening may be duplicated (Warwick 1951). More often the division is incomplete.

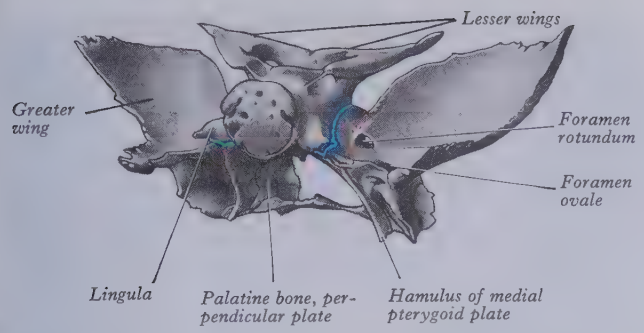
The superior orbital fissure, triangular and connecting the cranial cavity and orbit, is bounded medially by sphenoid body, above by the lesser wing, below by the medial margin of the orbital surface of the greater wing; it is completed laterally, between greater and lesser wings, by the frontal bone. For its contents see page 1209 and 7.329.

The pterygoid processes (3.127–129) descend perpendicularly from the junctions of greater wings and body. Each consists of a medial and lateral plate, their upper parts fused anteriorly. They are separated below by the angular *pterygoid fissure*, whose margins articulate with the palatine's pyramidal process. They diverge behind and the cuneiform *pterygoid fossa* between them contains the medial pterygoid and tensor veli palatini. Above is the small, oval, shallow *scaphoid fossa*, formed by division of the upper posterior border of the medial plate; to it part of the tensor veli palatini is attached. The anterior surface of the root of the pterygoid process is broad and triangular and is the pterygopalatine fossa's posterior wall, pierced by the anterior orifice of the *pterygoid canal*.

The lateral pterygoid plate is broad, thin and everted, its *lateral surface* part of the medial wall of the infratemporal fossa and an attachment of lower part of the lateral pterygoid; its *medial surface* is the pterygoid fossa's lateral wall and to it most of the medial pterygoid is attached. The upper part of its *anterior border* is a posterior boundary of the pterygomaxillary fissure; the lower part articulates with the palatine bone. Its *posterior border* is free.

The medial pterygoid plate is narrower and longer; its lower end curves into the lateral, unciform *pterygoid hamulus*, which deflects the tendon of the tensor veli palatini; the pterygomandibular raphe is attached to it. The *lateral surface* is the pterygoid fossa's medial wall; the tensor veli palatini adjoins it; the *medial surface* is a lateral boundary of the posterior nasal aperture. The medial plate is prolonged above on the sphenoid body's inferior aspect as the thin *vaginal process*, articulating anteriorly with the palatine's sphenoidal process and medially with the vomerine ala. Inferiorly it has a furrow, anteriorly made into a canal by the palatine sphenoidal process; this *palatovaginal canal* transmits pharyngeal branches of the maxillary artery and pterygopalatine ganglion. To the whole of the medial plate's posterior margin the pharyngobasilar fascia is attached and to its lower end the superior pharyngeal constrictor. At its upper end is a small *pterygoid tubercle*, just below the pterygoid canal's posterior opening. Projecting back near the margin's midpoint is the *processus tubarius*, supporting the auditory tube's pharyngeal end. The plate's anterior margin, in its lower part, articulates with the posterior border of the palatine's perpendicular plate.

3.130 Computed tomogram through the head at the level of the pituitary fossa of the sphenoid. (Supplied by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith).



The sphenoidal conchae (3.128) are two thin, curved platelets, attached antero-inferiorly to the sphenoid body; the superior concave surface of each is the anterior wall and partly floor of a sphenoidal sinus. They are largely destroyed in disarticulating a skull; in situ each has anterior vertical, quadrilateral and posterior horizontal, triangular parts. The anterior part consists of (*a*) a superolateral depressed area, completing the posterior ethmoidal sinuses and joining below with a palatine's orbital process, and (*b*) an inferomedial area, smooth and triangular and part of the nasal roof, perforated above by the round opening connecting sphenoidal sinus and spheno-ethmoidal recess. Anterior parts of the two bones meet in the midline, protruding as the sphenoidal crest. The horizontal part appears in the nasal roof and completes the sphenopalatine foramen; its medial edge articulates with the sphenoid's rostrum and vomerine ala; its apex, directed back, is superomedial to the vaginal process of the medial pterygoid plate and joins the posterior part of the ala. A small conchal part sometimes appears in the medial orbital wall between the ethmoid's orbital plate in front, the palatine's orbital process below and the frontal bone above.

Ossification. Until the seventh or eighth month in utero the sphenoid body has a *presphenoidal part*, anterior to tuberculum sellae, with which the lesser wings are continuous, and a postsphenoidal part, comprising sella turcica and dorsum sellae, and integral with the greater wings and pterygoid processes. Much of the bone is preformed in cartilage. There are six ossificatory centres for the presphenoidal and eight for postsphenoidal parts. This multiplicity accords with the sphenoid's evolution from a number of elements, such as the median presphenoid and basisphenoid homologous with the human parts defined above. The lesser wings, primitively separate orbitosphenoids, show a tendency to fusion with the body in mammals.

Presphenoidal part. About the ninth fetal week a centre appears in each wing, lateral to the optic canal; a little later two bilateral centres appear in the presphenoidal body. Each sphenoidal concha has a centre, appearing superoposteriorly in the nasal capsule in the fifth month in utero; as this enlarges it partly surrounds a posterosuperior expansion of nasal cavity, which becomes the sphenoidal sinus. The posterior conchal wall is absorbed and the sinus invades the presphenoid. In the fourth year the concha fuses with the ethmoidal labyrinth and before puberty with the sphenoid and palatine bones. Its anterior deficiency persists as an orifice of a sphenoidal sinus.

Postsphenoidal part. First centres appear in the greater wings about the eighth fetal week, one in each below the foramen rotundum in the wing's basal cartilage; this centre forms only the wing's root, near the foramen rotundum and pterygoid canal; the remainder is ossified in mesenchyme, spreading also into the lateral pterygoid plate. About the fourth fetal month two centres appear, flanking the sella turcica, and soon fuse. The medial pterygoid plates are also ossified in 'membrane', a centre in each probably appearing about the ninth or tenth week; the hamulus is *chondrified* during the third fetal month and at once begins to ossify (Fawcett 1905). Medial and lateral pterygoid plates join about the sixth fetal month; during the fourth a centre appears for each lingula, soon joining the body.

Presphenoidal and postsphenoidal parts fuse about the eighth month in utero, but an unciform cartilage persists after birth in lower parts of the junction. At birth the bone is tripartite (3.131): a central part, body and lesser wings, and lateral parts each comprising a greater wing and pterygoid process. During the first year the greater wings and body unite around the pterygoid canals and the lesser extend medially above the body's anterior part, meeting to form the smooth, elevated *jugum sphenoidale*. By the twenty-fifth year sphenoid and occipital bones are completely fused. Anterior in the hypophysial fossa is an occasional vascular

3.131 The sphenoid bone at birth, viewed from behind and from the right side. The blue strip indicates the cartilage between the central and the lateral parts on the right side; this is only partly visible on the left. Note that the two palatine bones are in situ.

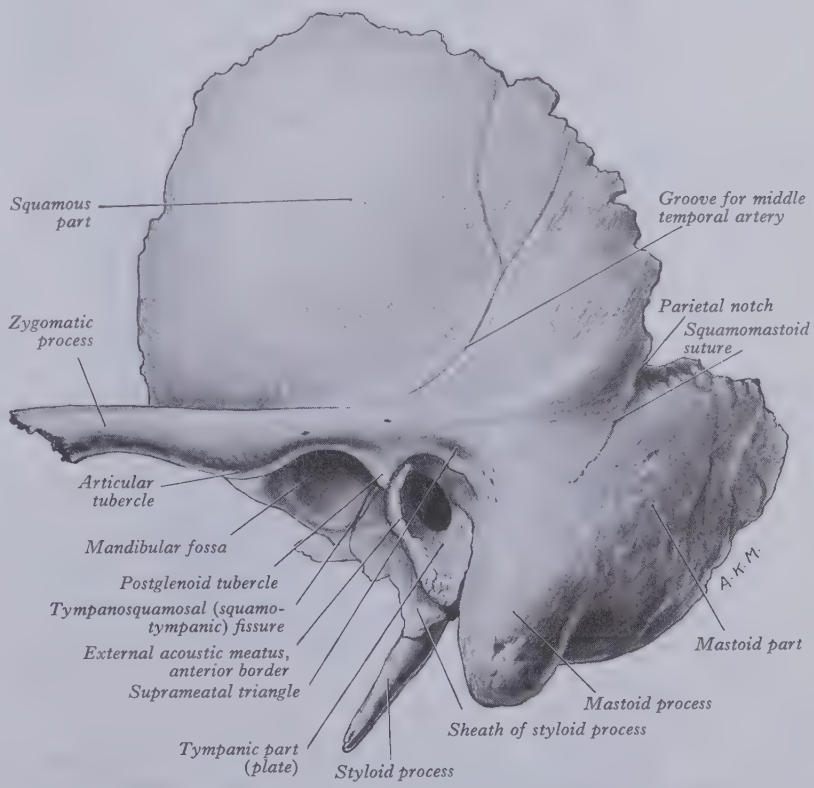
foramen, often erroneously termed the *craniopharyngeal canal* (p. 230). (For discussion of cartilage canals in fetal spheno-occipital synchondrosis consult Moss-Salentijn 1975.)

The sphenoidal sinus before birth is an extension of the nasal cavity into the sphenoidal concha. In the second or third year it spreads into the presphenoid and later invades the postsphenoid, reaching full size in adolescence. As age advances it often enlarges further by absorption of its walls.

Certain sphenoidal parts are connected by ligaments which occasionally ossify, such as the *pterygospinous*, between sphenoid spine and upper part of lateral pterygoid plate (p. 376); the *interclinoid*, joining anterior to posterior clinoid process; and the *caroticoclinoid*, connecting anterior to middle clinoid process. For details of fetal and perinatal development of optic foramen and canal consult Kier (1966). Lang (1977) has surveyed ossificatory variations of the sella turcica.

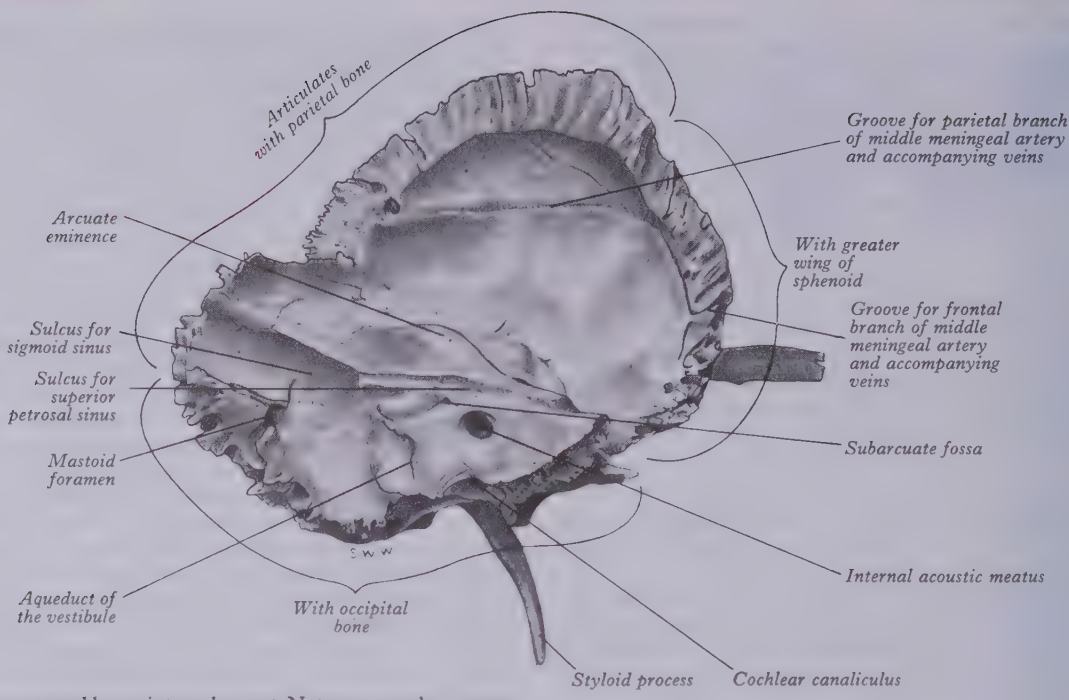
Premature synostosis of the junction between pre- and postsphenoidal parts, or of the spheno-occipital suture, produces a characteristic appearance, obvious in profile. It is an abnormal depression of the nasal bridge, often observed in achondroplasia. Anomalous development of presphenoidal elements may lead to excessive separation of orbits and an abnormally broad nasal bridge (*hypertelorism*).

The Temporal Bones



The temporal bones (3.132–136) in the sides and base of the skull are developmentally divisible into *squamous, petromastoid, tympanic* and *styloid parts*. These morphologically distinct elements have fused during the evolution of higher vertebrates. The *squamous part* is a dermal bone evolved to help enclosure of brain. The *petromastoid part* is preformed in cartilage; it preserves precise orientation of the membranous labyrinth. The *tympanic part*, formed in mesenchyme, is homologous with the os angulare, part of the composite lower jaw of many reptiles and osseous fishes, integrated into the skull and adapted to form part of the tympanic cavity and external acoustic meatus and to support the tympanic membrane, all concerned in sound transmission. The *styloid process* is the dorsal element of the hyoid arch. Fusion of these parts and inclusion of tympanic cavity and auditory ossicles are discussed on page 172.

The squamous part or squama, anterosuperior in the bone, is thin and partly translucent. Its *temporal surface* (3.132) is smooth, slightly convex, and part of the temporal fossa for attachment of temporalis; above the external acoustic meatus it is grooved vertically by the middle temporal artery. The *supramastoid crest* curves back and up across its posterior part; it is an attachment of temporal fascia and muscle. Junction between squamous and mastoid parts is about 1.5 cm below this crest; traces of the squamo-mastoid suture may persist. Between the anterior end of the crest and posterosuperior quadrant of the external acoustic meatus is the *suprameatal triangle*, a depression marking the mastoid antrum, medial to it at a depth of about 1.25 cm (p. 380); in it anteriorly is usually a small *suprameatal spine*.



The *temporal's zygomatic process*, part of the **zygoma,** juts forwards from the squama's lower region. Its triangular posterior part has a broad base directed laterally, its surfaces superior and inferior. The process then twists anteromedially, its surfaces becoming medial and lateral. The posterior part's superior surface is concave and continuous with that of the squama; the inferior surface is bounded by *anterior* and *posterior roots*, converging into the anterior part of the process. At the junction of the roots the *tubercle of the zygomatic root* gives attachment to the lateral temporomandibular ligament. The posterior root is prolonged forwards above the external acoustic meatus, its upper border continuing into the supramastoid crest. The anterior root juts almost horizontally from the squama; its inferior surface, with an anteroposterior convexity covered by cartilage, contacts the joint's articular disc, forming a short semicylindrical *articular tubercle*, the anterior limit of the mandibular fossa. Very rarely the squama is perforated above the posterior root by a *squamosal foramen*, transmitting the petrosquamous sinus (p. 801).

The zygomatic process' anterior part is thin and flat. To its superior border the temporal fascia is attached, to the inferior, short and arched, some fibres of masseter. The convex lateral surface is subcutaneous; the medial is concave and is an attachment for part of the masseter. The anterior end is deeply serrated and slopes obliquely back and down to articulate with the zygomatic bone's temporal process. Anterior to the articular tubercle a small triangular area is part of the roof of the infratemporal fossa, separated from the squama's temporal surface by a ridge, continuous behind with the zygomatic process' anterior root, in front with the infratemporal crest of the sphenoid's greater wing.

The mandibular fossa, limited in front by the articular tubercle, has an anterior articular area, formed by temporal squama, and a posterior non-articular area, formed by the tympanic element. The *articular surface*, smooth, oval and deeply hollow, articulates with the temporomandibular disc; the non-articular area sometimes contains part of the parotid gland. A small, conical *postglenoid tubercle* separates the articular surface laterally from the tympanic plate; it is prominent in some mammals, descending behind the mandibular condyle to prevent backward displacement; it is sometimes described as a third root of the zygomatic process. (For a multivariate analysis of this

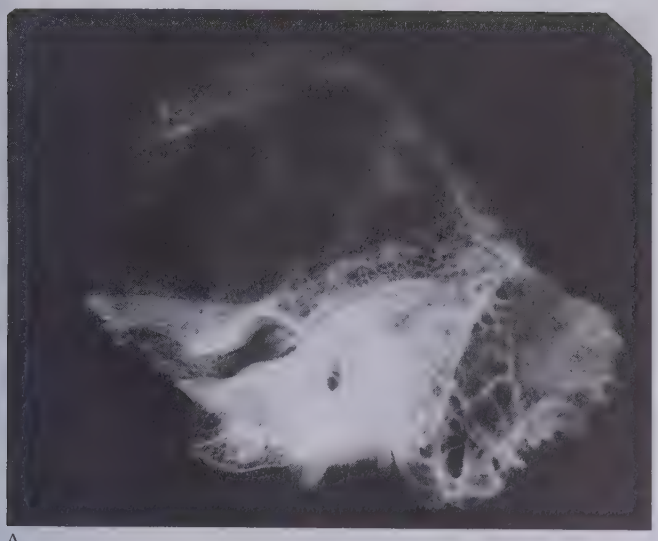
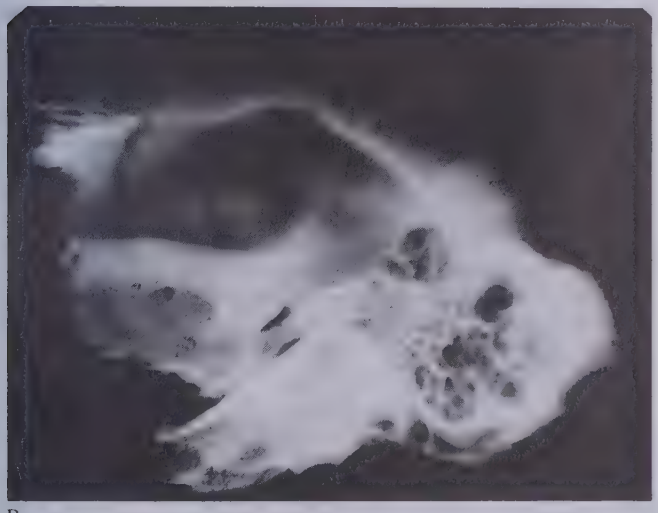
articular surface (and many other cranial parameters) in modern and fossil mankind and apes, and evaluation of functional deductions, consult Ashton et al 1976, Ashton & Moore 1980). Between the medial part of the articular fossa and the tympanic plate is the *squamotympanic fissure*, into which the anterolateral edge of tegmen tympani turns down; the *petrotympanic fissure* is between this plate and the tympanic part; it leads into the tympanic cavity and contains an anterior malleolar ligament and anterior tympanic branch of the maxillary artery. At the fissure's medial end is the anterior opening of the *anterior canaliculus for the chorda tympani*. Rarely, a *postglenoid foramen* exists anterior to the external acoustic meatus in the line of fusion of the squama and tympanic part; it replaces the squamosal foramen noted above and transmits the petrosquamous sinus (p. 801).

3.134 Oblique vertical section through the left temporal bone in the long axis of the tympanic cavity. The lateral surface of the medial half of the bone is shown.



The squama's *cerebral surface* (**3.133**) is concave; its depressions correspond to convolutions of the temporal lobe, its grooves to middle meningeal vessels; its lower border is fused to the anterior petrous surface, but traces of a petrosquamosal suture often appear in adult bones. The *superior border* is thin, bevelled internally and overlaps the parietal's inferior border at the squamosal suture. Posteriorly it forms an angle with the mastoid element. The *anteroinferior border*, thin above and thick below, joints with the greater wing; above it is bevelled internally, below externally.

The petromastoid part of the temporal bone, morphologically one element (p. 377), is conveniently described in mastoid and petrous parts.



The mastoid part, posterior region of the temporal bone, has an *outer surface* (**3.132**) roughened by attachments of occipital belly of occipitofrontalis and auricularis posterior. Frequently near its posterior border is a *mastoid foramen*, traversed by a vein from sigmoid sinus and a small dural ramus of the occipital artery. Its position and size vary; it may be in the occipital or occipitotemporal suture. It is parasutural in 40–50% of crania (p. 395) but may be absent. The mastoid part projects down as the conical **mastoid process**, larger in adult males. To its lateral surface sternocleidomastoid, splenius capitis and longissimus capitis are attached and, medially, in a deep *mastoid notch*, the posterior belly of digastric. Medial to this a shallow *occipital groove* contains the occipital artery. The *internal* mastoid surface (**3.133**) bears a deep, curved *sigmoid sulcus* for the venous sinus and posteriorly the mastoid foramen. The sulcus is separated from innermost mastoid air cells merely by a thin lamina of bone. The air cells (**3.134,135**) and *mastoid antrum* are described on page 1225. The mastoid bone's *superior border* is thick and serrated for articulation with the mastoid angle of the parietal. Its serrated *posterior border* articulates with the inferior border of the occipital between its lateral angle and jugular process. The mastoid element is fused with the descending process of the squamous part: below, it appears in the posterior wall of the tympanic cavity.

The petrous part of the temporal bone, wedged between sphenoid and occipital in the cranial base (**3.109A,B**), is inclined up and anteromedially; it has a base, apex, three surfaces and margins. The acoustic labyrinth is within it.

The *base*, an artificial concept, corresponds to the suture between petrous and squamous elements, though this disappears soon after birth. Since a mastoid process is a postnatal petrous

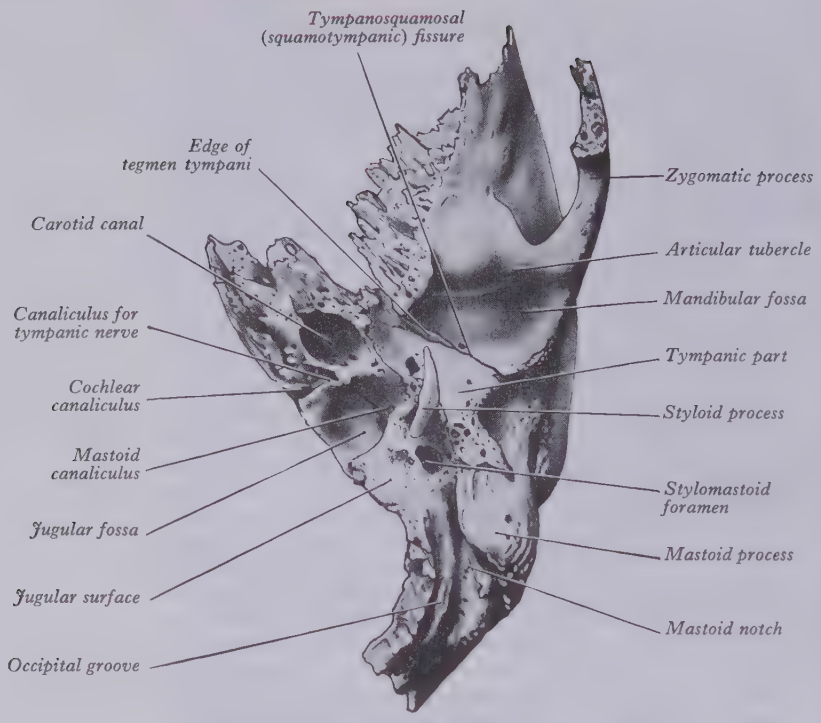
B

C

3.135 High resolution projection microradiographs of the petromastoid, tympanic and squamous parts of three temporal bones (mediolateral projection), showing marked variation in extent and mode of pneumatization. Above (A), the air-cells are comparatively large and extend beyond the mastoid process as far as the mandibular fossa. In the middle photograph (B) the cells are large but restricted to the post-otic and mastoid regions of the bone. Below (C), obvious pneumatization is absent; a fine meshwork of trabecular bone occupies the core of the mastoid process. (Prepared and contributed by C Buckland-Wright, Department of Anatomy, Guy's Hospital Medical School, London.)

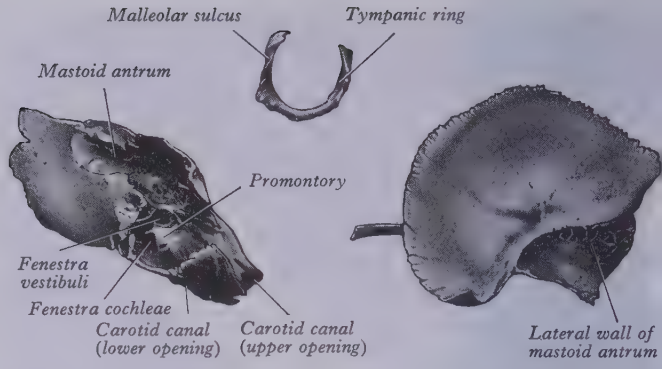
development, the base is arbitrary but indicated by partial separation due to the mastoid antrum.

The *apex*, blunt and irregular, is angled between the posterior border of the greater wing and the basi-occipital bone; it contains the carotid canal's anterior orifice and limits posterolaterally the foramen lacerum.



The *anterior surface* partly floors the middle cranial fossa and is continuous with the cerebral surface of the squamous part, although the petrosquamosal suture often persists late in life. The whole surface is adapted to the inferior temporal gyri. Behind the apex is a *trigeminal impression* for the ganglion. Bone anterolateral to this roofs the anterior part of the carotid canal, but is often deficient. A ridge separates the trigeminal impression from another hollow behind it which partly roofs the internal acoustic meatus and cochlea. This is limited behind by the *arcuate eminence* (**3**.133) and raised by the anterior semicircular canal. Laterally it roofs the vestibule and, partly, the facial canal. Between the squamous part laterally and medially, the arcuate eminence and the hollows just described, the surface is formed by the *tegmen tympani*. This thin plate of bone, roof of the mastoid antrum, extends forwards above the tympanic cavity (**3**.134) and the canal for the tensor tympani. Its lateral margin meets the squama at the petrosquamosal suture, turning down in front as the lateral wall of the canal for the tensor tympani and the osseous part of the auditory tube; its lower edge is in the squamotympanic fissure (p. 358). Anteriorly the tegmen bears a narrow groove, passing posterolaterally to enter bone anterior to the arcuate eminence by a hiatus for the greater petrosal nerve, passing forwards to the foramen lacerum. A smaller, more lateral hiatus transmits the lesser petrosal nerve from the tympanic plexus; the bone in front of this hiatus may be grooved. The posterior slope of the arcuate eminence overlies the posterior and lateral semicircular canals; lateral to it the posterior part of the tegmen tympani roofs the mastoid antrum.

The *posterior surface* of the petrous (**3**.133) is an anterior part of the posterior cranial fossa, continuous with the internal mastoid surface. Near its centre is the **internal acoustic meatus** (p. 365), behind which a small slit, almost hidden by a thin plate of bone, leads to the *vestibular aqueduct*, containing the saccus and ductus endolymphaticus with a small artery and vein. The terminal half of the saccus endolymphaticus protrudes through the slit between periosteum and dura mater. Above these openings is the *subarcuate fossa* (p. 365).



The irregular *inferior surface* (**3**.136) is part of the cranial base's exterior. Near the petrous apex a quadrilateral area is partly attachment for the levator veli palatini and cartilaginous auditory tube, and partly connected to the basi-occipital bone by dense fibrocartilage. Behind this is the large, circular aperture of the **carotid canal** (p. 355), behind which is the **jugular fossa** of variable depth and size and containing the superior jugular bulb. Anteromedial to this, below the internal acoustic meatus, is a triangular depression for the inferior glossopharyngeal ganglion; at its apex is a small opening into the *cochlear canaliculus*, occupied by the perilymphatic duct, a tube of dura mater and a vein from the cochlea to the internal jugular vein. On the ridge between the carotid canal and jugular fossa is a *canaliculus for the tympanic nerve* from the glossopharyngeal (p. 356). Lateral in the fossa is the *mastoid canaliculus* for the vagal auricular branch. Behind the fossa the *jugular surface*, a rough quadrilateral, is covered by cartilage joining it to the occipital's jugular process.

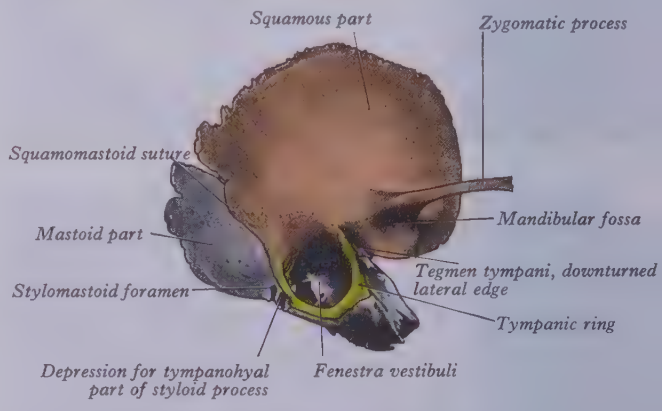
The *superior border*, the longest, is grooved by the superior petrosal sinus, the tentorium cerebelli being attached to the groove's edges except at its medial end, where it is crossed by trigeminal roots. The *posterior border*, intermediate in length, bears medially a sulcus which forms, with one on the occipital bone, a gutter for the inferior petrosal sinus. Behind this the **jugular fossa** forms, with the occipital jugular notch, the jugular foramen and is also notched by the glossopharyngeal nerve. Bone on either or both sides of the jugular notch may meet the occipital bone and divide the foramen into two or three. The *anterior border* is joined laterally to the temporal squama at the *petrosquamosal suture*; medially it articulates with the sphenoid's greater wing.

At the junction of petrous and squamous parts two canals exist, one above the other, separated by a thin osseous plate. Both lead

3.136 The left temporal bone: inferior aspect.

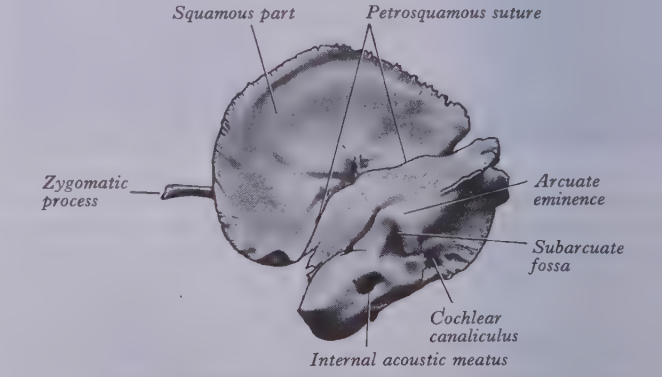
3.137 The three principal parts of the right temporal bone at birth, from left to right: lateral aspect of petromastoid part; medial aspect of tympanic ring; medial aspect of squama.

to the tympanic cavity, the upper containing the tensor tympani, the lower the auditory tube.



The tympanic part of the temporal bone (3.136) is a curved plate below the squama, anterior to the mastoid process. Internally it fuses with the petrous part and appears between this and the squama, where it is inferolateral to the auditory orifice. Behind, it fuses with the squama and mastoid process and is anterior limit of the tympanomastoid fissure. Its concave *posterior surface* forms anterior wall, floor and partly posterior wall of the external acoustic meatus. (Its postero-inferior wall may display a longitudinal *auditory torus*.) Medial on this surface is a narrow *tympanic sulcus* for attachment of the tympanic membrane. The *anterior surface*, quadrilateral and concave, is the posterior wall of the mandibular fossa and may contact the parotid gland. Its rough *lateral border* forms most of the external acoustic meatus' margin and is continuous with its cartilaginous part. Laterally the *upper border* is fused with the back of the postglenoid tubercle; medially it is the posterior edge of the petrotympanic fissure. The *inferior border* is sharp, splitting laterally to form, at its root, a *sheath of the styloid process* (vaginal process). Centrally the tympanic part is thin, often perforated. Between the styloid and mastoid processes the *stylomastoid foramen*, the external end of the facial canal, transmits the facial nerve and stylomastoid artery.

The external acoustic meatus, about 16 mm long, slopes down anteromedially; its floor is convex upwards. In sagittal section it is oval or elliptical with a long axis directed down and slightly back. Its anterior wall, floor and lower posterior wall are formed by the tympanic plate, its roof and upper posterior wall by the temporal squama. Its medial end is closed by tympanic membrane, the outer bounded above by the posterior zygomatic root, below which a *suprameatal spine* may exist.



The styloid process, slender, pointed, about 2.5 cm in length, projects down and forwards from the temporal bone's inferior aspect. Its curvature is somewhat variable (3.133). Its proximal part (*tympanohyal*) is sheathed by the tympanic plate, especially antero-laterally; to its distal part (*stylohyal*) are attached muscles and ligaments (p. 352). The process is covered laterally by the parotid gland; the facial nerve crosses its base, the external carotid artery its tip, embedded in the gland. Medially the process is separated from the commencement of the internal jugular vein by the attachment of the stylopharyngeus.

In structure the temporal squama is like other cranial bones: the mastoid part is trabecular and variably pneumatized, the petrous part compact.

Ossification. The four temporal components ossify independently (3.137,138). The *squama* is ossified in a sheet of condensed mesenchyme from a single centre near the zygomatic roots, appearing in the seventh or eighth week in utero. The *petromastoid part* has several centres appearing in the cartilaginous *otic capsule* (p. 204) during the fifth month. As many as 14 have been described, variable in order of appearance. Several are small and inconstant, soon fusing with others. This multiplicity accords with numerous otic bones in earlier forms. The otic capsule is almost fully ossified by the end of the sixth month. The *tympanic part* is also ossified in mesenchyme from a centre identifiable about the third month; at birth it is an incomplete *tympanic ring*, deficient above (3.137,138), its concavity grooved by a tympanic sulcus for the tympanic membrane. Inclined obliquely down and forwards across the medial aspect of the anterior part of the ring

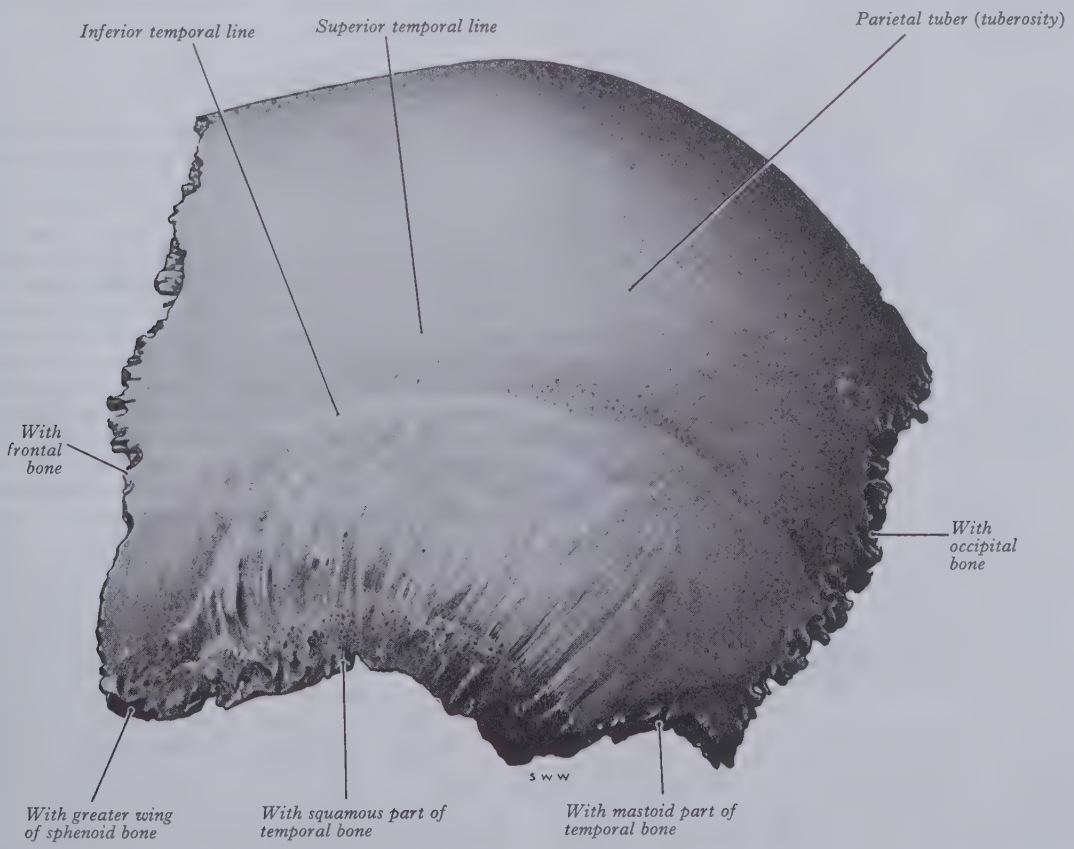
3.138A The right temporal bone at birth: lateral aspect. Note that the petromastoid part has not been coloured; the tympanic part is coloured yellow and the squamous part is coloured brown. The rudimentary base of the styloid process has been removed.

3.138B The right temporal bone at birth: medial aspect.

is the *malleolar sulcus*, (**3**.137) for the anterior malleolar process, chorda tympani and anterior tympanic artery. The *styloid process* is developed at the cranial end of cartilage in the second visceral or hyoid arch (p. 172) by two centres: a proximal, for the tympanohyal, appearing before birth; the other, for the distal stylohyal, after birth. The tympanic ring unites with the squama shortly before birth, the petromastoid fusing with it and the tympanohyal during the first year. The stylohyal does not unite with the rest of the process until after puberty and may never do so.

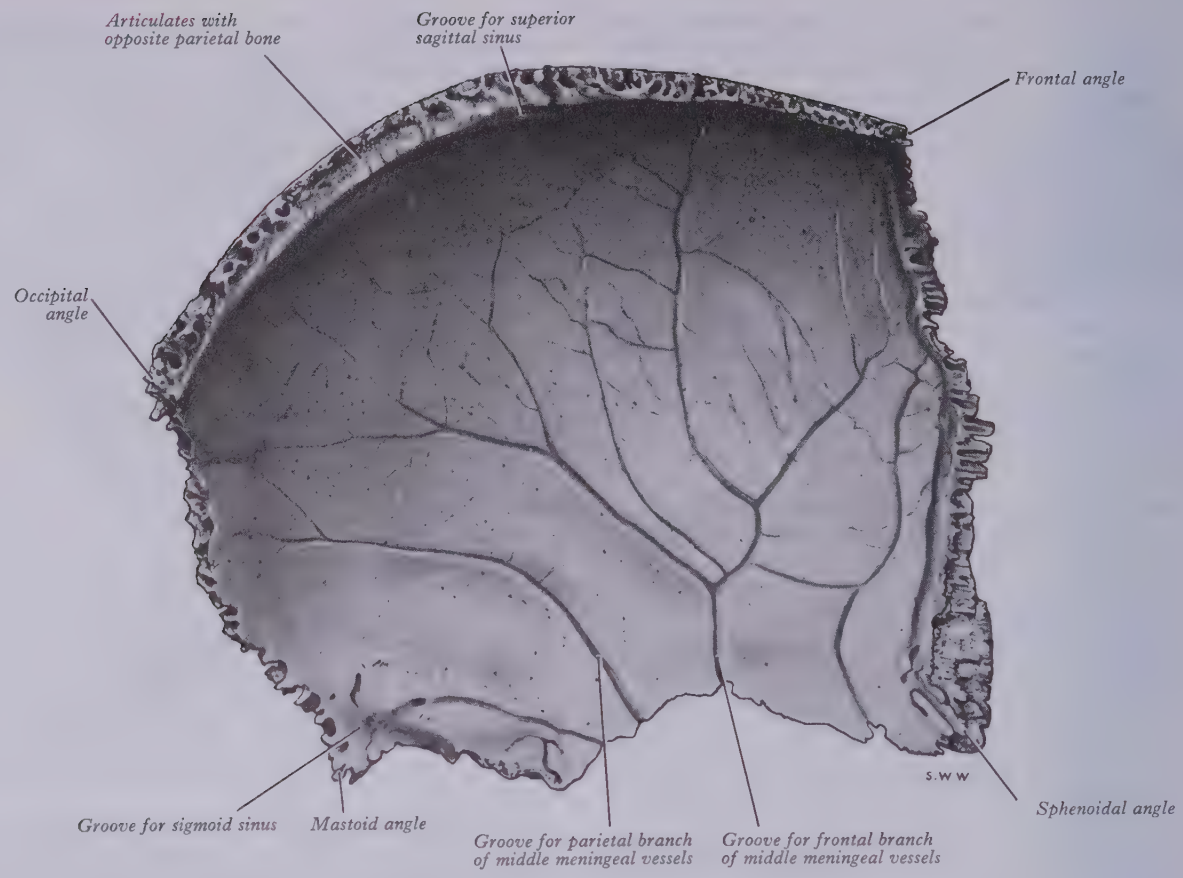
During ossification, the tympanic cavity, mastoid antrum and posterior end of the auditory tube are all in bone. The petrous part forms the roof, floor and medial wall of the cavity; the squama and tympanic part, with the membrana tympani, form its lateral wall. *At birth* the tympanic cavity, mastoid antrum and tympanic membrane are all almost *adult size*, as are the auditory ossicles; but its anterior process does not join the malleus until six months later. The internal acoustic meatus is about 6 mm in horizontal diameter, 4 mm vertically and 7 mm in length at birth, adult diameters being 7.7 mm and 11 mm.

After birth and apart from general growth, changes in the temporal bone are: (1) The tympanic *ring* extends posterolaterally to become cylindrical, growing into a fibrocartilaginous *tympanic plate*, which forms the adjacent part of external acoustic meatus at this stage. This growth is not equal but is rapid in the anterior and posterior regions, which meet and blend; thus, for a time, there is in the floor an opening (*foramen of Huschke*), usually closed at about the fifth year, but sometimes permanent (in 5–46% of adult crania from ancient and modern populations, p. 395); in Burmese crania a marked sexual difference occurs (25% in males, 40% in females). By posterior extension the tympanic plate ensheathes the styloid process and extends medially over the petrous bone to the carotid canal.
(2) The mandibular fossa is first shallow, facing more laterally, then deepening and ultimately facing downwards. Posteroinferiorly the squama grows down behind the tympanic ring to form the lateral wall of the mastoid antrum.
(3) The mastoid part is at first flat, the stylomastoid foramen and rudimentary styloid process being immediately behind the tympanic ring. As mastoid air cells develop the lateral mastoid region grows down and forwards to form the mastoid process, styloid process and stylomastoid foramen, becoming inferior. Descent of the foramen lengthens the facial canal. Not until late in the second year is the mastoid process perceptible.
(4) The subarcuate fossa is gradually filled and almost obliterated.



The external acoustic meatus is relatively as long in children as in adults, but the canal is fibrocartilaginous, whereas its medial two-thirds are osseous in adults. Surgical access to the tympanic cavity is via the mastoid antrum; in children only a thin scale of bone must be removed in the suprameatal triangle to reach antrum (p. 1225).

The Parietal Bones



Parietal bones (**3**.139,140) form most of the cranial roof and sides. Irregularly quadrilateral, each has two surfaces, four borders and four angles.

The *external surface* (**3**.139) is convex and smooth, with a central *parietal tuber (tuberosity)*. Curved *superior and inferior temporal lines* cross it, forming posterosuperior arches; to the superior arch is attached the temporal fascia; the inferior indicates the upper limit of attachment of the temporalis. Above these lines is the *epicranial aponeurosis* (galea aponeurotica), below them part of the temporal fossa. Posteriorly, close to the sagittal (superior) border, a *parietal foramen* transmits a vein from the superior sagittal sinus and sometimes a branch of occipital artery; the foramen is sometimes absent.

The concave *internal surface* (**3**.140) is marked by cerebral gyri and grooves for the middle meningeal vessels which ascend, inclining backwards, from the *sphenoidal (antero-inferior) angle* and posterior half or more of its inferior border. Along the sagittal border is a *groove for the superior sagittal sinus*, completed by the

3.139 The left parietal bone: external surface.

3.140 The left parietal bone: internal aspect.

opposite parietal; the falx cerebri is attached to its edges. *Granular foveolae* for arachnoid granulations flank the sagittal sulcus, most pronounced in old age.

The dentated *sagittal border*, longest and thickest, articulates with the opposite parietal at the sagittal suture. In the *squamosal (inferior) border* the anterior part is short, thin and truncated, bevelled externally and overlapped by the greater sphenoid wing; the middle is arched, bevelled externally and overlapped by temporal squama; the posterior part is short, thick and serrated for articulation with the mastoid bone. The *frontal border* is deeply serrated, bevelled externally above, internally below, and articulates with the frontal bone to form half the coronal suture. The *occipital border*, deeply dentated, articulates with the occipital, forming half the lambdoid suture.

The *frontal (anterosuperior) angle*, almost 90°, is at the *bregma* (meeting of the sagittal and coronal sutures). The *sphenoidal (anteroinferior) angle* is between the frontal bone and greater sphenoid wing, its internal surface marked by a deep groove, sometimes a canal, for the frontal branches of the middle meningeal vessels. The frontal sometimes meets the temporal squama, the parietal then failing to reach the greater wing. Where these four bones meet is the *pterion* (p. 352). (Frontotemporal articulation shows racial variation, probably epigenetic; its incidence varied from almost zero in a British seventeenth-century cemetery to 9.8% in Nigerian crania.) The rounded *occipital (posterosuperior) angle* is at the *lambda*, the meeting of sagittal and lambdoid sutures. The blunt *mastoid (postero-inferior) angle* articulates with the occipital and mastoid temporal bones. Internally it bears a broad, shallow groove for the junction of transverse and sigmoid sinuses.

Ossification. Each parietal is ossified from two centres, appearing one above the other near its tuberosity at about the seventh week in utero in dense mesenchyme. These unite early; ossification radiates towards the margins; the angles are consequently last to be ossified and hence fontanelles occur at these sites (p. 393). At birth the temporal lines are low down, reaching their final position after the eruption of molar teeth. Occasionally the parietal is divided by an anteroposterior suture.

The Frontal Bone

The frontal bone is like half a shallow, irregular cap forming the forehead or *frons*; on each side a horizontal *orbital part* roofs most of an orbital cavity.

The *external surface* (**3**.141) has a rounded *frontal tuber (tuberosity)* about 3 cm above midpoint of each supra-orbital margin. These tubera vary, but are especially prominent in young skulls and more so in adult females than males. Below them, separated by a shallow groove, are two curved *superciliary arches*, medially prominent and joined by a smooth median elevated *glabella*; they are more prominent in males, depending partly on size of frontal sinuses; but prominence is occasionally associated with small sinuses. Inferior to the arches are curved *supra-orbital margins* of the orbital openings, their lateral two-thirds sharp, the medial third rounded, and at each junction is a *supra-orbital notch* (or *foramen*) containing supra-orbital vessels and nerve. Medial to it a small *frontal notch* or *foramen* occurs in 50% of skulls. Berry (1975) has recorded incidences of frontal and supra-orbital *foramina* and *notches* (incisures). A supra-orbital notch or foramen occurs equally in some populations (e.g. 51% of Mexican crania). A frontal *foramen* occurs in 15–87% in various ethnic groups. Both features show sexual dimorphism (Kimura 1977).

The supra-orbital margin ends laterally in a *zygomatic process*, strong, prominent and meeting the zygomatic bone. From this a line curves posterosuperiorly, dividing into *superior* and *inferior temporal lines*, continued on the temporal squama.

The region between supra-orbital margins is the *nasal part*. Inferiorly a serrated *nasal notch* articulates with the nasal bones and, laterally, with the maxillary frontal processes and lacrimal bones. From the centre of the notch posteriorly the bone projects antero-inferiorly behind nasal bones (**3**.114) and maxillary frontal

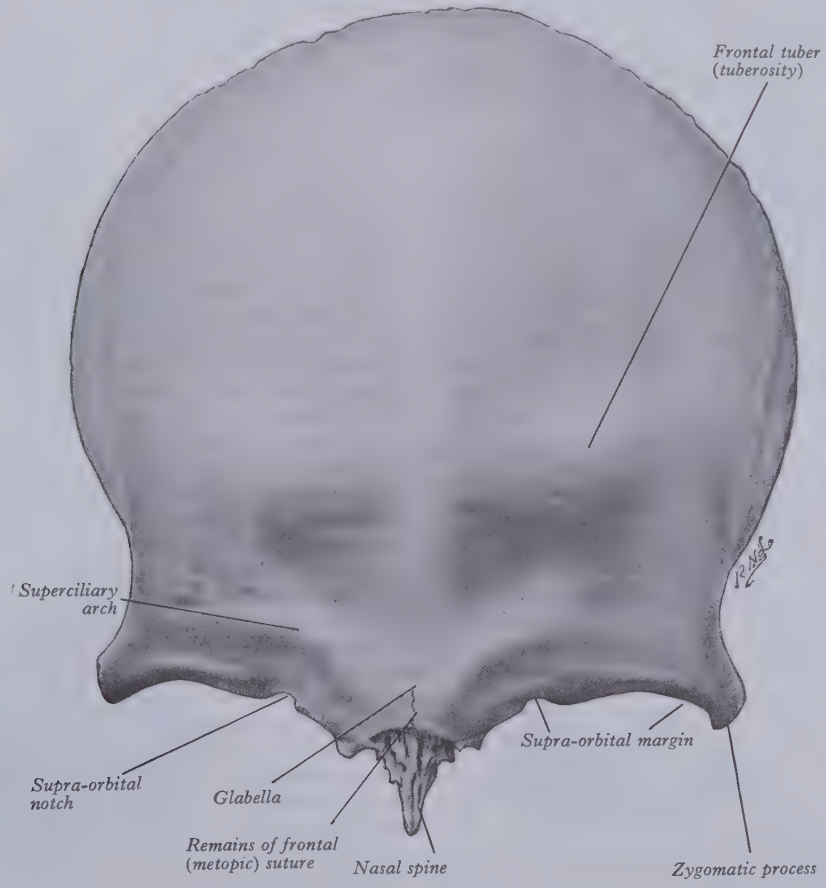
processes, supporting the nasal bridge. The region ends in a sharp *nasal spine*, on each side of which a small grooved surface partly roofs the ipsilateral nasal cavity. The nasal spine also contributes slightly to the nasal septum; in front it articulates with the crest of the nasal bones and behind with the perpendicular ethmoidal plate (**3**.114).

The *temporal surface*, postero-inferior to temporal lines, forms the anterior part of the temporal fossa and an attachment of temporalis (**3**.102). The *internal surface* (**3**.142) is concave. Its upper, median part has a vertical *sulcus for the sagittal sinus*, the edges of which unite below as the *frontal crest*; the sulcus contains the superior sagittal sinus (anterior part); to its margins and frontal crest part of falx cerebri is attached. The crest ends in a small notch, completed to form a *foramen caecum* (p. 362) by the ethmoid bone. The internal surface shows impressions of cerebral gyri and small furrows for meningeal vessels. Several *granular foveolae* usually exist near the sagittal sulcus, for arachnoid granulations.

The *parietal (posterior) margin* is thick, deeply serrated, bevelled internally above and externally below; inferiorly it becomes a rough, triangular surface for the greater sphenoid wing.

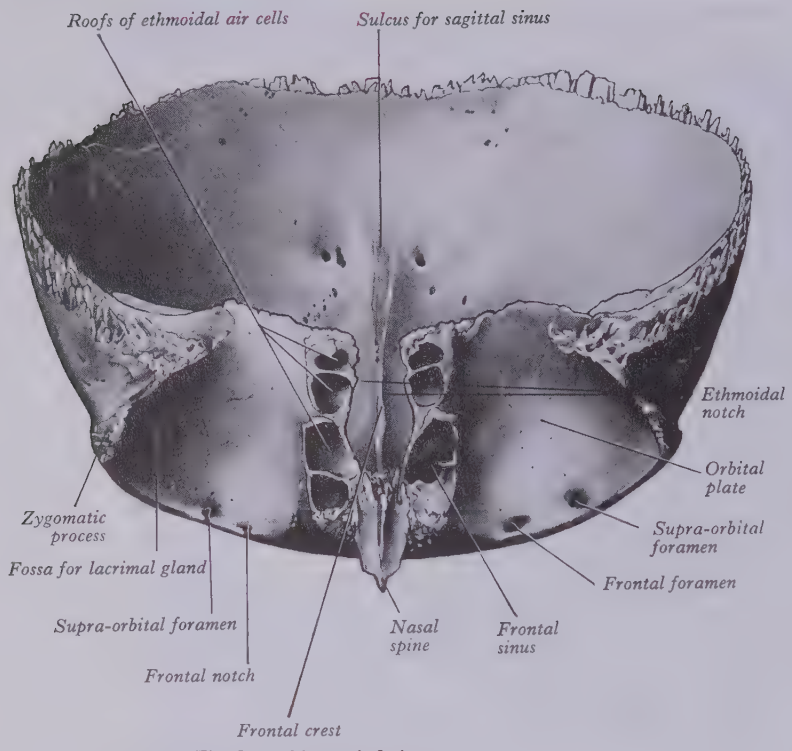
Orbital parts of the frontal bone are two thin, curved, triangular laminae, largely forming the orbital roofs and separated by a wide *ethmoidal notch*.

The *orbital surface* (**3**.142) of each plate is smooth and concave, with a shallow anterolateral *fossa for the lacrimal gland*. Below and behind the medial end of the supra-orbital margin, midway between supra-orbital notch and frontolacrimal suture, is the *trochlear fovea* (or *spine*) for attachment of a fibrocartilaginous trochlea for the superior oblique muscle. The convex *cerebral surface* is marked by frontal gyri of and faint grooves for meningeal vessels.



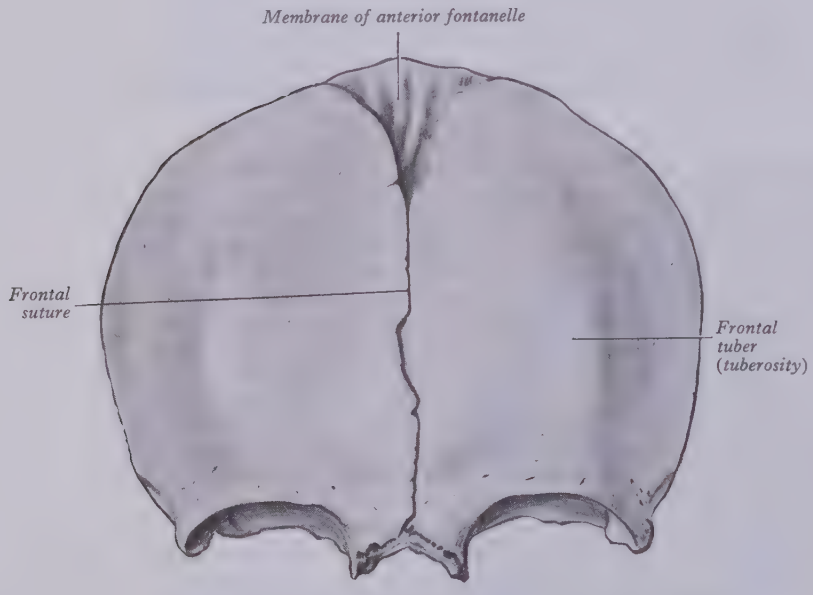
The quadrilateral *ethmoidal notch* (**3**.142) is occupied by the ethmoid's cribriform plate. Inferior to its lateral margins parts of several ethmoidal air cells are visible, completed when the ethmoid is in position. Two transverse grooves across each margin are converted into *anterior* and *posterior ethmoidal canals* by the ethmoid; these open on the medial orbital wall, transmitting anterior and posterior ethmoidal nerves and vessels.

Openings of *frontal sinuses* (**3**.142) are anterior to the ethmoidal notch, lateral to the nasal spine. These two irregular cavities ascend posterolaterally for a variable distance between the frontal laminae, separated by a thin septum, usually deflected from the median plane; the sinuses are hence rarely symmetrical. Rudimentary at birth, usually well-developed by the seventh or eighth year, they reach full size after puberty, being most variable in size and larger in males. Each communicates with the middle meatus in the ipsilateral nasal cavity by a *frontonasal canal*. Degree of development is linked to prominence of superciliary arches, which are a response to masticatory stresses (Weinmann & Sicher 1955). The sinuses show a primary expansion with eruption of the first deciduous molars and again when permanent molars begin to appear in the sixth year. With advancing age osseous absorption may lead to further enlargement.



Posterior borders of orbital plates are thin and serrated to articulate with lesser sphenoid wings; their lateral parts usually appear in the middle cranial fossa between greater and lesser wings.

Structure. The frontal bone is thick and has trabecular tissue between two compact laminae, trabeculae being absent near frontal sinuses. The orbital plates, entirely of compact bone, are thin and even translucent posteriorly, and may be partly absorbed in old age.



Ossification (**3**.143). The frontal bone is ossified in fibrous mesenchyme from two primary centres appearing in the eighth week in utero, one near each frontal tuber. Ossification extends up to form half the main part of the bone, back to form orbital and down to form nasal parts. No secondary centres occur, except two for the nasal spine described as appearing about the tenth year (Inman & Saunders 1937). At birth the bone consists of two halves which may remain separate, a *metopic suture* persisting (Montagu 1951, Tongerson 1951, Linc & Fleischmann 1968). Such

3.141 The frontal bone: external aspect.

3.142 The frontal bone: inferior aspect.

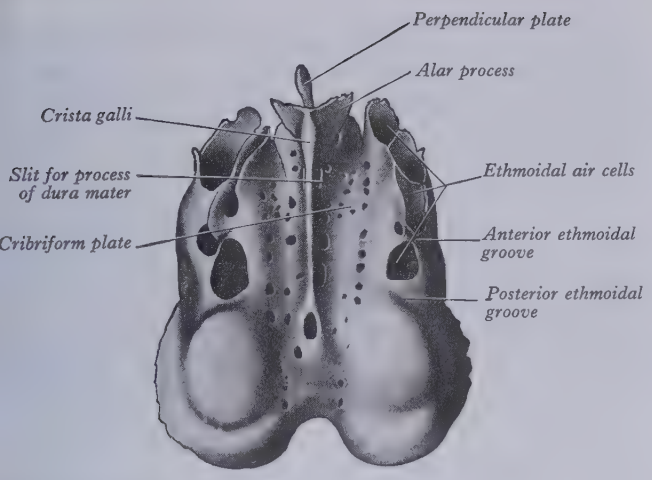
3.143 The frontal bone at birth: anterior aspect. Note that at this stage the bone consists of right and left halves connected by the frontal suture.

metopism has been assessed at 0–7.4% of individuals in various ethnic groups (Berry 1975). In a group of 206 Nigerian skulls (Ajmani et al 1983) incidence was 3.4%. It is high in mongoloids —10% according to Woo (1949).

The Ethmoid Bone

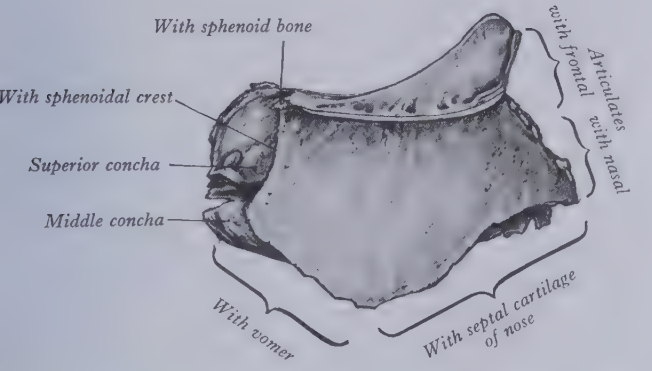
The ethmoid bone, cuboidal and fragile, lies anteriorly in the cranial base, and is involved in the structure of medial orbital walls, nasal septum, the roof and lateral walls of the nasal cavity. It is described as having a horizontal, perforated *cribriform plate*, a median *perpendicular plate* and two lateral *labyrinths*.

The cribriform plate (**3**.144) fills the frontal ethmoidal notch as a large part of the nasal roof. A thick, smooth, triangular, median *crista galli* projects up from this lamina; to its posterior border, thin and curved, the falx cerebri is attached. Its shorter, thick, anteror border joints with frontal bone by two small *alae*, completing the foramen caecum (p. 362). Its sides are smooth but sometimes bulged by air cells. On both sides of crista galli the cribriform plate is narrow, depressed and related to the gyrus rectus and olfactory bulb above it; its numerous foramina transmit olfactory nerves. Anteriorly on each side of the crista is a small slit occupied by dura mater. A foramen carrying anterior ethmoidal nerve and vessels to the nasal cavity is anterolateral to this slit; a groove runs forwards to it from the anterior ethmoidal canal.



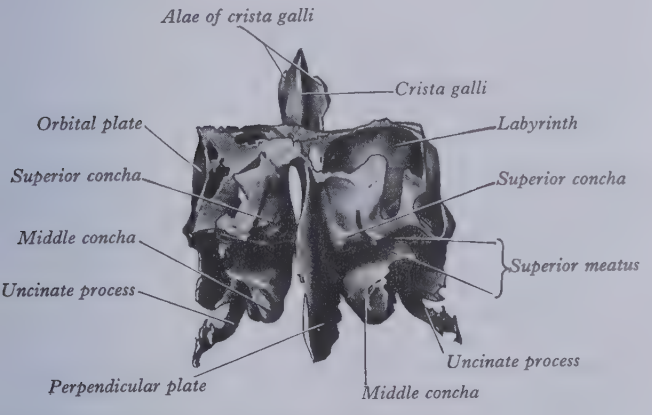
The perpendicular plate (**3**.145,146), thin, flat, quadrilateral and median, descends from the cribriform plate to form the upper part of the nasal septum, usually a little deflected. Its *anterior border* meets the frontal's nasal spine and crest of the nasal bones, its *posterior border* joining the sphenoidal crest above and vomer below. The thick *inferior border* is attached to the nasal septal cartilage. Its surfaces are smooth, except above, where numerous grooves and canals lead to medial foramina in the cribriform plate for filaments of olfactory nerves.

The ethmoidal labyrinths consist of thin-walled *ethmoidal air cells*, in *anterior*, *middle* and *posterior groups* between two vertical plates (p. 1178); the lateral, *orbital plate* is part of the medial orbital wall, the medial being part of lateral nasal wall. In the disarticulated bone many air cells are open, but closed when articulated with adjoining bones, except where they open into the nasal cavity. The *superior surface* (**3**.144) shows open air cells, completed by edges of the frontal ethmoidal notch (**3**.142). It is crossed by two grooves completing *anterior* and *posterior ethmoidal canals* with the frontal. On the *posterior surface* (**3**.146) large air cells are completed by sphenoidal conchae and the palatine's orbital process. The *lateral surface*, (**3**.147) thin, smooth and oblong, is the *orbital plate*, which covers middle and posterior ethmoidal sinuses. It articulates superiorly with the frontal's orbital plate, inferiorly with the maxilla and palatine's orbital process, anteriorly with the lacrimal and posteriorly with the sphenoid bone (**3**.98).

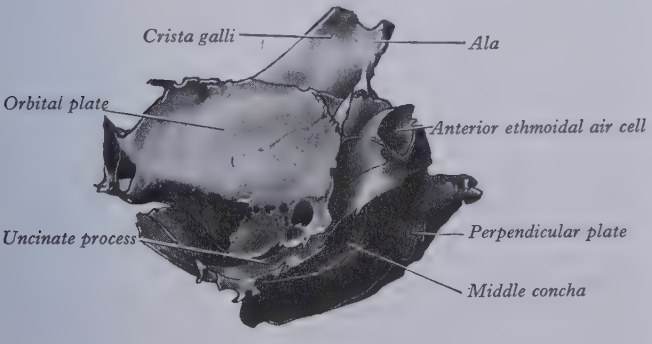


A few air cells lie anterior to the orbital plate, their walls completed by the lacrimal bone and frontal process of the maxilla. A thin, curved *uncinate process*, variable in size, projects posteroinferiorly from the labyrinth, appearing in the medial wall of the maxillary sinus (**3**.98A) as it crosses the hiatus maxillaris to join the inferior nasal concha's ethmoidal process. The upper edge of this process is a medial boundary of the hiatus semilunaris in the middle meatus.

The *medial surface* of the labyrinth (**3**.148) forms part of the lateral nasal wall as a thin lamella descending from the inferior surface of cribriform plate to end as the convoluted *middle nasal concha*. Above this the surface shows many vertical grooves for olfactory nerves. Posteriorly it is divided by the narrow, oblique *superior meatus*, bounded above by the thin, curved *superior nasal concha*; posterior ethmoidal air cells open into this meatus. Antero-inferior to the superior meatus the middle concha's convex surface extends along all the medial surface of the labyrinth, its lower edge thick, its lateral surface concave and part of the *middle meatus*. Middle ethmoidal air cells produce a swelling, *bulla ethmoidalis*, on the lateral wall of the middle meatus (**3**.116); on the bulla, or above it, these cells open into the meatus. A curved *infundibulum* extends up and forwards from the middle meatus, communicating with anterior ethmoidal sinuses; in more than 50% of crania it continues up as the frontonasal duct.



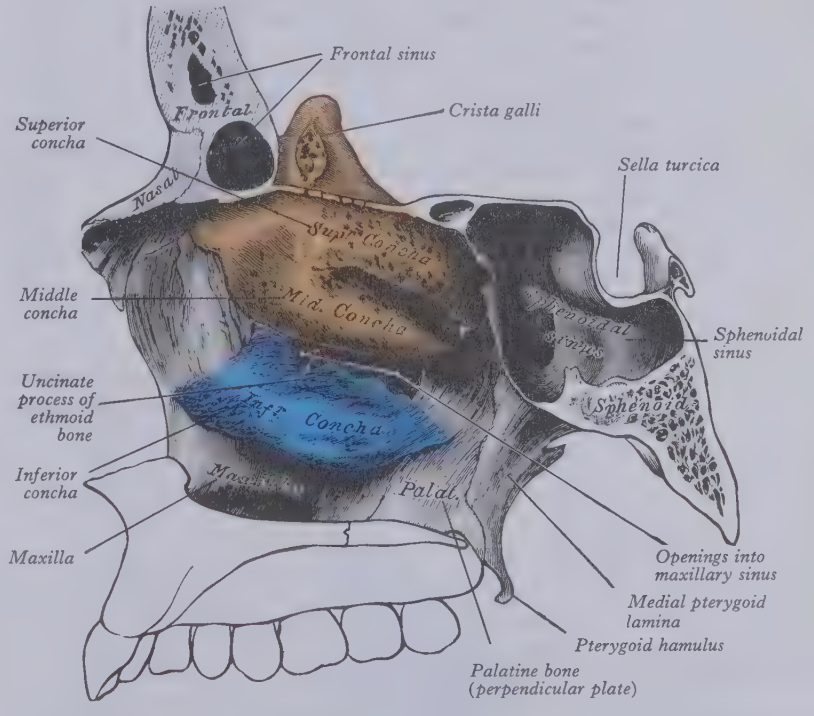
Ossification. The ethmoid bone ossifies in the cartilaginous *nasal capsule* from three centres: one in the perpendicular plate, one in each labyrinth. The latter two appear in the orbital plates between the fourth and fifth months in utero, extending into the ethmoid conchae. At birth, the labyrinths, although ill-developed, are partially ossified, the remainder cartilaginous. During the first year the perpendicular plate and crista galli begin to ossify from the median centre, fusing with labyrinths early in the second year. The cribriform plate is ossified partly from the perpendicular plate, partly from labyrinths. Ethmoidal air cells begin to develop in utero; in the newborn they are narrow pouches.



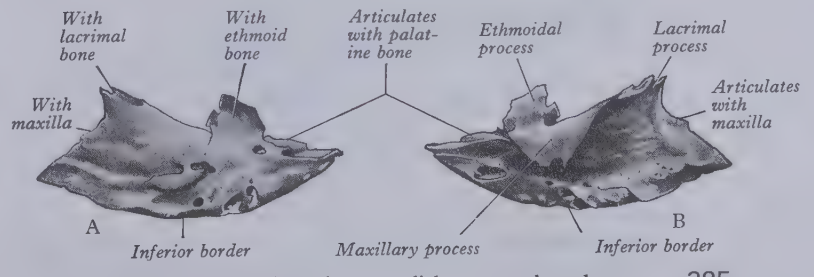
3.144 The ethmoid bone: superior aspect.

3.145 The perpendicular plate of the ethmoid bone: right lateral aspect, shown after removal of the right ethmoidal labyrinth.

3.146 The ethmoid bone: posterior aspect.



3.147 The ethmoid bone: right lateral aspect.



The Inferior Nasal Conchae

These bones are curved horizontal laminae in the lateral nasal walls (3.148). Each has two surfaces, borders and ends. The *medial surface* (3.149A) is convex, much perforated, and longitudinally grooved by vessels. The *lateral surface* is concave (3.149B) and part of the inferior meatus. The *superior border*, thin and irregular, may be divided into three regions: an anterior articulating with the maxillary conchal crest, a posterior with the palatine conchal crest and a middle with *three processes*, variable in size and form. Of these the *lacrimal process*, small and pointed, at the junction of anterior with posterior three-fourths of the border, articulates apically with a descending lacrimal process (3.150) and, by its margins, with edges of the nasolacrimal groove on the medial maxillary surface, thus completing the nasolacrimal canal. Most posterior, a thin *ethmoidal process* ascends to the ethmoid uncinate process (3.116). An intermediate thin *maxillary process* curves inferolaterally to articulate with the maxilla and maxillary process of the bone as part of the maxillary sinus' medial wall (p. 387). The *inferior conchal border* is thick and spongiose, especially in its midpart. Both *conchal ends* are more or less tapered, the posterior more so.

Ossification is from one centre, appearing at about the fifth month in utero in the incurved lower border of the cartilaginous nasal capsule's lateral wall. It loses continuity with the capsule during ossification.

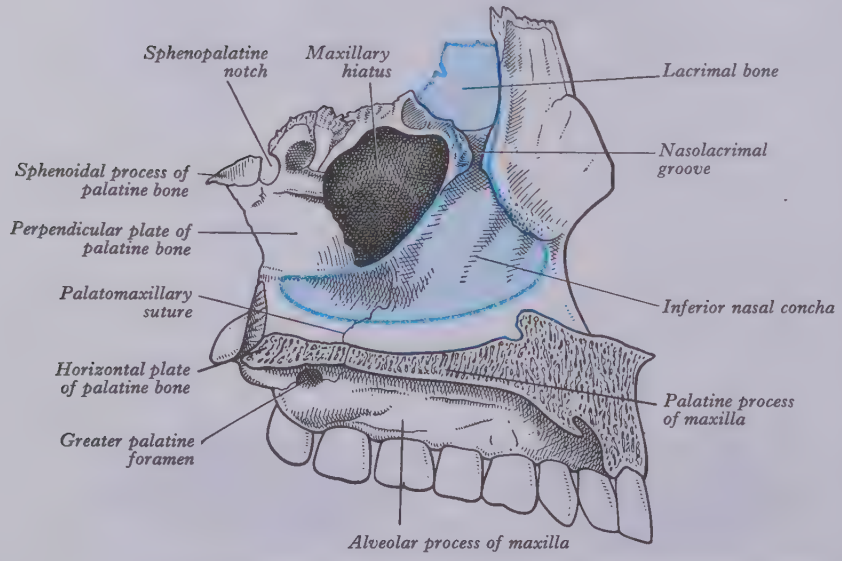
3.149 The right inferior nasal concha. A. medial aspect; B. lateral aspect.

The Lacrimal Bones

These smallest and most fragile of cranial bones lie anteriorly in the medial orbital walls (3.98A). Each has two surfaces and four borders. The *lateral, orbital surface* (3.150) is divided by a vertical *posterior lacrimal crest*, anterior to which is a vertical groove, its anterior edge meeting the posterior border of the frontal process of the maxilla to complete the *fossa for the lacrimal sac*. The groove's medial wall is prolonged by a descending process (3.151)



3.150 The right lacrimal bone: lateral aspect.

helping to form the nasolacrimal canal by joining the lips of the maxillary nasolacrimal groove and lacrimal process of the inferior nasal concha. Behind the crest is a smooth part of the medial orbital wall. To this surface and crest the lacrimal part of orbicularis oculi is attached; the surface ends below in the *lacrimal hamulus* which, with the maxilla, completes the upper orifice of the nasolacrimal canal (3.97); the hamulus may be a separate *lesser lacrimal bone*. The antero-inferior region of the *medial (nasal) surface* is part of the middle meatus; its posterosuperior part meets the ethmoid to complete some anterior ethmoidal air cells. The *anterior lacrimal border* articulates with the frontal process of the maxilla, the *posterior* with the ethmoid's orbital plate, the *superior* with the frontal bone, and *inferior* with the maxillary orbital surface (3.97).

Ossification is from a centre appearing at about the twelfth week in mesenchyme around the nasal capsule. In later life the lacrimal is subject to patchy erosion.

The Nasal Bones

These are small, oblong, variable in size and form, placed side by side between the frontal processes of the maxillae; they jointly form the nasal bridge (3.91A,B,116).

3.151 Drawing to show how the medial wall of the nasolacrimal canal is formed by the articulation of the descending process of the lacrimal bone with the lacrimal process of the inferior nasal concha.

Each has two surfaces and four borders. The *external surface* (3.152A) has a descending concavoconvex profile and is transversely convex. It is covered by the procerus and nasalis muscles and perforated centrally by a small venous foramen. The *internal surface* (3.152B), transversely concave, is traversed by a longitudinal groove for the anterior ethmoidal nerve. The *superior border*, thick and serrated, articulates with the frontal. The *inferior border*, thin and notched, is continuous with the lateral nasal cartilage. The *lateral border* joins the frontal process of the maxilla. The *medial border*, thicker above, meets its fellow and projects behind as a vertical crest, a small part of the nasal septum, articulating from above with the nasal spine of the frontal, the ethmoid's perpendicular plate and the nasal septal cartilage. **Ossification** is from a centre which appears early in the third month in mesenchyme overlying the cartilaginous anterior part of the nasal capsule.

The Vomer

The vomer is thin, flat, and almost trapezoid, forming the postero-inferior part of the nasal septum (3.114); it has lateral surfaces and four borders. Both *surfaces* (3.153A,B) are marked by grooves for nerves and vessels, one obliquely antero-inferior for nasopalatine nerve and vessels. The *superior border* is thickest, with a deep furrow between projecting *alae* which fits the sphenoidal rostrum; the alae articulate with the sphenoidal conchae, sphenoidal processes of the palatine bones and vaginal processes of medial pterygoid plates. Where each ala is between the sphenoid's body and the vaginal process its inferior surface helps to form the vomerovaginal canal (p. 355). The *inferior border* articulates with the median maxillary and palatine nasal crests. The *anterior border*, the longest, articulates in its upper half with the ethmoid's perpendicular plate; the lower half is cleft to receive the inferior margin of nasal septal cartilage. The *posterior border* is concave, separating the posterior nasal apertures; it is thick and bifid above, thin below. The anterior end articulates with the posterior margin of the maxillary incisor crest and descends between the incisive canals.

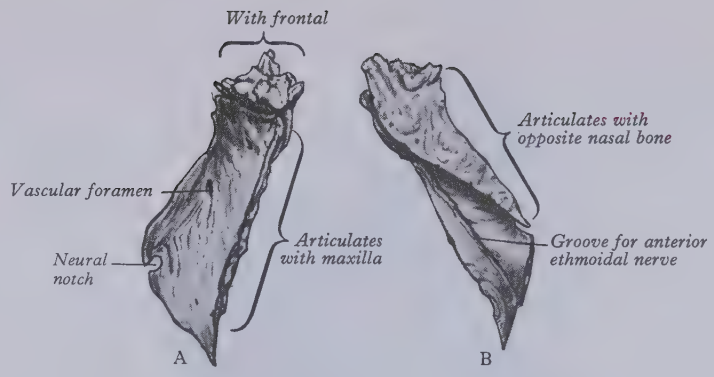
Ossification. The nasal septum is at first a plate of cartilage, part of which is ossified above to form the ethmoid's perpendicular plate; its antero-inferior region persists as septal cartilage, the vomer being ossified in strata of connective tissue covering it on each aspect in its postero-inferior part. About the eighth week two centres appear flanking the midline and in the twelfth these unite below the cartilage, forming a deep groove (3.153B) for the nasal septal cartilage. Union of the bony lamellae progresses anterosuperiorly, while intervening cartilage is absorbed; by puberty they are almost united, but the bilaminar origin remains in the everted alae and anterior marginal groove (3.153A).

Sutural Bones

Additional ossificatory centres may occur in or near sutures, giving rise to isolated *sutural bones* (3.154). Usually irregular in size and shape, and most frequent in the lambdoid suture, they sometimes occur at fontanelles, especially the posterior, perhaps representing a *pre-interparietal* element, a true *interparietal* or some composite. An isolated bone at the lambda is sometimes dubbed the *Inca bone* or *Goethe's ossicle* (p. 373). One or more *pterion ossicles* or *epipteric bones* may appear between the parietal's sphenoidal angle and sphenoid's greater wing, varying much in size, but more or less symmetrical. Sutural bones usually have little morphological significance, with notable exceptions (vide infra and p. 373). There are often only two or three, but they appear in great numbers in hydrocephalic skulls. They have therefore been linked with rapid cranial expansion, but this is unproven. For a detailed analysis of these and other *epigenetic variations* in 585 adult crania, consult Berry & Berry (1967), who discuss genetic identification of populations by such criteria, subsequently providing further data (Berry 1975). A report of their occurrence in fetal skulls (El-Najjar & Dawson 1977) supports a genetic factor.

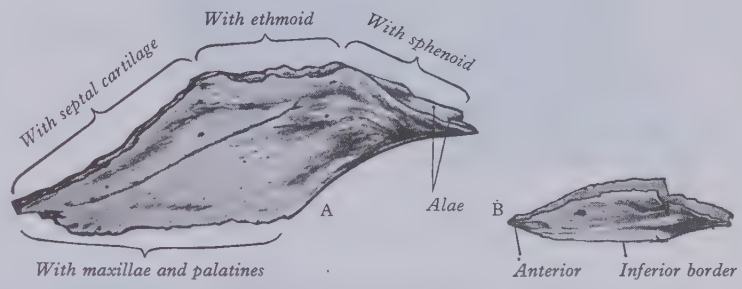
The Maxillae

The maxillae, largest of the facial bones excepting the mandible, jointly form the whole upper jaw (3.92A,B,93), most of the buccal roof, floor and lateral wall of nasal cavity, orbital floors, in part the infratemporal and pterygopalatine fossae and inferior orbital and pterygomaxillary fissures. Each has a body and zygomatic, frontal, alveolar and palatine processes (3.155–158).



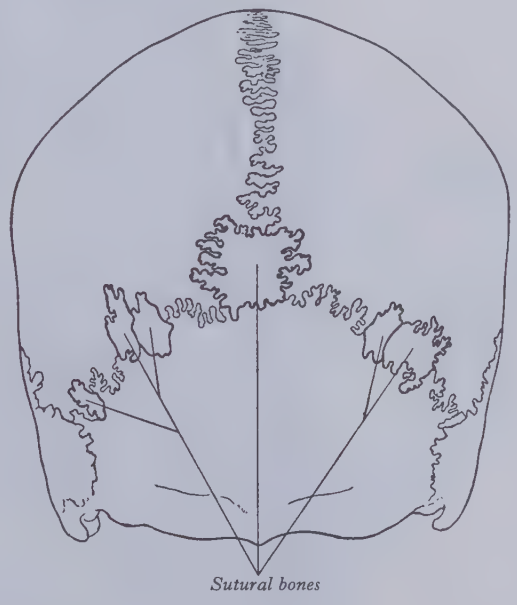
The maxillary body, roughly pyramidal, has anterior, infratemporal (posterior), orbital and nasal surfaces, enclosing the maxillary sinus. The *anterior surface* (3.95,102,155,156), facing anterolaterally, displays inferior elevations overlying the roots of teeth. Above the incisors is a shallow *incisive fossa* in which is attached the depressor septi; to the alveolar border below this a slip of orbicularis oris is attached, and superolateral to it is the nasalis. Lateral to this fossa is a larger, deeper *canine fossa*, separated from it by the *canine eminence*, over the canine socket. In the canine fossa the levator anguli oris is attached. Above it is the *infra-orbital foramen*, the anterior end of its canal, transmitting infra-orbital vessels and nerve. Above the foramen a sharp border, dividing anterior and orbital surfaces, is part of the orbital opening's rim; attached near it is the levator labii superioris. Medially the anterior surface ends at a deeply concave *nasal notch*, ending in a pointed process which, with its fellow, forms the *anterior nasal spine*. To the anterior surface near the notch, the nasalis and depressor septi are attached.

The convex *infratemporal surface* (3.155,156), facing posterolaterally, forms the anterior wall of the infratemporal fossa and is separated from the anterior surface by the maxilla's zygomatic process and a ridge ascending to it from the first molar socket. Near its centre are apertures of two or three *alveolar canals*, containing posterior superior alveolar vessels and nerves. Posteroinferior is the *maxillary tuberosity*, rough superomedially where it meets the palatine bone's pyramidal process (3.155,158); a few fibres of medial pterygoid are attached to it, and sometimes it articulates with the lateral pterygoid plate. Above this is the smooth anterior boundary of the pterygopalatine fossa, grooved by the maxillary nerve as it passes laterally and slightly upwards into the infra-orbital groove on the orbital surface.



The *orbital surface* (3.97,155), smooth and triangular, forms most of the orbital floor. Anteriorly its *medial border* bears a *lacrimal notch*, behind which it joints with the lacrimal bone, the ethmoid's orbital plate and, posteriorly, the palatine's orbital process (3.158). Its *posterior border* is smoothly rounded, forming most the anterior edge of the inferior orbital fissure; central is the infra-orbital groove. The *anterior border* is part of the orbital margin, continuous medially with the lacrimal crest of the maxilla's frontal process (p. 389). The *infra-orbital groove*, for so-named vessels and nerve, begins midway on the posterior border, continuous with a groove on the posterior surface and passes forwards into the *infra-orbital canal*, which opens on the anterior surface below the infra-orbital margin. Near its midpoint the canal has a small lateral branch for the anterior superior alveolar nerve and vessels; this *canalis sinuosus* (Wood Jones; see Jones 1939) descends in the orbital floor lateral to the infra-orbital canal and curves medially in the anterior wall of the maxillary sinus. It passes below the infra-orbital foramen to the margin of the anterior nasal aperture in front of the anterior end of the inferior concha; it then follows the aperture's lower margin to open near the nasal septum in front of the incisive canal. Anteromedial in the orbital surface and lateral to the lacrimal groove, the attachment of the inferior oblique muscle may make a small depression.

The *nasal surface* (3.158) displays posterosuperiorly the large, irregular *maxillary hiatus* leading into the sinus. At the upper hiatal border are parts of air sinuses completed by the ethmoid and lacrimal bones; the smooth concave surface below the hiatus is part of the inferior meatus, and behind it a rough surface meets the palatine's perpendicular plate; this surface is traversed by a groove, descending forwards from the mid posterior border; it is converted into a *greater palatine canal* by the palatine's perpendicular plate. Anterior to the hiatus a deep groove, continuous above with the lacrimal groove (p. 386), makes about two-thirds of the circumference of the nasolacrimal canal, the rest being the lacrimal's descending part, and the lacrimal process of the inferior nasal concha (3.151). This canal leads the nasolacrimal duct to the inferior meatus (3.116). More anterior is an oblique *conchal crest* for the inferior nasal concha; the concavity below it is part of the inferior meatus; above it the surface is part of the atrium of the middle meatus.



The maxillary sinus (3.157,158), a large pyramidal cavity, has thin walls corresponding to orbital, alveolar, facial and infratemporal aspects of the maxilla. Its lateral, truncated *apex* extends into the zygomatic process, sometimes into the zygomatic bone; its *base* is medial and is the lateral wall of the nasal cavity, displaying in the maxillary hiatus when seen in a disarticulated bone. This hiatal aperture is reduced by the ethmoidal uncinate process and descending part of the lacrimal bone above, the maxillary process of the inferior nasal concha below, and the

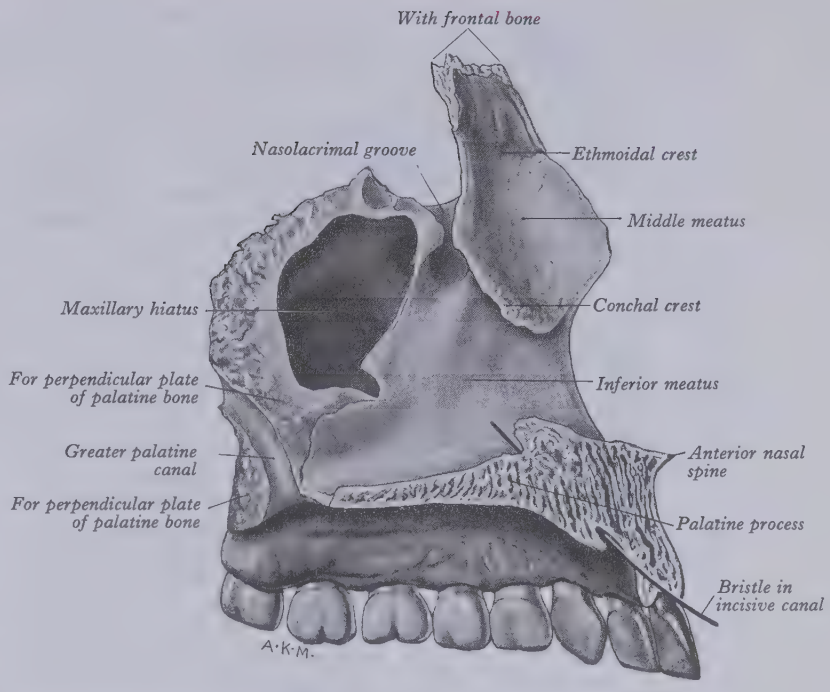
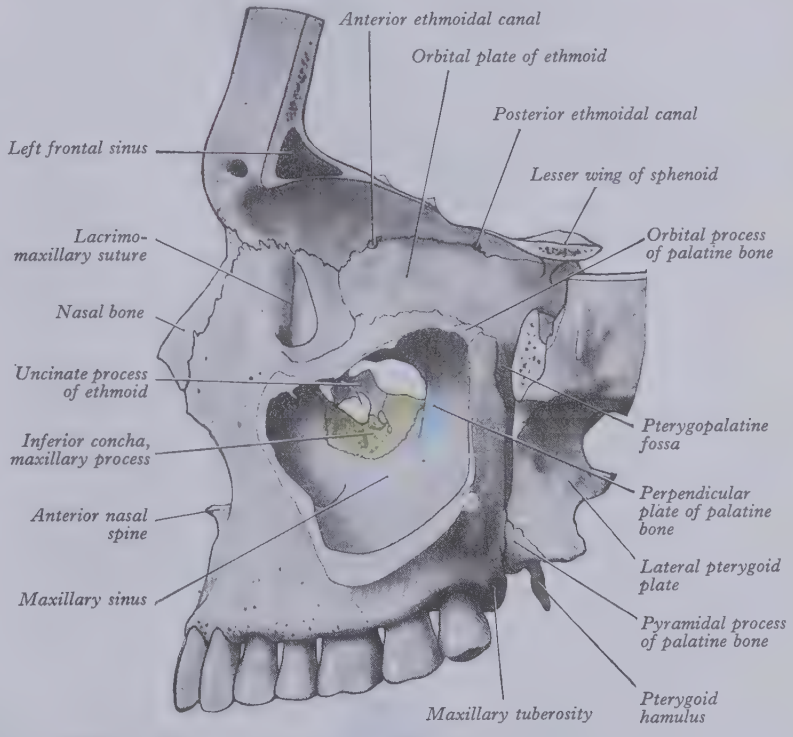
3.157A High resolution projection microradiograph of a maxilla (mediolateral view). Note particularly the distribution of compact and trabecular bone, the extent of the profile of the maxillary sinus and its relation to the dental alveoli, the compact bone of the *laminae durae* of the latter, the hard tissues, pulp cavities, root canals and foramina of the teeth. Contrast the dense shells of compact bone in the frontal, zygomatic and palatine processes with the fine filigree of trabecular bone in much of the alveolar process, interior of the zygomatic process and the posterior wall of the sinus. (Contributed by C Buckland-Wright, Guy's Hospital Medical School.)

palatine's perpendicular plate behind (3.116,158). The maxillary sinus hence connects only with the middle meatus, usually by two small holes, one usually closed by mucous membrane. Its *posterior wall* contains *alveolar canals*, conducting posterior superior alveolar vessels and nerves to molar teeth; these canals may ridge the sinus, whose *floor* is formed by the alveolar process, its lowest part about 1.25 cm below the nasal floor. Radiating septa of varying size usually spring from the sinual floor between adjacent dental roots; sometimes it is perforated by molar roots (p. 1179). The infra-orbital canal usually ridges the sinus from *roof* to *anterior wall*. The cavity's size varies, even between sides of a single skull (p. 1179).



Applied anatomy. Because of the extreme thinness of sinual walls, a tumour may push up the orbital floor and displace the eyeball, project into the nasal cavity, protrude on the cheek or spread back into the infratemporal fossa or down into the mouth. Extraction of molar teeth may damage the floor, and impact may fracture its walls.

The zygomatic process is a pyramidal projection where anterior, infratemporal and orbital surfaces converge. *In front* it merges into the maxillary body's facial surface; *behind* it is concave and continuous with the infratemporal surface; *above* it is roughly serrated for articulation with the zygomatic bone; *below* an arched border separates facial (anterior) and infratemporal surfaces.



The frontal process projects posterosuperiorly between nasal and lacrimal bones (3.89,158). Its *lateral surface* (3.101,158) is divided by a vertical *anterior lacrimal crest* for attachment of medial palpebral ligament and continuous below with the infra-orbital margin. At junction of the crest and orbital surface a small palpable tubercle is a guide to the lacrimal sac. The smooth area anterior to the lacrimal crest merges below with the body's anterior surface; part of orbicularis oculi and levator labii superioris alaeque nasi are attached here (3.95,102). Behind the crest a vertical groove combines with one on the lacrimal bone to complete the lacrimal fossa. The *medial surface* (3.160) is part of the lateral nasal wall. A rough subapical area joints with the ethmoid and closes anterior ethmoidal air cells. Below this an oblique *ethmoidal crest* articulates posteriorly with the middle nasal concha and anteriorly underlies the *agger nasi*, a ridge anterior to the concha on the lateral nasal wall; the crest is the upper limit of the atrium of the middle meatus. The frontal process joints apically with the frontal's nasal part, its *anterior border* with the nasal bone, its *posterior* with the lacrimal.

The alveolar process is thick and arched, wide behind, and socketed for dental roots. Eight sockets on each side vary according to contained teeth. That for the canine tooth is deepest, those for molars widest and subdivided into three by septa, those for incisors and second premolar single, that for first premolar sometimes double. The buccinator is attached to the external alveolar aspect, as far forwards as the first molar. In articulated maxillae the processes form the *alveolar arch*. Occasionally a longitudinal *maxillary torus*, variably prominent, appears on the palatal aspect of the process near upper molar sockets.

The palatine process, thick, strong and horizontal, projects medially from the lowest part of the medial maxillary aspect, forming a large part of the nasal floor and palate; it is much thicker in front. Its *inferior surface* (3.106) is concave, uneven and forms with its fellow about the anterior three-fourths of the osseous palate. It displays numerous vascular foramina and depressions for palatine glands and, posterolaterally, two grooves containing greater palatine vessels and nerves. Between the maxillae the infundibular *incisive fossa* appears behind incisor teeth, posterior to which is the median intermaxillary palatal suture—a little uneven but relatively flat on its oral aspect. However, its bony margins are sometimes raised into a prominent longitudinal *palatine torus* (p. 354), incidence of which varies (p. 396), e.g. it is rare in Burmese, but frequent in English crania (29% in males, 48% in females among nineteenth-century Londoners). In the *incisive fossa* are orifices of two lateral *incisive canals*; each ascends into its half of the nasal cavity, transmitting terminations of greater palatine artery and nasopalatine nerve. Occasionally two additional median apertures exist: *anterior* and *posterior incisive foramina*, transmitting the nasopalatine nerves, the left passing anterior. On the inferior palatine surface a fine groove, sometimes termed *incisive suture* and prominent in young skulls, may be observed in adults where it extends anterolaterally from the incisive fossa to the interval between lateral incisor and canine teeth. Anterior to this supposed suture is the *os incisivum*, long considered to represent the premaxilla, a separate element in most vertebrates including primates. This view has been criticized (vide infra). The *superior surface* of the palatine process is concave transversely, smooth and forms most of the nasal floor; anteriorly, near its median margin, is the incisive canal. The *lateral border* is continuous with the maxillary body. The *medial border*, thicker in front, is raised into

3.157B The left maxilla: medial aspect.

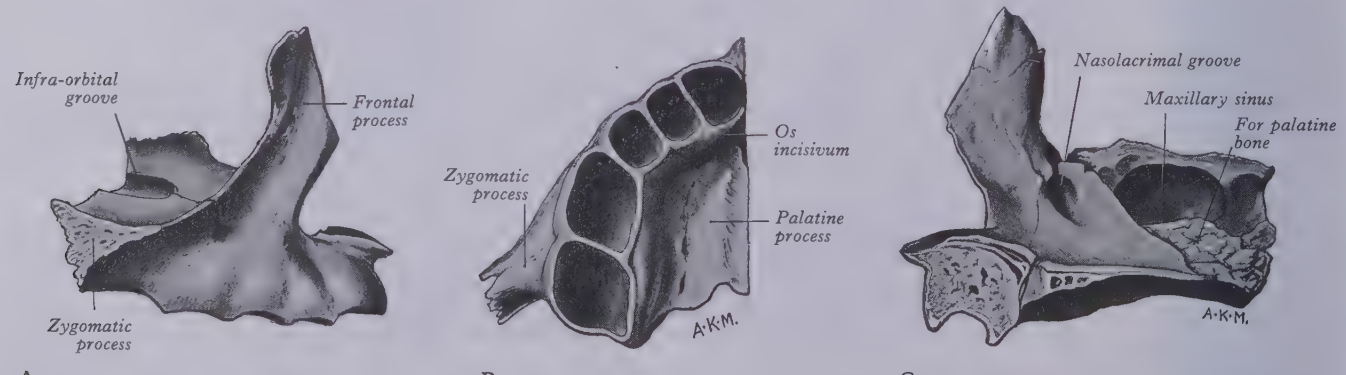
3.158 Oblique sagittal section through the anterior part of the skull, showing the medial wall of the left orbit and the medial wall of the left maxillary sinus. The inferior concha is shown in yellow and the perpendicular plate of the palatine bone in blue.

a *nasal crest* which, with its fellow, forms a groove for the vomer. The front of this ridge rises higher as an *incisor crest*, prolonged forwards into a sharp process which, with its fellow, forms an *anterior nasal spine*. The *posterior border* is serrated for the palatine's horizontal plate.

Ossification. The maxilla ossifies in a sheet of mesenchyme superficial to the nasal capsule. Three centres are described: one for the main maxillary mass appears above the canine fossa at about the sixth intra-uterine week; two others are ascribed to the *premaxillary* region, the so-called *os incisivum*, which corresponds in position with a true premaxilla. Of these two 'premaxillary' centres, reputed to occur in human embryonic upper jaw (Woo 1949, Noback & Moss 1953), the principal one is said to appear above the incisor tooth germs in the seventh week; a second, sometimes called *paraseptal* or *prevomerine*, is considered to begin in the medial wall of a paraseptal cartilage at the ventral margin of nasal septum, fusing almost at once with the maxillary's palatine process. Bone formed by the principal premaxillary centre is reputedly overgrown by bone from the main maxillary mass, fusing along its anterior limit with the maxilla's alveolar process. (This junction may be discernible as the *interalveolar suture of Farmer*.) This would explain the absence, after the third month in utero, of any *facial* indication of a premaxilla (*os incisivum*). However a suture, or what appears to be one, may occur on the nasal floor behind its anterior margin. When identifiable postnatally, this suture passes medially on each side to the incisive canal. Moreover, a suture or cleft is always visible at birth anterior in the palate; diverging on each side from the incisive fossa it runs to the septum between lateral incisor and canine teeth (rarely between canine and first premolar). This *palatal* sign of separation between the os incisivum and the rest of the maxilla may persist until the middle decades. Considered together, these features delineate a separate element, anterior to incisive fossa and canals, forming parts of incisor alveoli. Being fused anteriorly with an overlap from the maxillary centre, this 'os incisivum' has no facial representation.

Regular occurrence of a premaxilla in other primates, as a separate bone, has naturally prompted attempts to identify a human homologue. Despite early disagreements (Fawcett 1911a), the above description of maxillary development has become standard, conveniently equating the os incisivum with mammalian premaxilla. This argument depends primarily on supposed ossificatory centres in the os incisivum. One study of serial sections in human embryos strongly suggested that ossification in it is merely an extension from the maxillary centre (Wood et al 1969). The osseous lamina developing from this centre, as in the mandible, is complex, appearing in more than one place in some sections and suggesting multiple centres. It was claimed that their continuity is clear in serial sections, providing a welcome simplification for complexities of maxillary development. Extension from a supposed initial 'premaxillary' centre to form the frontal and palatine processes can thus be ascribed instead to the main maxillary centre. But this simplification does not explain various sutures, clefts and grooves held to delineate the human os incisivum. Whether patterns of pre-ossificatory mesenchymal condensation in the region have any phylogenetic significance remains uncertain; the status of a human premaxilla is thus problematical. There is strong evidence, at least, that it has no specific centre of ossification.

The maxillary sinus appears as a shallow groove (**3**.159C) on the nasal aspect at about the fourth month in utero. Infraorbital vessels and nerve are for a time in an open groove in the orbital floor; its anterior part is converted into a canal by a lamina growing in from the lateral side.



Age Changes in the Maxilla

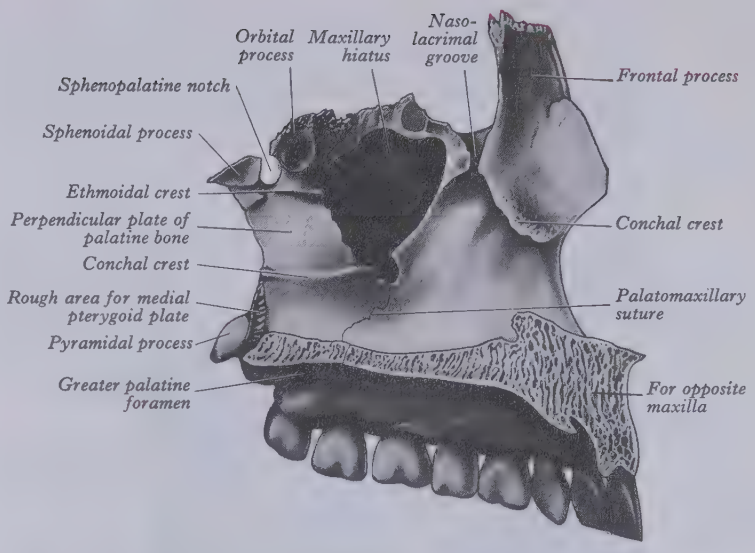
At birth transverse and sagittal maxillary dimensions are greater than vertical. The frontal process is prominent, but the body little more than an alveolar process, its alveoli reaching almost to the orbital floor, the maxillary sinus a mere furrow on the lateral nasal wall. In adults the vertical dimension is greatest, owing to development of the alveolar process and enlargement of the sinus. If all teeth are lost, in old age or earlier, the bone reverts towards infantile shape: its height diminishes, the alveolar process is absorbed (p. 393) and lower parts of the bone contracted and reduced in thickness at the expense of the labial wall (p. 369). Differences in mode of alveolar absorption in maxilla and mandible are of practical importance in fitting dentures.

The Palatine Bones

The palatine bones are posteriorly placed in the nasal cavity between the maxillae and sphenoid's pterygoid processes (**3**.116); they contribute to the nasal floor and lateral walls, to the palate and orbital floors, and to pterygopalatine and pterygoid fossae and inferior orbital fissures. Each resembles a letter L in its *horizontal* and *perpendicular plates*, with three processes: *pyramidal*, inclining down and posterolaterally from the junction of these plates, *orbital* and *sphenoidal*, surmounting each perpendicular plate and separated by the deep sphenopalatine notch.

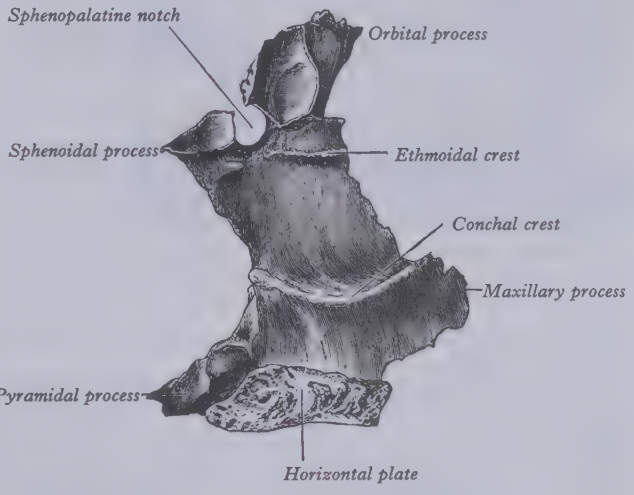
The palatine's horizontal plate (**3**.106,162) is quadrilateral, with two surfaces and four borders. The *nasal surface*, transversely concave, forms the posterior nasal floor; the *palatine surface* forms, with its fellow, a posterior quarter of the bony palate; near its posterior margin a curved *palatine crest* often exists. The *posterior border* is thin and concave; to it and its adjacent surface behind the palatine crest the expanded tendon of tensor veli palatini is attached. Medially the posterior border forms, with its fellow, a median *posterior nasal spine* for attachment of the uvular muscle. The serrated *anterior border* articulates with the maxillary palatine process. The *lateral border* is continuous with the perpendicular plate and marked by a *greater palatine groove*. The *medial border*, thick and serrated, articulates with its fellow at midline, forming the posterior part of the *nasal crest*, which articulates with the posterior part of the vomer's lower edge and the latter is continuous anteriorly with the maxillary nasal crest.

3.159 The right maxilla at birth. A. Lateral aspect; B. Inferior aspect; C. Medial aspect. Note alveoli for deciduous teeth (B) and rough articular area for opposite maxilla (C).



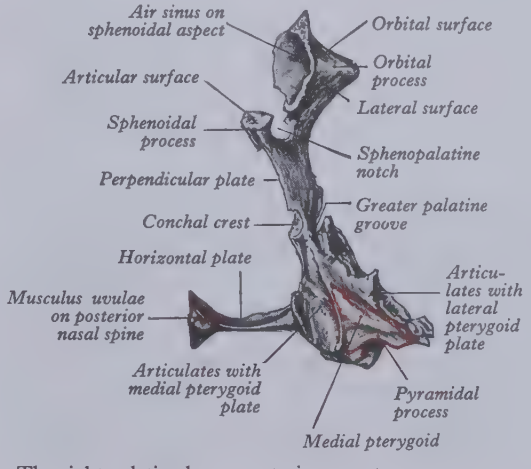
The perpendicular plate (3.161,162), thin and oblong, has two surfaces and four borders. The *nasal surface* bears inferiorly a broad depression, part of the inferior meatus. Above this the horizontal *conchal crest* articulates with the inferior concha; above this again a shallow depression forms part of middle meatus. This last depression is limited above by an *ethmoidal crest* for the middle nasal concha, above which a narrow, horizontal groove forms part of the superior meatus. The *maxillary surface*, largely rough and irregular, articulates with the maxillary's nasal surface; posterosuperiorly it is a smooth medial wall to the pterygopalatine fossa; its anterior area, also smooth, overlaps the maxillary hiatus from behind to form a posterior part of the medial wall of the maxillary sinus (3.158). Posteriorly on this maxillary surface is the deep, obliquely descending *greater palatine groove*, converted into a *canal* by the maxilla; it transmits the greater palatine vessels and nerve.

The *anterior border* is thin and irregular; level with the conchal crest a pointed lamina projects below and behind the maxillary process of the inferior concha, articulating with it and so appearing in the medial wall of the maxillary sinus (3.158). The *posterior border* (3.162) has a serrated suture with the medial pterygoid plate and is continuous above with the palatine's sphenoidal process, and expanding below into its pyramidal process. From the *superior border* project both the orbital and sphenoidal processes separated by the *sphenopalatine notch* (made into a *foramen* by the sphenoid body). This foramen connects the pterygopalatine fossa to the posterior part of the superior meatus, transmitting sphenopalatine vessels and posterior superior nasal nerves. The *inferior border*, continuous with the lateral border of the horizontal plate, bears the lower end of the greater palatine groove in front of the pyramidal process.



The pyramidal process slopes down posterolaterally from the junction of the horizontal and perpendicular palatine plates into the angle between the pterygoid plates. On its *posterior surface* a smooth, grooved triangular area, limited on each side by rough articular furrows articulating with pterygoid plates, completes the lower part of the pterygoid fossa, and is a partial attachment of the medial pterygoid muscle. Anteriorly the *lateral surface* articulates with maxillary tuberosity; posteriorly a smooth triangular area appears low in the infratemporal fossa between the tuberosity and lateral pterygoid plate (3.103A). The *inferior surface*, near its union with the horizontal plate, shows the *lesser palatine foramina* for the corresponding nerves and arteries (3.106).

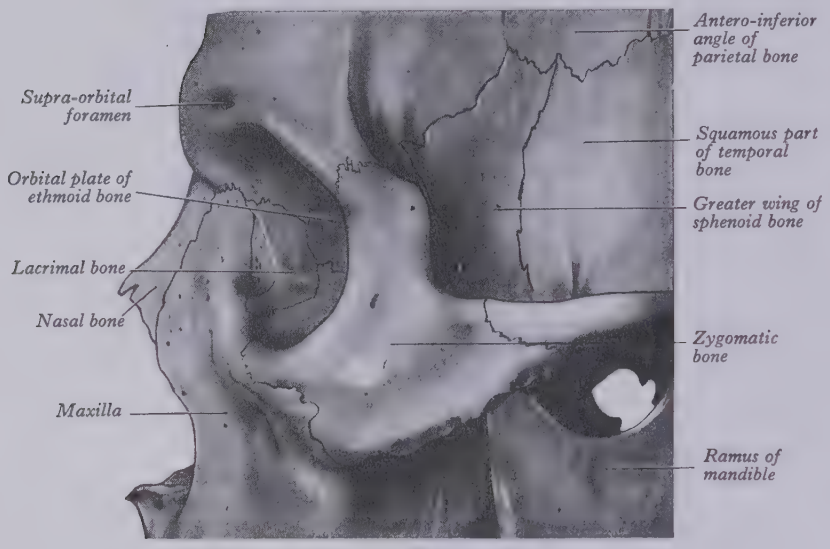
The orbital process (3.161,162), directed superolerally from in front of the perpendicular plate with a constricted 'neck', encloses an air sinus and presents three articular and two non-articular surfaces. Of the former (1) the oblong *anterior* or *maxillary* faces down and anterolaterally to articulate with the maxilla; (2) the *posterior* or *sphenoidal*, directed up and posteromedially, bears the opening of an air sinus, usually connecting with the sphenoidal sinus and completed by a sphenoidal concha; (3) the *medial* or *ethmoidal*, facing anteromedially, articulates with the ethmoid's labyrinth. The sinus sometimes opens on this surface, connecting with posterior ethmoidal air cells; more rarely it opens on ethmoidal *and* sphenoidal surfaces, communicating with posterior ethmoidal air cells *and* the sphenoidal sinus. Of the non-articular surfaces, (1) the triangular *superior* or *orbital* is directed superolaterally to the posterior part of the orbital floor (3.97); (2) the *lateral* is oblong, faces the pterygopalatine fossa and is separated from the orbital surface by a rounded border, a medial part of the lower margin of the inferior orbital fissure; this surface may present a groove, directed superolaterally, for the maxillary nerve and is continuous with the groove on the upper maxillary's posterior surface (p. 389). The border between the lateral and posterior surfaces descends anterior to the sphenopalatine notch.



The sphenoidal process (3.161,162), a thin plate smaller and lower than the orbital, is directed superomedially. Its *superior surface* articulates with the sphenoidal concha and, above it, the root of the medial pterygoid plate; it carries a groove helping to form the palatovaginal canal. The concave *inferomedial surface* is part of the nasal roof and lateral wall. Posteriorly the *lateral surface* articulates with the medial pterygoid plate; its smooth anterior region is part of the medial wall of the pterygopalatine fossa.

3.160 The left palatine bone in articulation with the left maxilla: medial aspect.

3.161 The left palatine bone: medial aspect (enlarged).



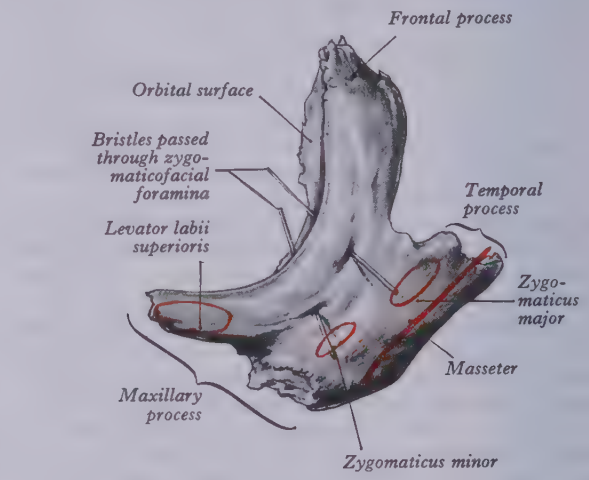
3.162 The right palatine bone: posterior aspect.

The *posterior border* articulates with the vaginal process of the medial pterygoid plate. The *anterior border* is the posterior edge of the sphenopalatine notch. The *medial border* articulates with the vomerine ala. The *sphenopalatine notch*, between the two processes, becomes a foramen by articulation with the sphenoidal body; sometimes the processes themselves unite.

Ossification is in mesenchyme from one centre, appearing during the eighth week in the perpendicular plate. From this, ossification spreads into all parts. At birth height of the perpendicular plate equals width of the horizontal, but in adults is almost twice as much, a change in proportions according with those in the maxilla.

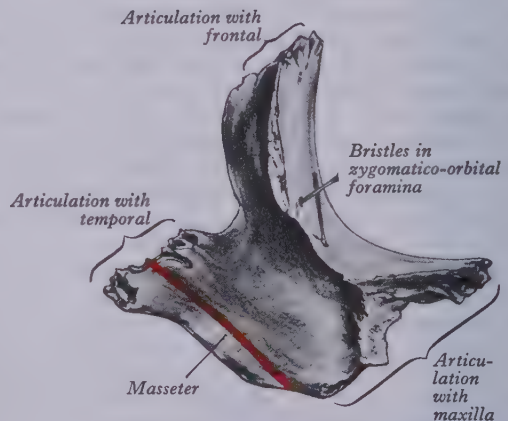
The Zygomatic Bones

Each zygomatic bone forms the prominence of a cheek, contributes to the lateral orbital wall and floor, parts of the walls of temporal and infratemporal fossae and completes the zygomatic arch (3.163). It is roughly quadrangular with anteromedial and frontal processes. It can be described as having three surfaces, five borders and two processes.



3.163 The left zygomatic bone in situ.

The *lateral surface* (3.163,164A), really anterolateral, is convex and pierced near its orbital border by the *zygomaticofacial foramen* (often double) for the zygomaticofacial nerve and vessels; below this the zygomaticus minor and, posteriorly, zygomaticus major are attached. The zygomaticofacial foramen is sometimes absent (p. 396). The postero-medial *temporal surface* (3.164B) has a rough anterior area for articulation with the maxilla and a smooth, concave posterior area extending up posteriorly on its frontal process as the anterior aspect of the temporal fossa. It also extends back on the medial aspect of the temporal process as an incomplete lateral wall for the infratemporal fossa. The *zygomaticotemporal foramen* pierces this surface near the base of the frontal process. The *orbital surface* (3.164A,B), smooth and concave, is the anterolateral part of the orbital floor and adjoining lateral wall, extending up on the medial aspect of its frontal process. It usually bears *zygomatico-orbital foramina*, openings of canals leading to zygomaticofacial and temporal foramina.



The smoothly concave *anterosuperior* or *orbital border* forms the inferolateral circumference of the orbital opening, separating orbital and lateral surfaces. The *antero-inferior* or *maxillary border* articulates with the maxilla; its medial end tapers to a point above the infraorbital foramen; near the orbital margin a part of the levator labii superioris is attached. The *posterosuperior* or *temporal border* is sinuous, convex above, concave below and continuous with the posterior border of the frontal process and upper border of the zygomatic arch; attached to it is the temporal fascia. Below the frontozygomatic suture is often a small *marginal tubercle*, easily palpable. The *postero-inferior border* is roughened by attachment of the masseter. The serrated *posteromedial border* articulates with the sphenoid's greater wing above, and orbital surface of the maxilla below. Between these serrated regions a short, concave, non-articular part usually forms the lateral edge of the inferior orbital fissure; it is sometimes absent, the fissure then being completed by junction of the maxilla and sphenoid or a small sutural bone between them.

The *frontal process*, thick and serrated, articulates above with the the frontal's zygomatic process and behind with sphenoid's greater wing. On its orbital aspect, within the orbital opening and about 1 cm below the frontozygomatic suture, a tubercle of varying size and form, observed in 95% of skulls (Whitnall 1932), is the attachment of the lateral palpebrae ligament (p. 1215), suspensory ligament and part of the aponeurosis of levator palpebrae superioris (p. 1207). The *temporal process*, directed backwards, has an oblique, serrated end articulating with the temporal zygomatic process to complete the zygomatic arch.

Ossification is from one centre, appearing in fibrous tissue about the eighth week. The bone is sometimes divided by a horizontal suture into a larger upper and lower divisions.

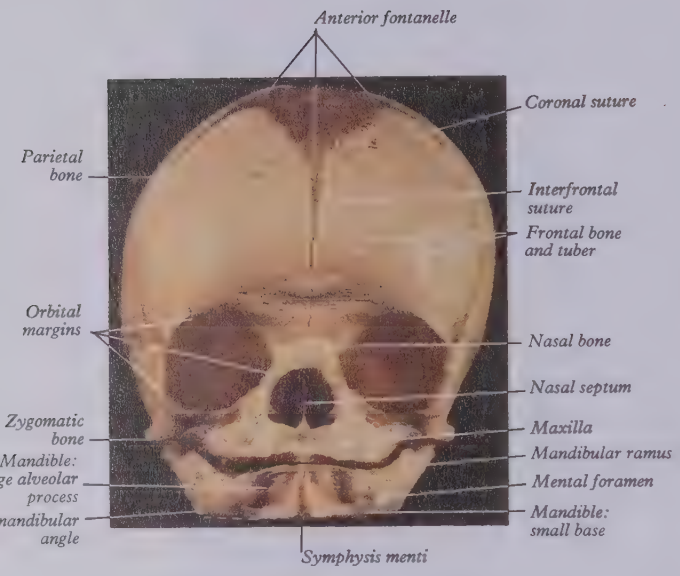
CRANIAL CHARACTERISTICS AT DIFFERENT AGES

The skull at birth is large in proportion to other skeletal parts, but the facial region is relatively small, only about one-eighth of the neonatal cranium, compared with half in adult life. Smallness of face at birth is due to the rudimentary state of mandible and maxillae, non-eruption of teeth and the small size of maxillary sinuses and nasal cavity. The latter is almost entirely between the orbits, the lower border of the piriform nasal aperture being only slightly below the orbital floors. The large size of the calvaria, especially the cranial vault, is related to precocious cerebral growth. The cranial base is relatively short and narrow and, although middle and internal auditory parts are almost adult in size, petrous temporal bones are generally far from adult dimensions. Bones of the cranial vault are unilaminar and without diploë. Frontal and parietal tuberosities are prominent and in norma verticalis the greatest width is between parietal tuberosities (p. 396). The glabella, superciliary arches and mastoid processes are not developed.

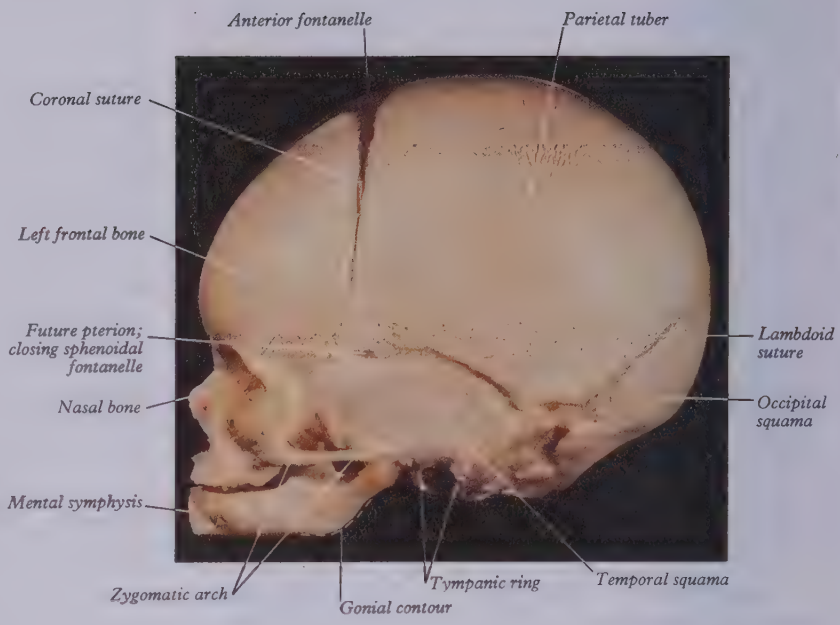
Ossification is incomplete, many bones being still in several elements united by fibrous tissue or cartilage. The 'os incisivum' is continuous with the maxilla (p. 390); pre- and postsphenoids have just united, but halves of frontal bone and mandible, and squamous, lateral and basilar parts of occipital bone are all separate. A second styloid centre (*stylohyal*) has not appeared and parts of the temporal bones are separate except for the commencing fusion of the tympanic with petrous and squamous parts. The fibrous membrane, forming the cranial vault before ossification, is unossified at the angles of parietal bones, leaving six *fonticuli* (*fontanelles*), two median (anterior and posterior) and two lateral pairs (sphenoidal and mastoid). The *anterior fontanelle* (3.165), the largest, is at the junction of sagittal, coronal and frontal sutures, hence rhomboid, and about 4 cm in anteroposterior and 2.5 cm in transverse dimensions. The *posterior fontanelle* (3.165), at the junction of sagittal and lambdoid sutures, is hence triangular. The *sphenoidal* (anterolateral) and *mastoid* (posterolateral) *fontanelles* (3.165) are small, irregular and at sphenoidal and mastoid angles of the parietal bones.

At birth the orbits are large and the germs of developing teeth are near their orbital floors. Temporal bones differ greatly from their adult form. Internal ear, tympanic cavity, auditory ossicles and mastoid antrum are almost adult, the tympanic plate is an incomplete ring and the mastoid process absent. Hence the external acoustic meatus is short, straight, unossified and wholly fibrocartilaginous. The external aspect of the tympanic membrane faces *down* rather than laterally, in accord with the basal cranial contour. The stylomastoid foramen is exposed on the lateral surface of the skull; the styloid process has not fused with the temporal bone; the mandibular fossa is flat and more lateral and its articular tubercle undeveloped. Paranasal sinuses are rudimentary or absent; only the maxillary sinuses are usually identifiable.



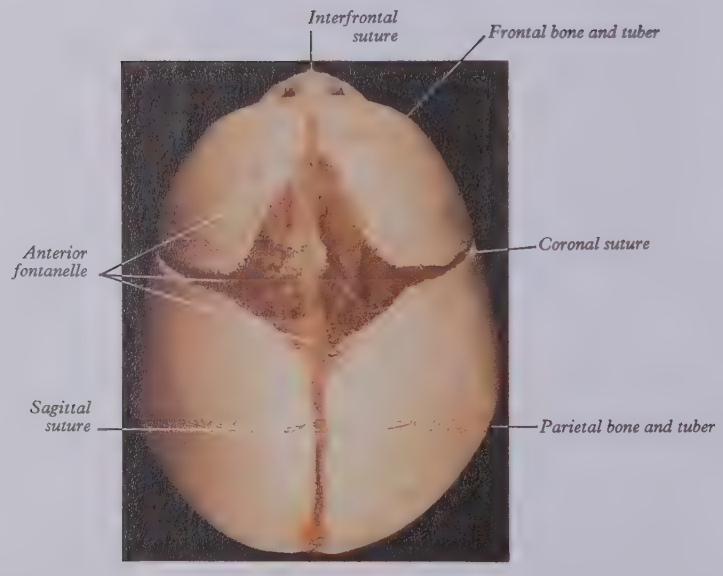
During birth the skull is moulded by slow compression; that part of the scalp which is more central in the birth canal is often temporarily oedematous due to interference with venous return and is called the *caput succedaneum*. Fontanelles and width of sutures allow bones of the cranial vault some overlap. The skull is compressed in one plane with compensatory elongation orthogonal to this. These effects disappear within a week.

Postnatal growth. Co-ordinated postnatal growth of the calvarial and facial skeleton proceeds at different rates and periods, the cranial cavity being related to cerebral growth, facial skeleton to the development of teeth, muscles of mastication and tongue; but growth of the cranial base is not at the same rate as that of the vault. Therefore the three regions must be considered separately. The anterior part of the cranial base is a *zone of interaction* between facial and cerebral growth (Brash 1924, Scott 1967).



Growth of the vault is rapid during the first year and slower to the seventh, by which time it has reached almost adult dimensions. For most of this period expansion is largely concentric; form is determined early in the first year, remaining thereafter largely unaltered (Weinmann & Sicher 1955, Scott & Symons 1977, Brodie 1941, Hoyte 1966). That *shape* of the vault is not directly related to cerebral growth but to genetic factors is supported by the great range of cranial indices and shapes in racial groups. During the first and early second years growth of the vault is mainly by ossification at apposed margins of bones, which possess an osteogenic layer (p. 468), accompanied by some accretion and absorption of bone at surfaces to adapt to continually altering curvatures. Growth in *breadth* occurs at sagittal, sphenofrontal, spheno-temporal and occipitomastoid sutures and petro-occipital cartilaginous joints, growth in *height* at fronto-zygomatic and squamosal sutures, pterion (p. 352) and asterion (p. 396). During this period fontanelles are closed by ossification of bones around them, but separate centres may convert them into sutural bones. Sphenoidal and posterior fontanelles 'fill in' within two or three months of birth, mastoid fontanelles usually near the end of the first year and the anterior fontanelle at about the middle of the second, by which time calvarial bones have interlocked at sutures, commencing early in the first year. Further expansion is chiefly by accretion and absorption on external and internal surfaces respectively (Ford 1956). Meanwhile bones thicken, but not uniformly. At birth the vault is unilaminar, tables and intervening diploë appearing about the fourth year, with maximal differentiation at about 35 years, when diploic veins are prominent in radiograms. Thickening of the vault and development of external muscular markings are related to the development of masticatory and neck muscles. The mastoid process is a visible bulge in the second year and invaded by air cells in the sixth; Galli et al (1976) have recorded metrical studies of it.

Growth of the base is responsible for much of the cranial *lengthening*, mostly at cartilaginous joints between the sphenoid and ethmoid, and especially between sphenoid and occipital. It is largely independent of cerebral growth, and continues at the occipitosphenoid synchondrosis until the eighteenth to twenty-fifth year, a period prolonged by continued expansion of jaws to accommodate erupting teeth, and by growth in muscles of mastication and those of the nasopharynx. However there is some evidence that growth may cease at about 15 years (Latham 1966). A pubertal growth spurt has been ascribed to both sexes, about two years earlier in females; considerable postpubertal growth, up to 17.5 years in males (Roche & Lewis 1974), has been described. For a review of studies on basal growth consult Hoyte (1975), and for labelling studies of growth in craniofacial cartilages (in rats) see Kvinnsland & Kvinnsland (1975). Buranaruga & Houghton (1981) have applied multivariate analysis to Cartesian co-ordinates of cranial landmarks in Polynesian crania; they claim considerable independence in the growth and positioning of segments noted above. Trenouth (1984) has contributed an extensive study of 60 fetal cranial profiles and he draws attention to the effects of disproportionate growth of brain and face and the result of this in changing the developing cranial base. It is to be hoped that this series of observations can be linked with pre- and postnatal changes.



Growth of the face occupies a longer period than the calvaria. Much information is derived from serial radiography (Salzmann 1961). Ethmoid bone, orbital and upper nasal cavities have almost completed growth by the seventh year. Orbital and upper nasal growth is achieved by sutural accretion with deposition of bone on the facial aspects of margins. The maxilla is carried *down and forwards* by expansion of orbits and nasal septum and sutural growth, especially at fontanelles and zygomaticomaxillary and pterygomaxillary sutures. In the first year growth in width occurs at symphysis menti and midpalatal, internasal and frontal sutures; but such growth is diminished or even ended when the symphysis menti and frontal suture close during the first few years, even though the midpalatal suture persists until mature years. Facial growth in this period continues to puberty and later, linked with the eruption of permanent teeth. After sutural growth, near the end of the second year, expansion of the facial skeleton is by surface accretion on the face, alveolar processes and palate, with resorption in the walls of the maxillary sinuses, the upper surface of hard palate and the labial aspect of the alveolar process. Co-ordinated growth and divergence of the pterygoid processes is due

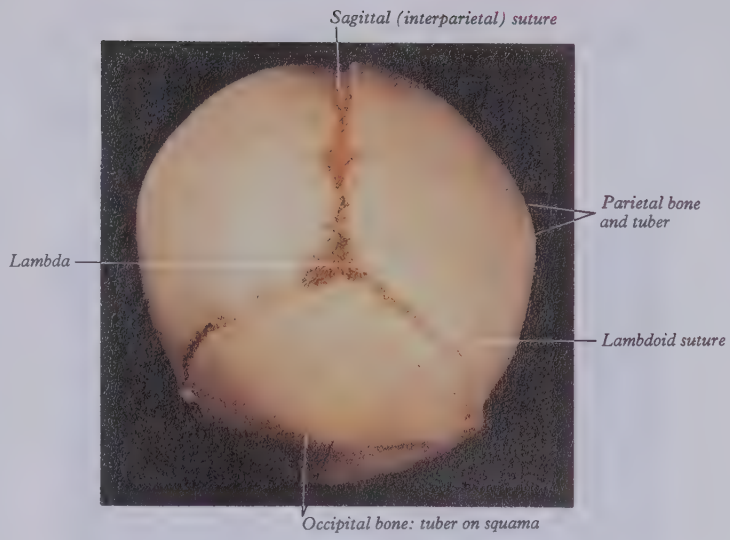
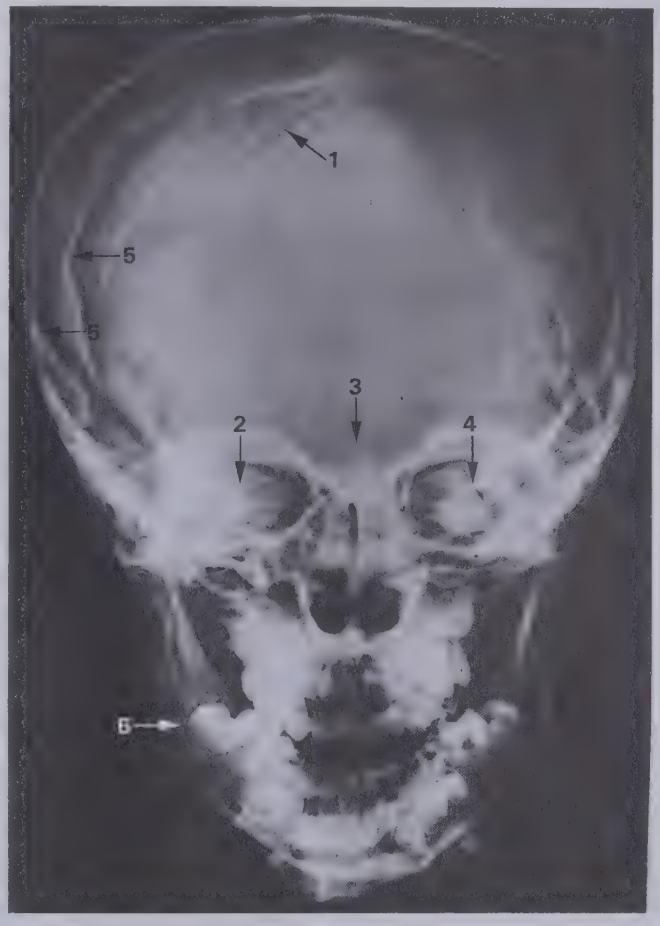
to deposition and resorption of bone on appropriate surfaces. Mandibular growth is described on pages 369-370.



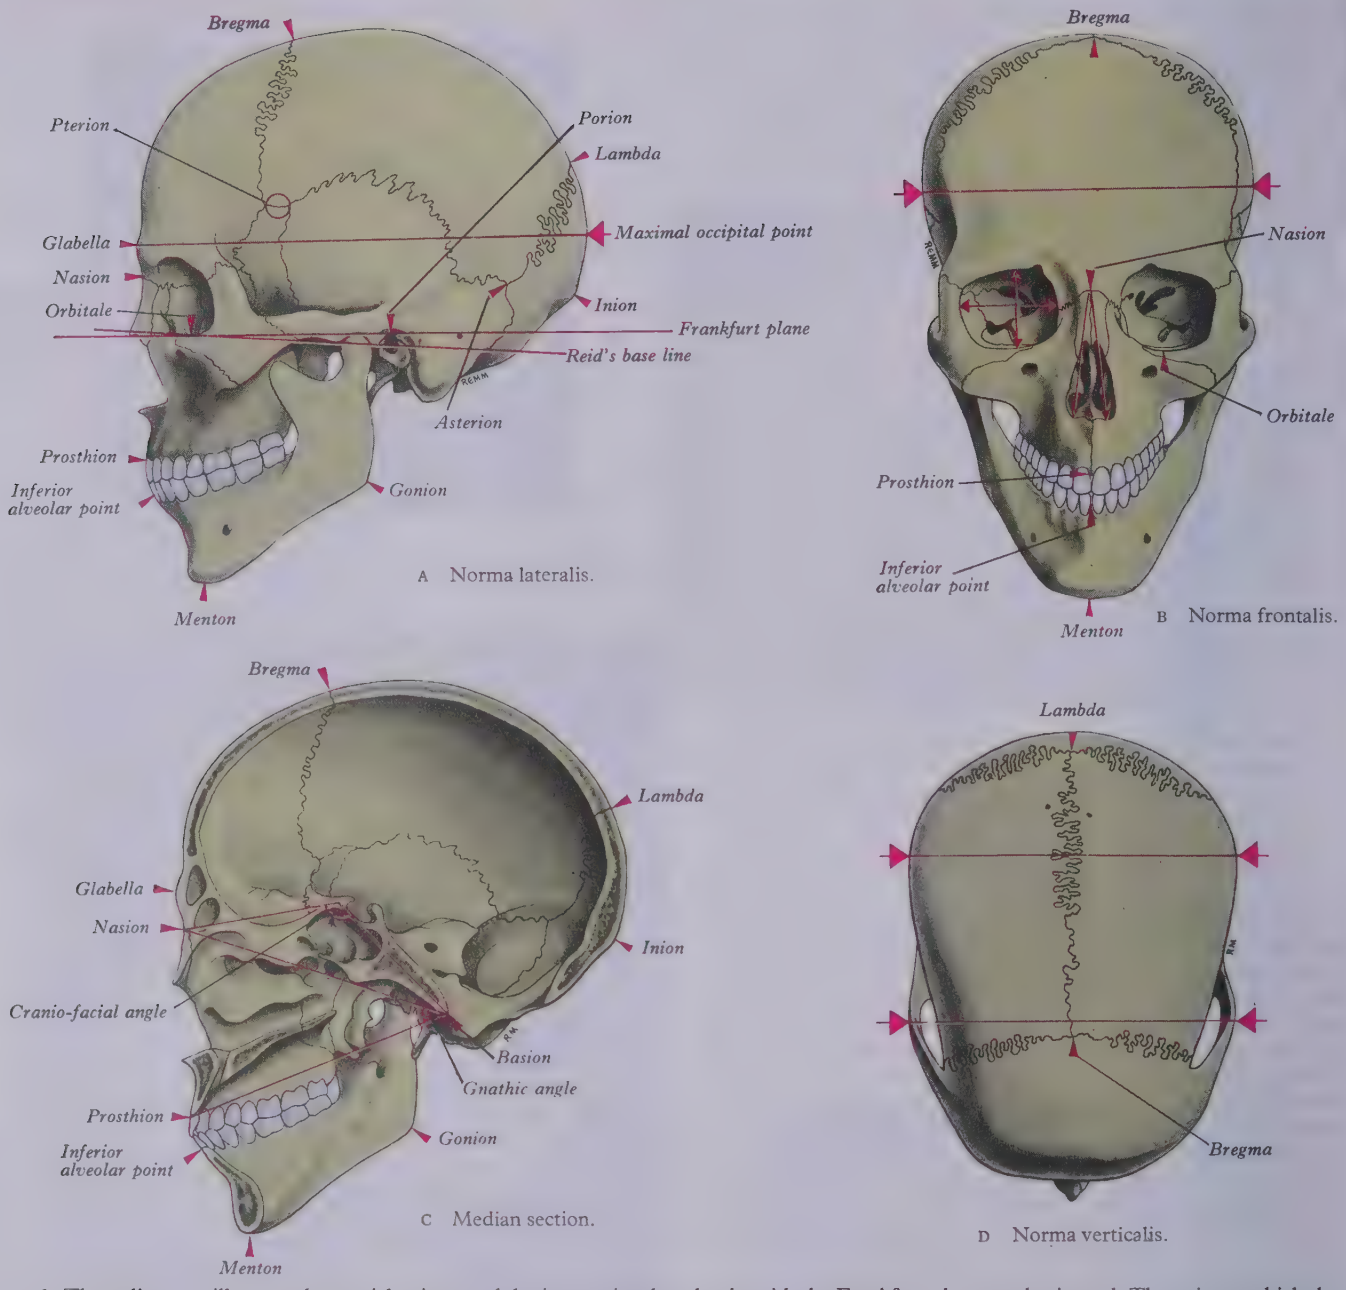
Obliteration of the calvarial sutures progresses with age, commencing between 30 and 40 years internally, about 10 years later on the exterior, but closure times vary greatly (Todd & Lyon 1924, 1925, Abbie 1950, Singer 1953). Obliteration usually begins at the bregma, extending into sagittal, coronal and lambdoid sutures, in that order. In old age the skull becomes thinner and lighter, but occasionally the reverse. The most striking senile feature is diminution in size of the mandible and maxillae following loss of teeth and absorption of alveolar bone. This reduces the vertical depth of the face and increases the mandibular angles (3.120) (pp. 369-370).

Sexual and Racial Differences in the Cranium



Until puberty there is little sexual difference in skulls; the adult female's is a little lighter and smaller, its capacity about 10% less; its walls are thinner and muscular ridges less marked; the glabella, superciliary arches, and mastoid processes are less prominent; air sinuses are smaller; tympanic plates are smaller and their margins less rough; the upper orbital margins are sharper, the forehead vertical, frontal and parietal tuberosities prominent and the vault somewhat flattened; the facial contour is rounder, facial bones smoother and mandible and maxillae and contained teeth are smaller. Thus, more childhood characteristics are retained in females. Typical male or female skulls are easily recognized, but in some characteristics are so indeterminate that diagnosis of sex is difficult or impossible.

Sexual dimorphism is generally less marked in humans than other primates. This is associated with the *paedomorphic* tendency of human stock, females and even males being less divergent in adult development from their own juvenile form, a tendency less apparent in other primates, especially in males (Abbie 1952, Schultze 1956). Exaggerated sexual differences occur in most anthropoid apes and some monkeys in the form of enlarged canines in males, with associated jaw development, accentuated muscular ridges and total size of skull. These excesses are typified in the gorilla, orang utan, and many species of baboon, in which males also much exceed females in stature and physique. Even in extinct human forms sexual dimorphism, on available fossil evidence, appears to have been less than in other primates. In modern humans differences are further reduced but degree of sexual divergence in cranial size and proportions varies in racial groups. Such sexual differences have been less exactly assessed than general ethnic differences. In both, assessment depends on observation of two kinds of feature: (*a*) those which cannot be measured, for which no satisfactory quantitative technique has, as yet, been devised (e.g. size of mastoid process, prominence of chin); and (*b*) those expressed as actual measurements or indices (e.g. cranial capacity, orbital index). Examples of the former category in distinguishing sex have been cited above; more exhaustive lists exist (Keen 1950). Use of such features in judging sex or race in isolated crania is dependent on observers' experience but, where many are available from a single ethnic group, both types of assessment are more certain. Distinction of three major races by non-metrical traits can be effected with some confidence (Todd & Tracey 1930). Incidences of many variations have been observed on a racial basis, e.g. metopism and other sutural variants (Berry & Berry 1967), and are of considerable ethnic but lesser forensic interest. Berry (1975) made a special study of *non-metrical* human cranial variations; these include:



1. Highest nuchal line (p. 348).
2. Os suturale at lambda (pp. 373, 378).
3. Ossa suturalia in lambdoid suture (pp. 347,371).
4. Parietal foramen (p. 342).
5. Os suturale at bregma (p. 386).
6. Frontal suture (metopism) (p. 383).
7. Ossa suturalia in coronal suture (p. 383).
8. Epipteric os suturale (p. 386).
9. Frontotemporal articulation (p. 352).
10. Parietomastoid os suturale (p. 352).
11. Os suturale at asterion (p. 352).
12. Tympanic foramen of Huschke (p. 381).
13. Extrasutural mastoid foramen (p. 378).
14. Absence of mastoid foramen (p. 378).
15. Patent condylar canal (p. 359).
16. Double condylar facet (p. 373).
17. Precondylar tubercle (p. 373).
18. Double hypoglossal canal (p. 373).
19. Incomplete foramen ovale (p. 355).

3.165E Skull of newborn infant: posterior (occipital) aspect. (Photograph by K. Fitzpatrick)

3.166 Radiograph of child's skull, aged seven: occipitofrontal view. 1. Lambdoid suture. 2. Petrous portion of right temporal bone, seen through the cavity of the orbit. 3. Crista galli of the ethmoid bone. 4. Fracture through petrous portion of left temporal bone, seen through the cavity of the orbit. 5. Impressions for cerebral gyri. 6. Second permanent molar tooth, not yet erupted.

3.167 These diagrams illustrate the cranial points used, by international agreement, in making linear and certain angular measurements in anthropometry. In all four views the skull is in the standard orientation, that is, with the Frankfurt plane as a horizontal. The point at which the cranio-facial angle is measured is not named; it corresponds to the midpoint of the chiasmal groove.

20. Incomplete foramen spinosum (p. 355).
21. Accessory palatine foramina (p. 354).
22. Maxillary torus (p. 389).
23. Palatine torus (pp. 354, 389).
24. Occurrence of zygomaticofacial foramen (pp. 343, 392).
25. Supraorbital foramen or incisure (p. 382).
26. Frontal foramen or incisure (p. 382).
27. Extrasutural anterior ethmoid foramen (p. 347).
28. Absence of posterior ethmoid foramen (p. 347).
29. Accessory infraorbital foramen (p. 346).
30. Interparietal bone (pp. 373, 386).
31. Paramastoid process (p. 373).
32. Auditory torus (p. 380).

Although many have studied these and other cranial variants (e.g. the mandibular torus, p. 367), few studies have been quantitative. They have been reviewed by Berry & Berry (1967) and Berry (1975), with extensive statistical data; they have assessed which cranial variations exhibit racial (and sometimes sexual) correlation. The interested reader should also consult Czarnetzki (1971) and Hjarnø et al (1974).

To achieve a more objective racial assessment, metrical studies have long been practised; internationally accepted techniques of *craniometry* have promoted a large corpus of comparable ethnic data for males and, to a lesser extent, females. Many standard measurements are used; only major dimensions and examples of indices derived from them are included here (3.167,168). The calvarial part of the skull is measured as follows:

A. Maximal cranial length	summit of glabella to furthest occipital point.
B. Maximal cranial breadth	greatest breadth, at right angles to median plane.
C. Cranial height	from basion (median point on anterior rim of foramen magnum) to bregma.

All measurements are to the nearest millimetre. From these three dimensions, three indices are calculated: B/A, C/A and C/B and expressed as percentages.

The breadth/length ratio is the *cranial index* (*cephalic index* in the living). Its recorded range of variation is high, as with other skull or head indices. All ranges are arbitrarily divided into steps,

usually covering 5% sections of the total range; to each step a specific term is applied. For example:

(Maximal breadth/maximal length) × 100 = cranial or cephalic index

Up to 74.9 = dolichocranic or dolichocephalic

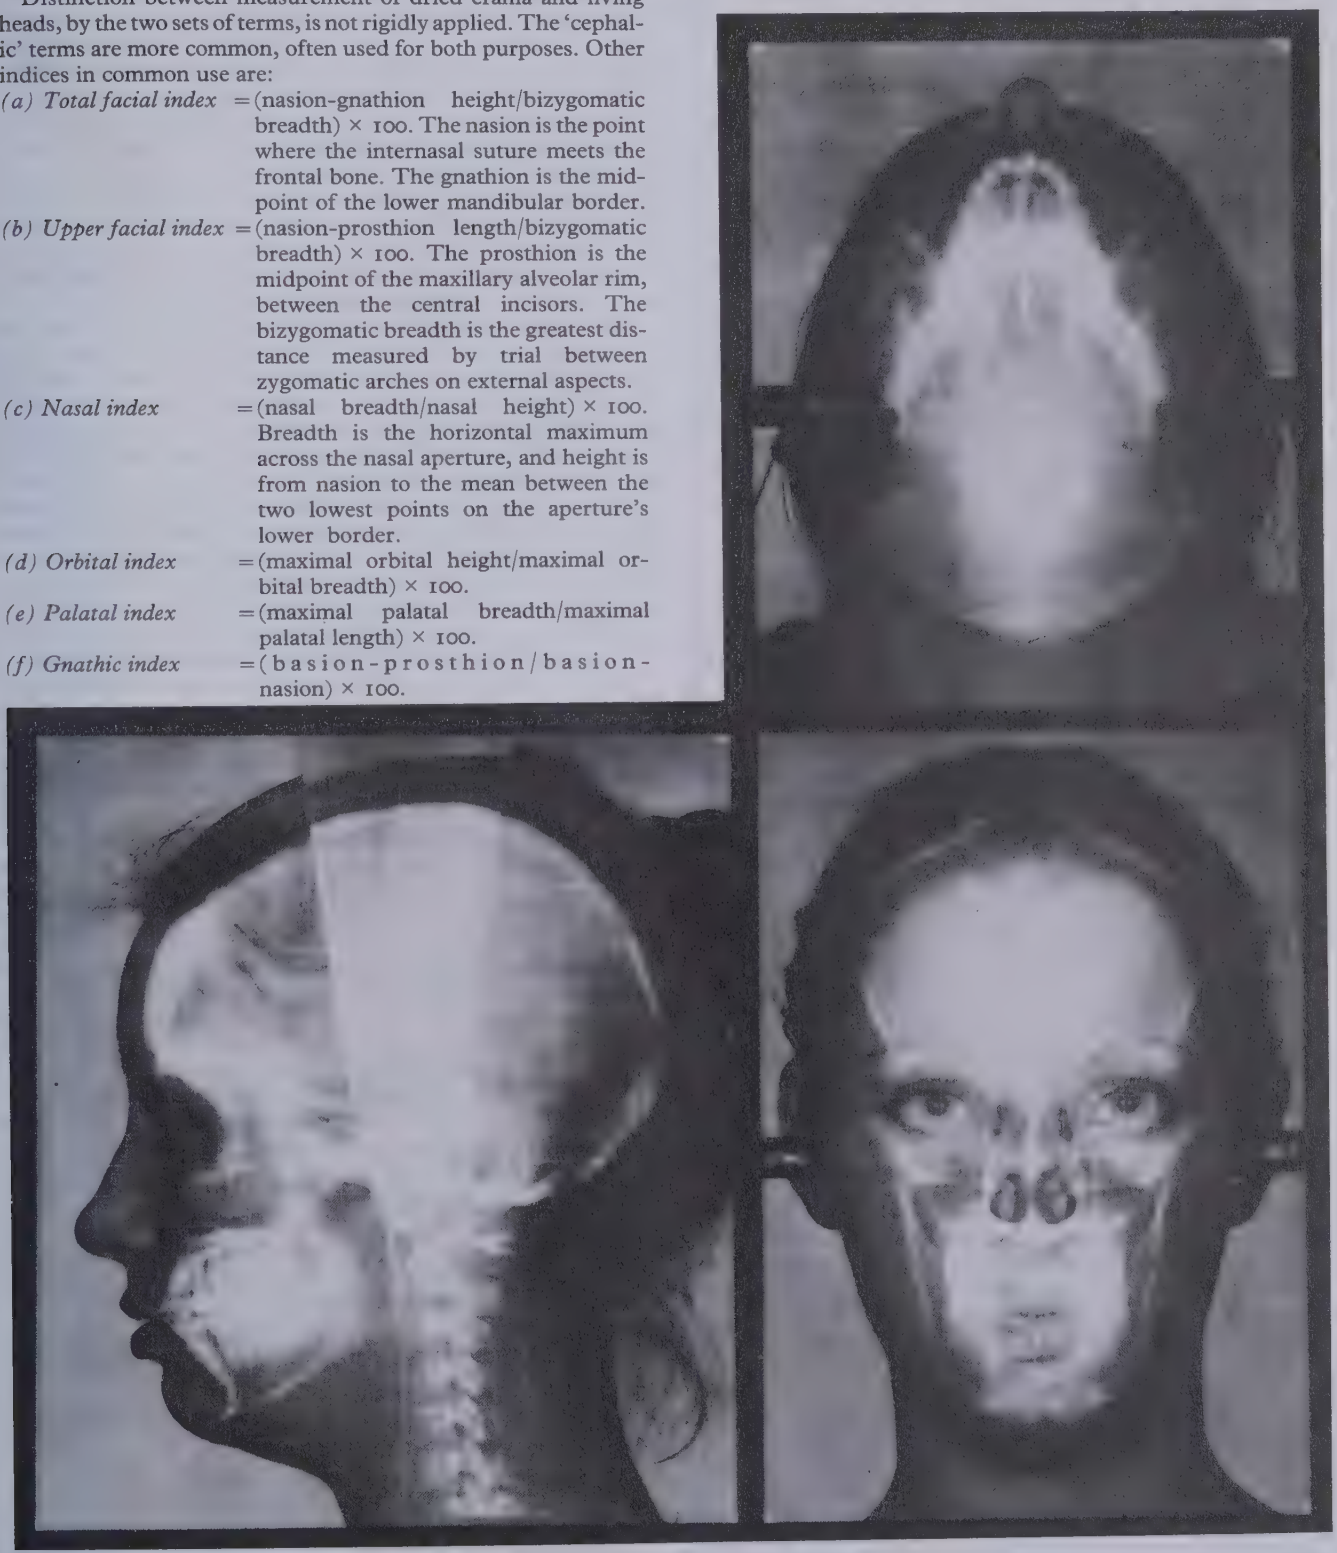
75.0 to 79.9 = mesocranic or mesocephalic

80.0 to 84.9 = brachycranic or brachycephalic

Distinction between measurement of dried crania and living heads, by the two sets of terms, is not rigidly applied. The 'cephalic' terms are more common, often used for both purposes. Other indices in common use are:

(a) Total facial index = (nasion-gnathion height/bizygomatic breadth) × 100. The nasion is the point where the internasal suture meets the frontal bone. The gnathion is the midpoint of the lower mandibular border.

(b) Upper facial index = (nasion-prosthion length/bizygomatic breadth) × 100. The prosthion is the midpoint of the maxillary alveolar rim, between the central incisors. The bizygomatic breadth is the greatest distance measured by trial between zygomatic arches on external aspects.



(c) Nasal index = (nasal breadth/nasal height) × 100. Breadth is the horizontal maximum across the nasal aperture, and height is from nasion to the mean between the two lowest points on the aperture's lower border.

(d) Orbital index = (maximal orbital height/maximal orbital breadth) × 100.

(e) Palatal index = (maximal palatal breadth/maximal palatal length) × 100.

(f) Gnathic index = (basion-prosthion/basion-nasion) × 100.

Indices provide a system for *metrical* record of sizes and proportions of cranial features in place of subjective impressions. If a group is said to be dolichocephalic, this does not (or should not) imply a vague comparison, but that the index is within known numerical limits. It can be observed that the orbital opening appears rounder in females, but this statement can be quantified and

3.168 Combined, accurately superimposed photographs and radiographs of the kind shown here are currently being used to produce a computerized analysis of metrical relations between a selection of datum points in the skeletal and soft tissue components of human heads and faces. The technique, known as morphanalysis, has been elaborated by Dr G P Rabey, to whom we are indebted for these records. Both photographs and radiographs are produced in the three primary planes and hence the morphometric analysis is three-dimensional. For further information see Rabey (1968, 1971, 1980).

is then far more valuable. Again, jaws project more in some races, a fact determinable by inspection alone when the condition is pronounced; the gnathic index yields a numerical expression and comparisons are then permissible.

The following measurements are applied to mandibles: *(a)* height of symphysis, *(b)* length of body, *(c)* length of ramus, *(d)* bigonial width (between angles), *(e)* bicondylar width, and so on. The angle between body and ramus is also often estimated. Since the mandible is often missing from skulls and moreover is considered less reliable in assessing racial affinity (Morant 1936), its measurements are less widely used.

Other forms of cranial measurement are employed. Horizontal circumference and various arcs and contours are sometimes measured. Radiographic studies make it possible to extend classic craniometry and to measure directly certain angles, e.g. the *gnathic angle*, between basion–nasion and basion–prosthion lines. The *craniofacial* or *cranial base angle* is of special interest, representing the degree of cranial flexure. The human angle has a value of about 130°, probably achieved by birth, little further change occurring. Its high human value has been linked with translation of tongue towards pharynx, a change sometimes regarded as essential to speech (Schulter 1976). Radiographic technique for the estimation of endocranial volume has been evolved (Haas 1952). *Cranial capacity*, an indication of brain volume, can be assessed directly by filling the cavity with lead shot, millet seed or other particulate materials suitable for volumetric measurement when poured out again. Several formulae have also been constructed to give cranial capacity from length, breadth and height of the cranium. Examples are:

Males: 0.000337 $(L—11)$ $(B—11)$ $(H—11)+406.01$ cc.

Females: 0.000400 $(L—11)$ $(B—11)$ $(H—11)+206.60$ cc.

In these formulae, L and B are length and breadth, and H is the *auricular height*, measured to the vertex from the external acoustic meatus. All measurements are in millimetres, but such methods involve some inaccuracy, and various corrections do not entirely remove this (Hrdlička 1947, Montagu 1960).

Attempts to establish reliable craniometric differentiation between races are as old as craniometry. Though mandibular data and cranial capacity are less dependable, satisfactory differentiation is possible in some groups, especially between Caucasians and Negroes. When several measurements are treated by discriminant analysis, an accuracy of over 90% can be expected (Giles & Elliot 1960). Multivariate analysis may also elucidate cranial growth (Liebgott 1977). Craniometric methods are useful in forensic identification when cranial remains can be compared with existing photographic and radiographic records (Glaister & Brash 1937), and in attempts to reconstruct appearance in life of individuals represented only by skeletal remains (Stewart 1954). Cephalometry has also been applied in plastic and oral surgery concerned with craniofacial deformity. A development in this field is *morphanalysis*, which uses gridded radiographs and photographs universally related in three dimensions (**3**.168). Such standardized records enable diagnostic comparison between patients and the normal population (Rabey 1968, 1971).

Applied anatomy. Factors preventing cranial fracture are elasticity, round shape and construction from secondary elastic arches, each derived from a single bone. Where bone is thin, overlying muscles may cushion blows, e.g. temporal squama and inferior occipital fossa. Thickness of calvaria in 28 Caucasians (from 15 to 82 years) averaged 5.8 mm. In males thickness increased with age, in females the reverse is true (Lippert & Käfer 1974).

The commonest site of basal fracture is through the middle fossa; fracture starts from the point struck, usually near the parietal tuberosity, descends through parietal and temporal squamata and across the petrous region, often traversing the internal acoustic meatus, to the foramen lacerum. This explains various sequelae: thus, if the internal acoustic meatus is damaged, injury to facial and vestibulocochlear nerves may result, with consequent facial paralysis and deafness; if it extends through semicircular ducts, vertigo ensues; if the arachnoid around these nerves in the meatus is torn and when the internal ear and tympanic cavity communicate and the tympanic membrane is torn, as it often is, cerebrospinal fluid may escape.

Facial bones are sometimes fractured by direct violence, most commonly the nasal bones and mandible. Nasal fracture is usually transverse, about 1.25 cm from the free margin, broken edges being displaced backwards or more often to one side by direct blows. The commonest site of mandibular fracture is near the canine tooth, whose deep socket weakens the bone; next most frequent is the angle. Occasionally a double fracture may occur, in both halves of the bone, and is usually compound, with laceration of oral mucosa.

THE APPENDICULAR SKELETON

Phylogeny and Functions

The ancestral vertebrates, *Agnatha*, were not only jawless but limbless, like surviving representatives such as lampreys (Young 1962, Romer 1970). Two continuous ventrolateral finfolds probably preceded the separated fins which appear in fossil remains of the earliest fish possessing jaws, the *Placoderms*. These sometimes displayed more than two pairs of appendages, but in their descendant bony and cartilaginous classes, the *Osteicthyes* and *Chondricthyes*, the vertebrate pattern of two pairs, pectoral and pelvic, was stabilized, except in such forms as snakes, which have subsequently lost their limbs. Appendicular skeletons of fossil and extant fish vary but show a common plan of 'girdle' bones, embedded in body musculature, and rodlike elements radiating into the mobile fin, with an intermediate joint of the ball and socket type. In many orders of *Osteicthyes* homologues of the pectoral and pelvic components of terrestrial limbs can be identified, as well as those of the proximal segments, arm and forearm or thigh and foreleg (Bolk et al 1931–9). Distal equivalence is less clear; but the multiplicity of small bony units in fins at least resembles the extremities, hand and foot, of land tetrapods.

Terrestrial vertebrates are grouped as *tetrapods* because their four limbs are an outstanding common feature, although the pectoral pair may be modified for flight. They are probably derived from a primitive order, the *Crossopterygii* ('fringe-finned'), related to another ancient group, *Dipnoi* or lungfish, species of which still survive. The crossopterygians were known only as fossils until 1938, when a living specimen of a suborder, *Coelacanthus*, was captured off the coast of South Africa; further coelacanths have been secured near the Comoro Islands and elsewhere in the Indian Ocean. These possess lobed fins with a narrowed attachment, and from such appendages tetrapod limbs can most plausibly be derived.

In the change to terrestrial environment, during evolution of primitive amphibians from crossopterygians, two major adaptions began. The first, already foreshadowed in fins, was a repositioning of these limb-like paddles for more effective support and propulsion on land. The *forelimbs* rotated *laterally* at joints with pectoral girdles so that the hinging of the elbow, at first pointing away from the body as it still does in amphibians and reptiles, finally projected backwards. In contrast, the *hindlimbs* rotated *medially* at their pelvic joints into opposite positions, knees projecting forwards. These opposite changes rotated the *preaxial* or leading *border*, corresponding with the 'first' digit, pollex or hallux, from an anterior to lateral position in the pectoral limb. (As described later on p. 399, this changed orientation of the forelimb necessitates a complementary *pronation* of its radioulnar segment to achieve a plantigrade appendage, a compensation unnecessary in the hindlimb.) Coupled with these growing distinctions between fore and hind extremities was a second

modification—articulation of pelvic girdles with the spinal column, a condition unknown in fish but uniform in tetrapods, except some fossil amphibians.

With evolution of amphibians, a general skeletal pattern of tetrapod limb was defined and, apart from minor modifications, has persisted through subsequent vertebrates. This *primitive pentadactyl limb* terminates typically in five digits, reduction in which is frequent, especially in mammals. But the primates, including humans, have retained the full number and are in this respect unspecialized.

Of the girdles the *pectoral* always comprises a dorsal *scapula*, but varies in ventral components, commonly a mixture of endochondral and dermal bones. Of these the *coracoid* and *clavicle* persist in mammals, the former reduced in size and fused to the scapula. The clavicle, sole mammalian survivor of a variety of dermal elements in lower vertebrates (e.g. the *cleithrum* and *interclavicle*), is also often reduced and even lost in some mammals, especially fast-running or bounding types of quadruped. Its persistence in primates is linked with the development of forelimbs for grasping and climbing; the clavicle acts as a mobile strut, at the lateral end of which the rest of the limb can be variably positioned (Watson 1917). The *pelvic girdle*, in contrast, contains only endochondral elements; the primitive dermal armour only extended far enough caudally to permit incorporation of dermal elements into the pectoral but not the pelvic girdle. The latter developed a ventral *symphysis* in fish, which in tetrapods contains distinguishable pubic and ischial elements. The dorsal ilium, though present in some fish, is not well developed. In land animals the need of larger muscles to support the body's weight and to impart thrust through hindlimbs, leads to greater iliac size and articulation with the sacral spinal column. Throughout tetrapods these pelvic entities, *pubis*, *ischium* and *ilium*, are more uniformly arranged than in fish. They also show an increasing tendency to fuse into an *innominate* bone, especially in adult mammals. The two innominate bones are joined ventrally at a symphysis pubis and to the sacrum dorsally at sacroiliac articulations. Thus is established a *pelvis*, primarily locomotor, conducting stresses between axial skeleton and limbs. The term pelvis, a basin, is misleading; it is more of an irregular ring which, being at the caudal end of the body cavity, inevitably surrounds certain viscera, a relation which in human anatomy obscures its essentially appendicular origin and function. Since the cloaca is immediately caudal to it, not only the hindgut but other tubes, urinary and genital, must traverse the pelvis, even though separate external openings evolve in mammals. During birth, the offspring must also traverse the pelvis, and their comparatively large size in human females entails obstetric considerations (p. 431), which again may temporarily overshadow the somatic locomotor nature of hindlimb girdles.

In mammals functional differences between fore- and hindlimbs, accentuated in the human primate, are associated with structural divergence in their girdles. Major differences, (ignoring the possible status of e.g. the coracoid complex) are as follows:

Pectoral Girdle	**Pelvic Girdle**
1. Dermal and endochondral	Entirely endochondral.
2. Two principal components, clavicle and scapula, which remain separate. (However, see above and p. 406.)	Three components, pubis, ischium and ilium, which fuse into a single innominate bone.
3. No articulation with vertebral column.	Articulates with sacral vertebrae.
4. No direct ventral articulation (clavicles connected only by interclavicular ligament).	Direct ventral articulation at symphysis pubis.
5. Articulations of clavicles with axial skeleton (sternum) are relatively small, mobile and ventral.	Articulations of innominate bones with axial skeleton (sacrum) are relatively large, capable of limited movement only, and dorsal.
6. Comparatively lightly built for mobility.	Massively constructed for resistance to stress, rather than for mobility.
7. Resilient to thrust.	Transmits thrust between vertebral column and leg.
8. Shallow joint with limb, allowing wide range of movement.	Deep joint with limb, limiting range of movement.

Both girdles articulate with the distal, freely movable parts of limbs by 'ball and socket' joints, the first segment of each limb containing a single *humerus* or *femur*. Shoulder and hip joints are the same in mechanism, allowing some movement in all directions, though more limited in the hip. Even in quadrupedal mammals, where limbs are walking props mainly adapted to fore and aft movement, greater mobility is usual at the shoulder, particularly in abduction, permitting splaying of the forelimbs. Throughout tetrapods the shoulder region shows a greater range of structural adaptation to changing function. Scapular orientation in relation to the thorax and humerus varies far more than hindlimb equivalents, even in quadrupeds, but the difference is most extreme in bipedal primates (Ashton et al 1976), whose adoption of an arboreal habitat, in which they climb, walk, run and swing, accords with the development of highly mobile and prehensile forelimbs and similar but lesser changes in hindlimbs. Equally to be emphasized is the habit of *sitting* upright, even in primates such as baboons which have returned to predominantly quadrupedal life on the ground; arms are thus released for manipulative use, activities of the profoundest significance to human evolution.

In modern mammals, *Eutheria*, the articular head of the humerus is usually directed dorsocaudally and the scapular glenoid socket reciprocally. While this may favour quadrupedal use, it prevents movement of the humerus into the vertical position so easily assumed by primates in reaching up above the head. This entails reorientation of the humeral head relative to its shaft, the head being directed *medially* rather than caudally. Coincident with reorganization of the shoulder is a change in maximal thoracic diameter from dorsoventral to transverse, the former being typical of quadrupeds, the latter of bipedal primates. This is coupled with the retention of clavicles in primate mammals and altered scapular orientation. The scapulae come to face ventrally, rather than medially, and their glenoid fossae more laterally. These changes and correlated muscular alterations are linked with a wider range of movement at the shoulder.

The tubercles and bicipital groove of the humerus partly share in the rotation of its head, but the distal end retains its transverse orientation (Martin 1932). Hence a radial axis through the centre of the head is approximately at right angles to the axis of the lower end in most *Eutheria*, because the head is directed caudally. As it becomes more medial this angle increases above 90°. It is still 95° in carnivora, rises to about 100° in monkeys, 120° in apes, and from 135° to 165° or more in man. This change in the primate humerus has been considered torsional and the angle termed *angle of torsion*. The term is misleading; there is no evidence of any true 'twisting' of the humeral shaft; spiralling of the radial nerve and its groove predates this change. Nor is there anything specially human in the torsion angle. It reaches 180° (where the axes are parallel) in birds and was apparently nearly as high in mammal-like reptiles, returning to about 90° in *Metatheria* (marsupials). A word of caution is needed concerning methods of recording angles of humeral torsion. As defined here, the angle is measured between articular 'axes' of the shoulder and elbow joints. However, Krahl (1944, 1976), sometimes quoted in textbooks, measured the angle between the axis of the elbow joint and a line orthogonal to the axis of the shoulder joint; his values, therefore, differ by 90° from those cited here. Neither method is conceptually satisfactory, but very similar figures are obtained (*mutatis mutandis*). Krahl's work thus supports the view put forward here, that change in orientation of the humeral head has involved alterations at the proximal end of the bone and has not been accomplished by an evolutionary twisting of the shaft. Racial and sexual differences have been recorded (Kate 1968).

In the lower limb the state is like that of mammal-like reptiles (and birds), with the two axes almost parallel. (The human femoral head and long axis of its neck are anteverted about 16° relative to the transcondylar femoral axis.) This condition is said

not to have varied in the lower limbs, unlike the upper. Lability of the humeral 'torsion' angle may be coupled with greater variability in forelimb activity, especially in bipedal forms, with the consequent release of the forelimbs.

Intermediate segments of limbs, and their joints with humerus and femur, show similarities and differences. The differences are greater in bipeds; in quadrupeds similarities are more evident. Both segments initially contained *parallel* elements, radius and ulna, tibia and fibula (but vide infra). Primitively both pairs articulate with the single proximal element but in most mammals, as in man, fibulae withdraw from knee joints, leaving a *preaxial* tibia as major lever and prop. In the forearm the ulna, a *postaxial* bone, becomes the main force-transmitting strut at the elbow.

Both elbow and knee are hinge joints in quadruped mammals; but, while this was the primitive tetrapod state in knees, elbows had an initial potentiality for *rotation*. The hindlimb turns medially, bringing its extensor surface forwards, so that the foot, hinged at the ankle, projects forwards with its plantar surface on the ground. This typical *plantigrade* habit of many quadrupeds brings the hind-limbs under the body as serially hinged levers adapted for propulsion and support. Note that tibia and fibula remain *parallel*; but the *lateral* rotation of fore-limbs which turns the extensor aspects backwards, entails *pronation* at the elbow to bring the 'hand' forwards, palm downwards, for plantigrade locomotion. This brings the *preaxial* radius anteromedially across the ulna, and both are stabilized in this relation in a large majority of quadrupeds, including all four-*footed* mammals. Both forearm and foreleg bones tend to fuse in such mammals, particularly in those with a reduced number of digits and usually *digitigrade* in habit (e.g. Carnivora), contact with the ground being restricted to flexor aspects of the remaining digits.

A rotatory potential at the elbow, retained and refined in primates, allows free *pronation* and *supination*, essential to the development of manual skills. These movements are impossible in legs. At primate elbows, the ulna forms a massive hinge with the humerus but tapers to a small distal end; the radius is reciprocal: its upper end is small and adapted for rotation, the lower enlarged to carry the hand. Thus, when the radius revolves it takes the hand with it, turning round the distal end of the ulna.

Both wrist and ankle joints are hinges, but wrists can also adduct and abduct. The *carpus* and *tarsus* contain small bones between forearm or foreleg and digits. They are much modified throughout tetrapods, and the two groups show some divergence. But, however modified, both are derivable from the same primary arrangement in the primitive *pentadactyl limb*. This consisted of a proximal row of three, a distal row of five, articulating with five digits, and a central intermediate group, probably four, wedged between these rows. By fusion, loss and modification in size, shape and articulation, carpal and tarsal bones display much variation (particularly reduction). Tracing homologies between primitive elements and subsequent transformations (structural and functional) has aroused much controversy (Broom 1901, Wood Jones 1949, Lewis 1964a), but agreement has largely been reached. Authorities disagree in minor details, but generally accepted homologies are shown in the accompanying table.

Main divergencies between mammalian carpus and tarsus, apart from the latter's greater size in primates, are three. Firstly, the carpus usually remains more primitive, retaining a full proximal row, all articulating with the forearm bones; in the tarsus only one (talus) retains this role in most mammals, including the primates. Secondly, the single proximal tarsal bone (calcaneus) projects back as a lever behind the tibia and fibula; this does not occur in the carpus. Thirdly, tarsal bones at intermediate joints permit some rotation (inversion/eversion and pronation/supination), an adaptation to uneven surfaces, which may be met in some forelimbs by pronation and supination between *forearm* bones and some abduction and adduction at the wrist and intercarpal joints. In all three modifications the tarsus is more advanced. Evolution of the calcanean lever is a *mammalian*, not a solely primitive or a human modification. Its high development in the human foot and the resemblance of other primate feet to hands, may superficially suggest that it is a *human* characteristic. (Consult Lewis 1983 for a detailed account, with extensive bibliography, of the evolution of the architecture of the mammalian foot.)

Occurrence of small supernumerary bones, pre- or postaxial in position in both carpus and tarsus, has been taken as evidence of additional digits (Wood Jones 1941), suggesting an ancestral

HOMOLOGIZATION OF THE PRIMITIVE TETRAPOD AND HUMAN CARPUS AND TARSUS

	TETRAPOD CARPUS	HUMAN CARPUS		HUMAN TARSUS		TETRAPOD TARSUS	
PROXIMAL ROW	Os Radiale	Scaphoid	Scaphoid minus tubercle	Talus	Navicular minus tubercle	Os Tibiale	PRE-AXIAL
	Os Intermedium	Lunate			Talus	Os Intermedium	
	Os Ulnare	Triquetral		Calcaneus		Os Fibulare	POST-AXIAL
CENTRAL ELEMENTS	Os Centrale	Absent	Tubercle of Scaphoid	Navicular	Tubercle of Navicular	Os Centrale	
DISTAL ROW	Os Carpale 1	Trapezium		Medial Cuneiform		Os Tarsale 1	PRE-AXIAL
	Os Carpale 2	Trapezoid		Intermediate Cuneiform		Os Tarsale 2	
	Os Carpale 3	Capitate		Lateral Cuneiform		Os Tarsale 3	
	Ossa Carpalia 4 and 5	Hamate		Cuboid		Ossa Tarsalia 4 and 5	POST-AXIAL

N.B. Alternative views have been stated for the carpal scaphoid and the tarsal navicular. In each case the most widely accepted view is on the left. In the case of the talus the anomalous persistence of its posterior process as a separate element, an *os trigonum*, may have influenced the orthodox view of the talus as an amalgam of ossa tibiale et intermedium. If it becomes accepted that the talus is merely the os intermedium, the main residual controversies concern the scaphoid and navicular, centred on the possible derivation of each bone's tubercle from the corresponding os centrale. It should be added that the *centrale* element has been shown as singular in this table, though there were probably a variable number of centralia in the ancestral forms.

pattern of more than five digits, but all known tetrapods show the orthodox five and often less. The five metacarpal and metatarsal bones originally articulated each with a separate carpal or tarsal, which are reduced to four by fusion of fourth and fifth even in the pentadactyl primates. In mammals with reduced or lost digits, metacarpals and metatarsals as well as phalanges are involved. An example exists in Carnivora, whose first digit, pollex or hallux, is degenerate and useless, though often still clawed; another more extreme example is the horse, which retains only the middle digit, with a greatly enlarged metapodial bone.

The *metapodial* (metacarpal or metatarsal) *formula* puts these bones in order of length and number. In humans it is usually 2>3>4>5>1 in hands, and 1>2>3>4>5 in feet. The *phalangeal formula*, starting from the preaxial digit, pollex or hallux, numbers the phalanges in each digit. In many primitive reptiles it is 2.3.4.5.3, in primitive mammals 2.3.3.3.3.for hand and foot, as in humans. In horses it is 0.0.3.0.0. A *digital formula* denoting relative lengths of digits is sometimes used, especially in comparing primate extremities.

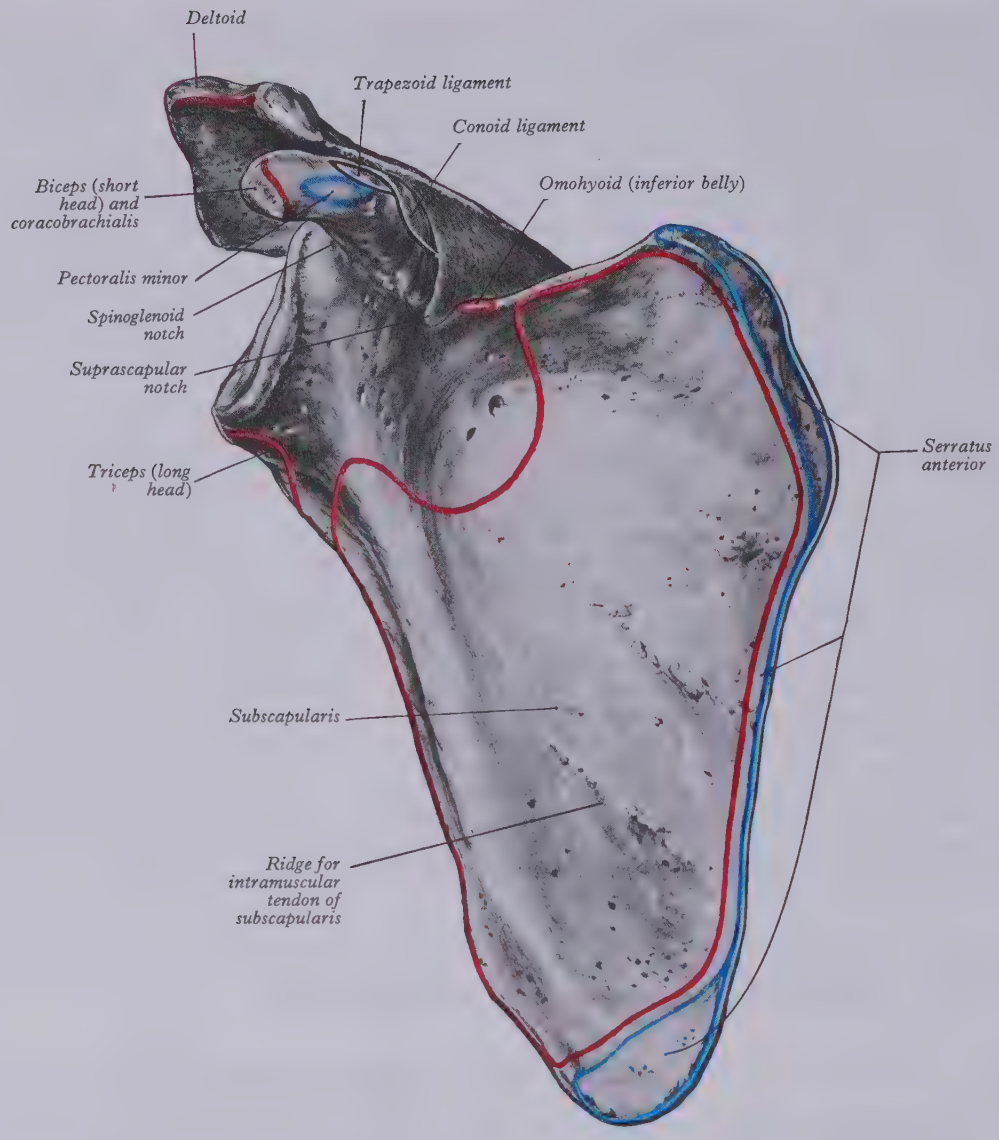
In all tetrapods pollex and hallux tend to diverge from other digits, perhaps as a prop. Some early mammals were probably arboreal, using hands as primates do, with a grasp between the preaxial digit and the rest. Primate prehension is developed in hands and feet, though absent from human feet and not always effective in primate hands. In gibbons hands are used as hooks in brachiating from branch to branch; thumbs are not effectively opposable to other digits, though the feet have an excellent grasp. In most primates the distal end of the first metatarsal is not tied by ligaments to the second, allowing the hallux marked freedom. But the human first and second metatarsals *are* so connected, all five metatarsal heads being tied by ligaments. Human thumbs, on the contrary, are even better developed for *opposition* than in other primates, in which the joint between the pollicial metacarpal and *trapezium* (*os carpale I* of the primitive tetrapod carpus) permits thumbs to flex and rotate towards fingers, either in a 'power' grip, when thumb and fingers wrap around opposite sides of an object such as a branch, weapon or tool, or in a 'precision' grip, in which the thumb is opposed to a single finger, often the index, in more accurate manipulations (Napier 1966).

Bones in human limbs, when compared functionally, are excellent examples of adaptation. In legs, the massive, almost immobile pelvic girdle is directly articulated to the vertebral column; the limited ball-and-socket mechanism at the hip is adapted for fore and aft swinging but allows some abduction to effect a steady stance in bipeds; the hinging knee and ankle joints give resilient propulsion in walking, running and springing; and the powerful lever of the foot is arched for resilience in the final thrust of take-off and impact of landing. All these features produce a limb highly developed for *locomotion*.

Arms present different adaptions, divisible into various components, but integrated in action. The scapula floats in a muscular suspension, strutted by a slender mobile clavicle, its only axial connexion. A *shallow* ball-and-socket joint allows a far wider range for the reaching, grasping, 'inquisitive' hand. Flexion *and* rotation at the elbow bring the hands within the arena of vision, providing a steady but adjustable carpal base for fine movements of opposable thumb and highly mobile fingers. Endlessly variable manipulations, entailing delicate muscular adjustments, are thus developed; with the constant feedback of stereoscopic vision and tactile sensation, a limitless horizon for manual dexterity in invention and cerebral development has been opened.

In ourselves we see the arm and hand at the end of several hundred million years of evolution. Perhaps it is not the 'end' but, even were the human upper limb to evolve no further, it has, with growing excellence of cerebral control, accomplished such a mastery over the environment as to deflect the whole course of evolution into a new channel (Huxley 1942).

THE SKELETON OF THE UPPER LIMB



The Scapula

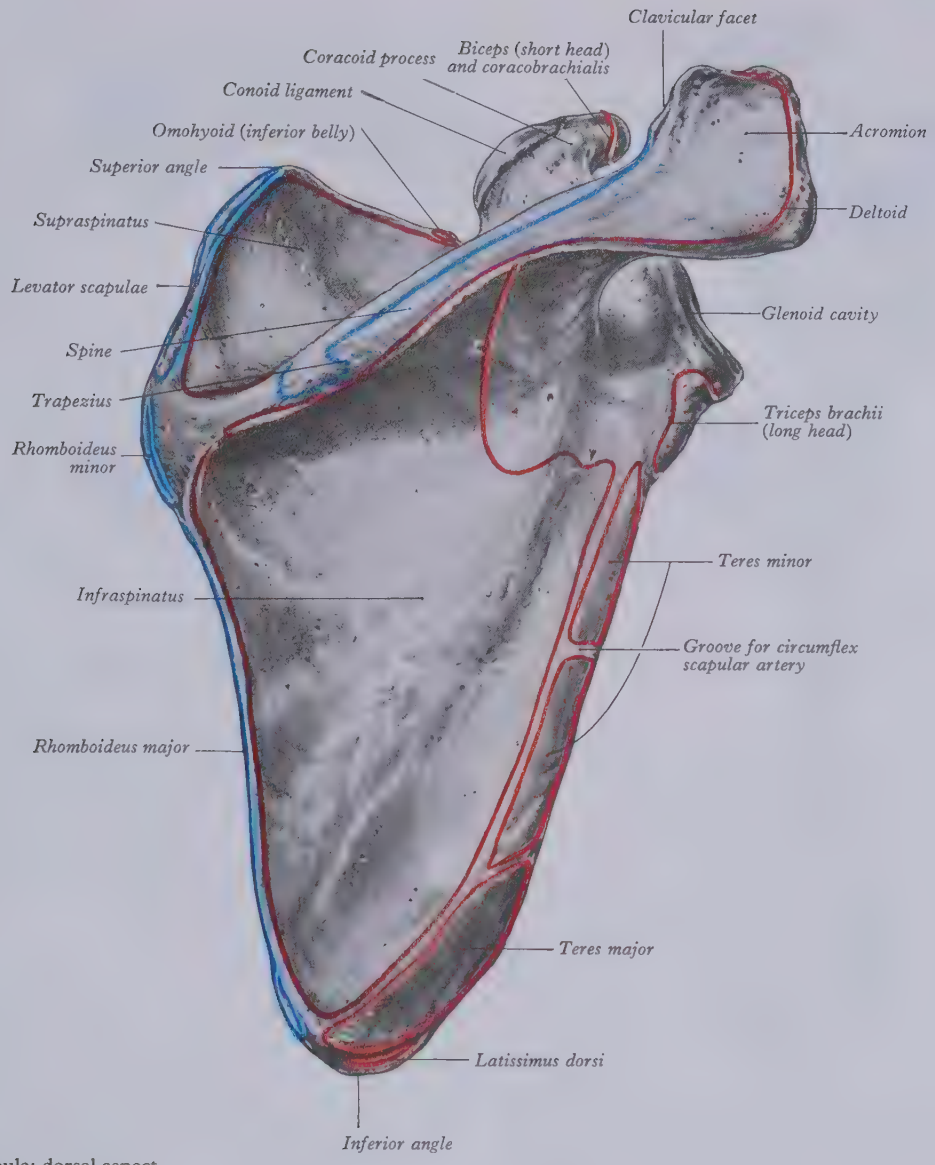
The scapula (**3**.169,170,171), a large, flat, triangular bone, overlaps in part the second to seventh ribs on the posterolateral thoracic aspect. It has costal and dorsal surfaces, superior, lateral and medial borders, inferior, superior and lateral angles, and three processes—spinous, acromial and coracoid. The lateral angle is truncated by a glenoid cavity for articulation with the humerus, sometimes regarded as the *head*, connected to the body by an inconspicuous neck. The long axis of the scapula (from 'head' to inferior angle) is nearly vertical and much thickened. The relatively featureless costal surface contrasts with the dorsal, which is divided by the spine (**3**.170).

The costal surface (**3**.169), anteromedial when the arm is pendent, is slightly hollow especially above, and presents near the lateral border a rounded ridge, prominent near the neck, less so below and separated from the border by a narrow groove. **The dorsal surface** (**3**.170) is divided by the shelf-like *spine of the scapula* into a small upper and a large lower area, which are confluent at a *spinoglenoid notch* between the spine's lateral border and the neck's dorsal aspect. A flat dorsal strip, for muscular attachments, adjoins the **lateral border**, which is a sharp, rough and sinuous ridge, from the inferior angle to the glenoid cavity. Superiorly it widens into a rough, triangular *infraglenoid tubercle* (**3**.169,170). It is covered by muscles and cannot clearly be palpated. It is described as thick because the grooved part of the costal surface, the narrow flat lateral strip of the dorsal surface and adjacent thickened ridge (**3**.169), are often included in it during clinical examination. The **medial border**, from the inferior to the superior angle, is easily felt in its inferior two-thirds but its upper third is too deep. The **superior border**, thin, sharp and shortest, is separated laterally from the coracoid process by a *suprascapular notch*.

The scapular angles: the inferior angle overlies the seventh rib or intercostal space. Palpable through the skin and covering muscles, it is also visible as it advances round the thoracic wall when the arm is raised. The *superior angle*, at the junction of superior and medial borders, is obscured by muscles. The *lateral angle*, truncated and broad, is the 'head', bearing the *glenoid cavity* and forming a glenohumeral joint with the humerus. It provides a shallow, and a limited socket for the humeral head; its outline is piriform, narrower above (**3**.171). Just above it a small rough *supraglenoid tubercle* encroaches on the root of the coracoid process. The *anatomical neck*, the constriction adjoining the rim of the glenoid cavity, is most distinct at its inferior and dorsal aspects. Ventrally and dorsally it extends between the infraglenoid and supraglenoid tubercles, passing lateral to the root of the coracoid process. Some authorities describe a *surgical neck*, best distinguished dorsally. Commencing inferiorly, near the glenoidal rim, it passes upwards and laterally through the deepest part of the spinoglenoid (great scapular) notch continuing to the anterior border of the suprascapular notch, thence medial to the coracoid and is completed by an ill-defined, but corresponding ventral line.

The scapular spine (**3**.170) projects from the upper dorsal surface and is triangular. Its lateral border, thick and rounded, helps to form the *spinoglenoid (great scapular) notch*, between it and the neck's dorsal aspect. Anteriorly it joins the dorsal surface along a line running laterally and slightly up from the junction of upper and middle thirds of the medial border. The fairly flat scapular body is, however, bent along this junction, accentuating the concavity of the upper costal surface. The dorsal border is the *crest of the spine*, mainly subcutaneous; this expands medially into a smooth, triangular area. Elsewhere its upper and lower borders and surface are roughened by muscular attachments. The concave superior surface of the spine widens laterally, forming with the

3.169 The right scapula: anterior (costal) aspect.



dorsal surface of the upper body the *supraspinous fossa*. The spine's inferior surface is overhung by the crest's medial, narrow end, but is gently convex in its wider lateral part; with the lower dorsal surface it forms the *infraspinous fossa*, continuous with the supraspinous at the spinoglenoid notch.

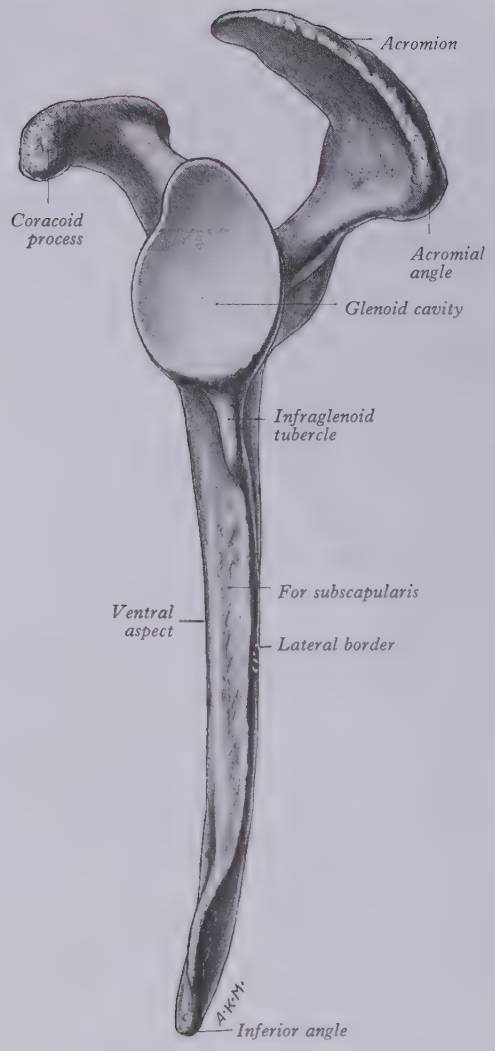
The acromion projects forwards, almost at right angles, from the lateral end of the spine. The inferior border of the crest and lateral border of the acromion are continuous at the *acromial angle*, a visible, subcutaneous landmark. The medial acromial border is short, bearing anteriorly a small, oval facet directed superomedially for articulation with the clavicle's lateral end. The lateral border, tip and superior surface are easily palpable. An accessory articular facet may occur on the acromion's inferior surface.

The coracoid process (3.169,170) springs from the summit of the scapular head and hooks slightly laterally and forwards. With the arm pendent, it points almost straight forwards. Its enlarged tip is palpable, though covered by the anterior part of the deltoid. It is about 2.5 cm below the junction of lateral fourth and the rest of the clavicle. The supraglenoid tubercle at the root of the process adjoins the upper part of the glenoid cavity. On the coracoid's dorsal aspect, where it changes direction, is an impression for the conoid part of the coracoclavicular ligament.

Further details. On the costal surface the subscapularis (3.169) is attached to almost the whole area, including much of the lateral groove but excluding the vicinity of the neck. Intramuscular tendons are attached to radiating rough ridges dividing this surface incompletely into smooth areas. The neck's anterior aspect is separated from the tendon of subscapularis by a synovial protrusion of the joint (subscapular 'bursa'). To an almost oval area near the inferior angle, the lower five or six digitations of serratus anterior are attached. The upper (3.167) fibres are attached to a narrow ventral strip along the medial border, which is wider above for the large first digitation. Longitudinal thickening near the lateral border provides a lever to withstand the pull of the serratus anterior on the inferior angle during anterior scapular rotation, by which the glenoid cavity is turned up as the arm is raised against gravity.

On the dorsal surface, in the medial two-thirds of the supraspinous fossa, is attached the supraspinatus, and the fascia over it attaches to the fossa's margins. The flat strip near the lateral border has teres minor attached to it in its upper two-thirds. It is grooved near midpoint by the circumflex scapular vessels, which pass between muscle and bone into the infraspinous fossa. The lower limit of the muscle's attachment is an oblique ridge, which runs from the lateral border towards the inferior angle, separating the attachment of teres minor from a somewhat oval area for teres major. Except for the area near the neck, the remaining infraspinous fossa is the attachment of infraspinatus, the aponeurosis of which passes on to teres minor and major and sends the fascial septa between them marking the bone at the limits of their attachments.

3.170 The right scapula: dorsal aspect.



The *lateral border* separates attachments of subscapularis and the teretes. These muscles project beyond bone and, with latissimus dorsi, make the border impalpable. To the infraglenoid tubercle the long head of the triceps brachii is attached. The *medial border* is thin and angled opposite the spine; to a narrow strip, from the superior angle to this point, is attached levator scapulae and, below this opposite the spine, rhomboideus minor. The rest of the border is taken up by rhomboideus major (p. 610). The *superior border* is thin; near the suprascapular notch the inferior belly of the omohyoid is attached. Crossing the notch is the superior transverse ligament, attached laterally to the root of the coracoid process, medially to the notch; it is sometimes ossified. The foramen, thus completed, conducts the suprascapular nerve to the supraspinous fossa, the suprascapular vessels passing above the ligament.

The *inferior angle* is covered dorsally by the upper border of latissimus dorsi, which frequently receives a small slip from it. The *superior angle* is covered by the upper part of trapezius. The *lateral angle* bears the *glenoid cavity* covered by hyaline articular cartilage; to its anterior margin are attached glenohumeral ligaments (p. 501), to the *supraglenoid tubercle* the long head of biceps, to the *infraglenoid tubercle* the long head of triceps brachii.

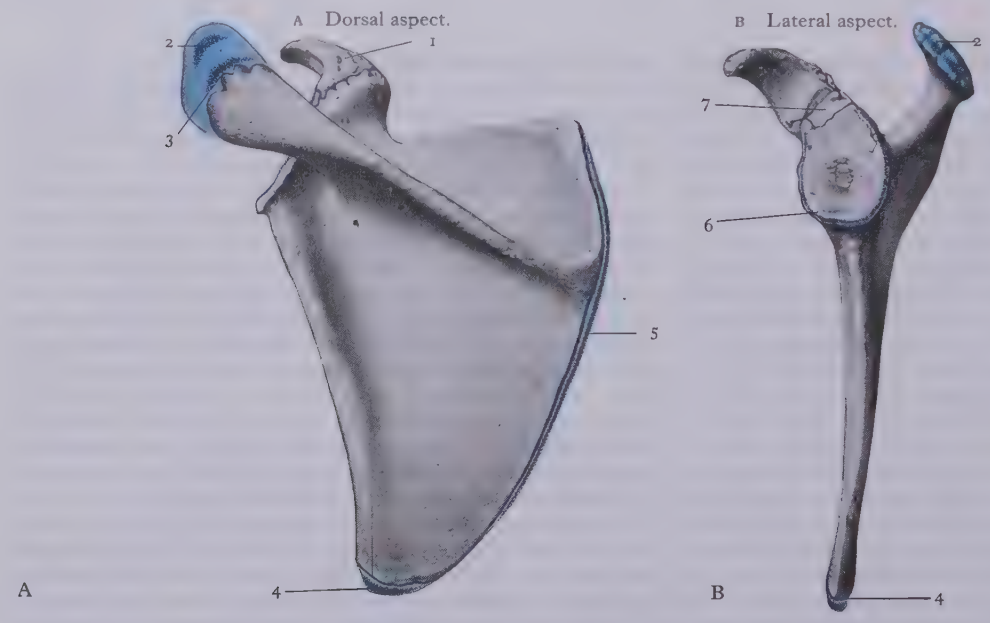
To the *scapular spine's* upper and lower surfaces the supra- and infraspinatus muscles are attached. The triangular area at its root, opposite the third thoracic spine, is played over by the tendon of the trapezius, a bursa intervening. The crest's lower border is occupied by posterior fibres of the deltoid, its upper border by middle fibres of trapezius, the lowest part of which ends as a flat triangular tendon gliding over the area noted above and attached to the so-called *deltoid tubercle* on the spine's dorsum lateral to the area.

The *acromion* is dorsally subcutaneous, covered only by skin and superficial fascia. Its lateral border, thick and irregular, and its tip as far round as the clavicular facet are the attachment of the mid part of the deltoid. To its summit medially, and below the deltoid, the lateral end of the coracoacromial ligament is attached. The articular capsule of the acromioclavicular joint is attached to the rim of the clavicular facet. Behind the facet, the acromion's medial border receives the horizontal fibres of trapezius. The smooth inferior aspect of the acromion, together with the coracoacromial ligament and coracoid process, forms a *coracoacromial arch* over the shoulder joint. The tendon of supraspinatus, below the overhanging acromion, is separated from both it and the deltoid by the subacromial bursa.

The *coracoid process*, below the junction of the lateral fourth with the rest of the clavicle, is connected to it by the coracoclavicular ligament. For attachment of its *conoid* part see page 402; the *trapezoid* part is attached to the superior aspect of the horizontal part of the process (3.169), which also receives the pectoralis minor. To its lateral border is attached the wider, medial end of the coracoacromial ligament and, below this, the coracohumeral ligament. To the coracoid apex is attached the

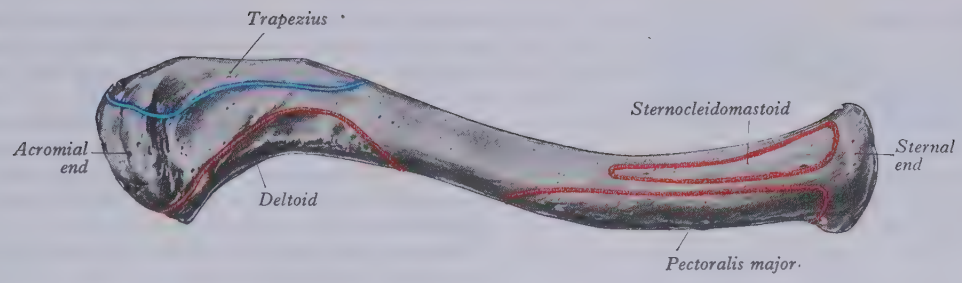
3.171 The left scapula: lateral aspect.

coracobrachialis medially and the short head of biceps laterally. The apex is covered by the anterior edge of the deltoid and is palpable under the lateral border of the infraclavicular fossa.



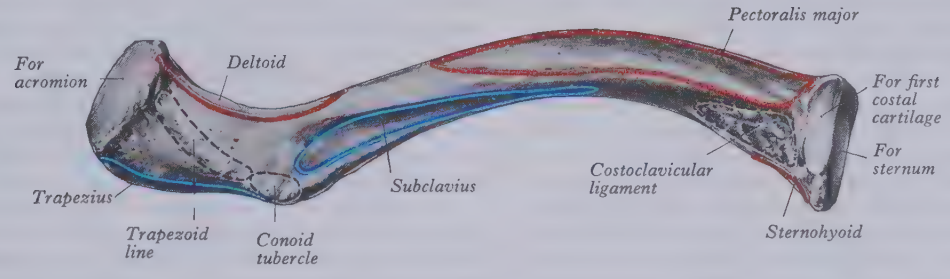
The human coracro-acromial ligament is a trait shared only with other hominoid primates, according to Ciochon & Corruccini (1977), who devised a *coracoacromial projection index: projection height* (i.e. vertical distance from supraglenoid tubercle to a line between most lateral points on acromial and coracoid apices) divided by *height of the glenoid cavity*. They claim that their observations reflect specialized locomotor and feeding adaptations in *Hominoidea*.

Structure. The main processes, and thicker parts of the scapula, contain trabecular bone; the rest consists of a thin compact layer. The central supraspinous fossa and most of the infraspinous are thin and even translucent; occasionally the bone is deficient in them, gaps being filled by aponeurotic tissue.



Ossification (3.172A,B). The cartilaginous scapula is ossified from eight or more centres: one in the body, two each in the coracoid process and the acromion, one each in the medial border, inferior angle and lower glenoid rim. The centre for the body appears in the eighth intrauterine week. Ossification begins centrally in the coracoid process in the first year, occasionally before birth; it joins the rest of the bone in about the fifteenth year. At or soon after puberty, centres appear in the coracoid root (subcoracoid centre), in the lower glenoid rim, often in the coracoid apex, in the acromion, inferior angle and contiguous medial border and in the medial border. A variable part of the glenoid cavity, usually the upper third, is ossified from the subcoracoid centre, uniting in the fourteenth (females) to seventeenth (males) year. A crescentic epiphysis for the lower glenoid rim, thicker peripherally, converts the child's flat cavity into the gently concave adult fossa. The acromial base is an extension from the spine; the remaining acromion is ossified from two centres which unite and join the spinous extension. The various scapular epiphyses have all fused by about the twentieth year.

The Clavicle



The clavicle (3.173,174) extends laterally and almost horizontally across the neck from manubrium to acromion, being wholly subcutaneous. It struts the shoulder and enables the limb to swing clear of the trunk, transmitting part of its weight to the axial skeleton. Its flat *lateral, acromial end* articulates with the medial aspect of the acromion; the enlarged *medial, sternal end* articulates

3.172 The ossification of the scapula. A. Dorsal aspect; B. Lateral aspect. 1. Coracoid centre. 2. Distal acromial centre. 3. Proximal acromial centre. 4. Centre at inferior angle. 5. Centre for medial border. 6. Glenoid centre. 7. Subcoracoid centre.

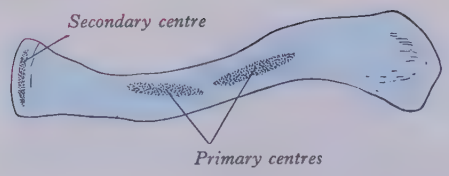
3.173 The right clavicle: superior aspect.

3.174 The right clavicle: inferior aspect.

with the manubrial clavicular facet and first costal cartilage. The *shaft* is sinuous, being convex forwards in its medial two-thirds, and concave lateral to this. The *inferior* aspect of its intermediate part is grooved in its long axis.

The clavicle's lateral third is flat, with superior and inferior surfaces, and anterior and posterior borders. The *anterior border* is concave, thin, rough and may show a small *deltoid tubercle*. The *posterior border*, also roughened by muscular attachments, is convex. The palpable *superior surface* is rough near its margins but otherwise smooth. The *inferior surface* presents, near its posterior border and at the junction of the lateral fourth with the rest of the shaft, a prominent *conoid tubercle* for the conoid part of the coracoclavicular ligament; from the lateral side of this a narrow, rough strip (*trapezoid line*) runs anterolaterally, almost to the acromial apex (3.174), for the ligament's trapezoid part. **The medial clavicular two-thirds** is roughly cylindrical or prismatic with four surfaces, the inferior often a mere ridge. *Anterior* and *superior* surfaces are largely rough but laterally smooth and rounded above the infraclavicular fossa (p. 611). The *posterior surface* is smooth, the *inferior* marked near its sternal end by a rough oval area, often depressed, for the costoclavicular ligament. Rarely, this area is smooth or even raised and may form a synovial joint with the first rib (Cave 1961). The lateral half the inferior surface is a groove for attachment of the subclavius.

Further details. The acromial end is flat, with a small oval articular facet for the medial aspect of the acromion which faces laterally and slightly down. **The sternal end**, directed medially and a little down and forwards, articulates with the manubrial clavicular notch. The sternal surface is quadrangular (sometimes triangular) and slightly rough above for ligamentous attachments. The articular surface is otherwise smooth and extends on to the inferior surface to articulate with the first costal cartilage. The sternal end projects above the manubrium and can be felt and usually seen (a prominent clinical landmark) in the lateral wall of the jugular fossa.



The shaft's lateral third has attached to it anteriorly the deltoid, posteriorly the trapezius, both reaching the superior surface. The coracoclavicular ligament, attached to the conoid tubercle and trapezoid line (3.174), transmits the weight of the upper limb to the clavicle, counteracted by the trapezius supporting its lateral part (p. 609). From the conoid tubercle weight is transmitted medially by the shaft to the axial skeleton; a fracture medial to it interrupts this transmission, almost all weight then being supported by the trapezius which is unable to meet the demand, and the limb therefore droops.

The clavicle's medial two-thirds provides attachment, anteriorly, to the clavicular part of pectoralis major, the area being usually visibly marked. The clavicular part of sternocleidomastoid is attached to the medial half of the superior surface but marks it little. The smooth *posterior surface* is devoid of attachments except near its sternal end, where part of the sternohyoid is attached. Medially this surface is related to the internal jugular vein's lower end (separated by sternohyoid), the end of the subclavian and beginning of the brachiocephalic vein. More laterally, the clavicle curves in front of the trunks of the brachial plexus and the third part of the subclavian artery. The suprascapular vessels are related to the upper part of this surface. On the *inferior surface* is the subclavius in its groove (3.174). To the edges of this groove is attached the clavipectoral fascia, which encloses the muscle; the posterior edge of the groove runs to the conoid tubercle, where fascia and conoid ligament merge. A nutrient foramen, lateral in the groove, is inclined laterally. Medially an impression for the costoclavicular ligament varies greatly in texture and outline (vide supra and Cave 1961).

To the margins of the *acromial* articular facet is attached the acromioclavicular capsule, and to the rough upper part of the *sternal end* the interclavicular ligament, sternoclavicular capsule and articular disc. The sternal (osseous) articular surface is usually irregular and pitted.

The female clavicle is shorter, thinner, less curved and smoother, its acromial end carried lower than the sternal; in males it is level with, or slightly above, the sternal end when the arm is pendent. Midshaft circumference is the most reliable single indicator of sex, but a combination of this with weight and length yields better results (Olivier 1951, Jit & Singh 1966); however consult Jit & Sahni (1983) for statistical analysis and literature. The clavicle is thicker and more curved in manual workers, its muscular attachments marked. The clavicle is trabecular internally, with a shell of compact bone much thicker in its shaft. Although elongate, the clavicle is unlike typical long bones; it usually has no medullary cavity.

Ossification (3.175). The clavicle begins to ossify before any other bone, the shaft from medial and lateral primary centres, appearing in condensed mesenchyme between fifth and sixth weeks and fusing about the forty-fifth day. A secondary centre for the sternal end appears in late teens, or even early twenties, usually two years earlier in females. Fusion is probably rapid but reliable data are lacking. An acromial secondary centre sometimes develops at about 18 to 20, but this epiphysis is always small and rapidly joins the shaft (Todd & D'Erico 1928). In a study of the

3.175 Diagram showing the three constant centres of ossification of the clavicle.

sternal epiphysis in 684 Punjabis, ossification occurred from 11 to 19 years (both sexes) and fusion at 18 to 25 years (Jit & Kulkaria 1976). Comparison suggests racial differences. Such assessment by radiological appearances is, of course, not devoid of fallacy.

However, clavicular development is not only by intramembranous ossification. In 14 mm embryos the clavicle is a band of condensed mesenchyme between the acromion and apex of the first rib, and continuous with the sternal rudiment. In this band medial and lateral zones of early cartilage transformation ('precartilage') occur, and in mesenchyme between them intramembranous centres of ossification appear and soon fuse. Sternal and acromial zones soon become true cartilage, into which ossification extends from the shaft. Length increases by interstitial growth of these terminal cartilages, which develop zones of hypertrophy, calcification and advancing endochondral ossification as in other growth cartilages. Diameter is increased by subperichondrial deposition in the extremities and subperiosteal deposition in the shaft. Epiphyses are endochondral and probably fuse as in long bones which are *primarily* cartilaginous. Defects of ossification in clavicle and primarily intramembranous cranial bones occasionally coincide as the condition of cleidocranial dysostosis.

The primitive reptilian pectoral girdle comprises a dorsal scapula and two ventral elements, an anterior (cranial) precoracoid and posterior (caudal) coracoid. Of the three pelvic elements, the ilium is homologous with the scapula, the pubis with the precoracoid, the ischium with the coracoid. The clavicle, dermal in origin and therefore morphologically distinct, is an addition to the pectoral girdle with no pelvic equivalent. It is doubtful whether any trace of precoracoid persists in the human skeleton, but the double primary clavicular centre may indicate that human clavicles contain reptilian precoracoid and clavicle. Some believe that the first coracoid centre represents the precoracoid element and subcoracoid centre the caudal ventral element of reptilian girdles. The clavicle is absent from forelimbs used principally or entirely for progression, e.g. in ungulates and carnivores; but it is present and well-developed in prehensile limbs, e.g. in many rodents, primates and man.

The clavicle is often fractured, commonly by indirect forces, due to violent impacts to hand or shoulder, the break being at the junction of lateral and intermediate thirds, where its curvature changes, for this is its weakest part. Consequent deformity is caused by the weight of the arm, which depresses the lateral fragment, forces being transmitted through the coracoclavicular ligament; the medial fragment is usually little displaced.

The Humerus

The humerus (**3**.176A,B,177A,B et seq), the longest and largest bone in the arm, has expanded ends and a shaft. Proximally a round 'head' forms with the scapular glenoid cavity an enarthrodial articulation (cf p. 502). The distal end, loosely termed 'condylar', is adapted to the forearm bones at the cubital joint.

The head (**3**.176,177), at the proximal end, is slightly less than half a spheroid; it has an articular surface covered by hyaline cartilage, directed posteromedially and upwards to the glenoid cavity in the pendent arm. The humeral articular surface much exceeds that of the glenoid cavity, only part of it being in glenoid contact in any position of the joint.

The anatomical neck, directly adjoining the articular head's margin, is a slight constriction, least apparent near the greater tubercle, and superiorly, and for some distance continuing anteriorly and posteriorly, indicates the line of capsular attachment of the glenohumeral joint. However, inferiorly, the capsular attachment diverges markedly from the anatomical neck (vide infra).

The lesser tubercle (tuberosity) is anterior and just beyond the anatomical neck; it has a smooth, muscular impression palpable through the deltoid 3 cm below the acromial apex, moving when the humerus rotates. Its sharp lateral edge is part of the medial border of the intertubercular sulcus.

The greater tubercle (tuberosity), is the most lateral part of the humeral proximal end and in the shoulder region projects beyond the acromion and, covered by the deltoid, produces the shoulder's round contour. Its posterosuperior aspect, near the anatomical neck, bears three smooth impressions for tendons. Between the tubercles is the **intertubercular sulcus**. The humeral proximal end tapers into the shaft as an ill-defined '*surgical neck*', medial to which are the axillary nerve and posterior humeral circumflex artery (**3**.177A).

The humeral shaft, in its proximal half almost cylindrical, is distally prismatic (in section) and anteroposteriorly compressed. It is not directly palpable due to the large muscles around it. Its three surfaces and borders are not equally obvious.

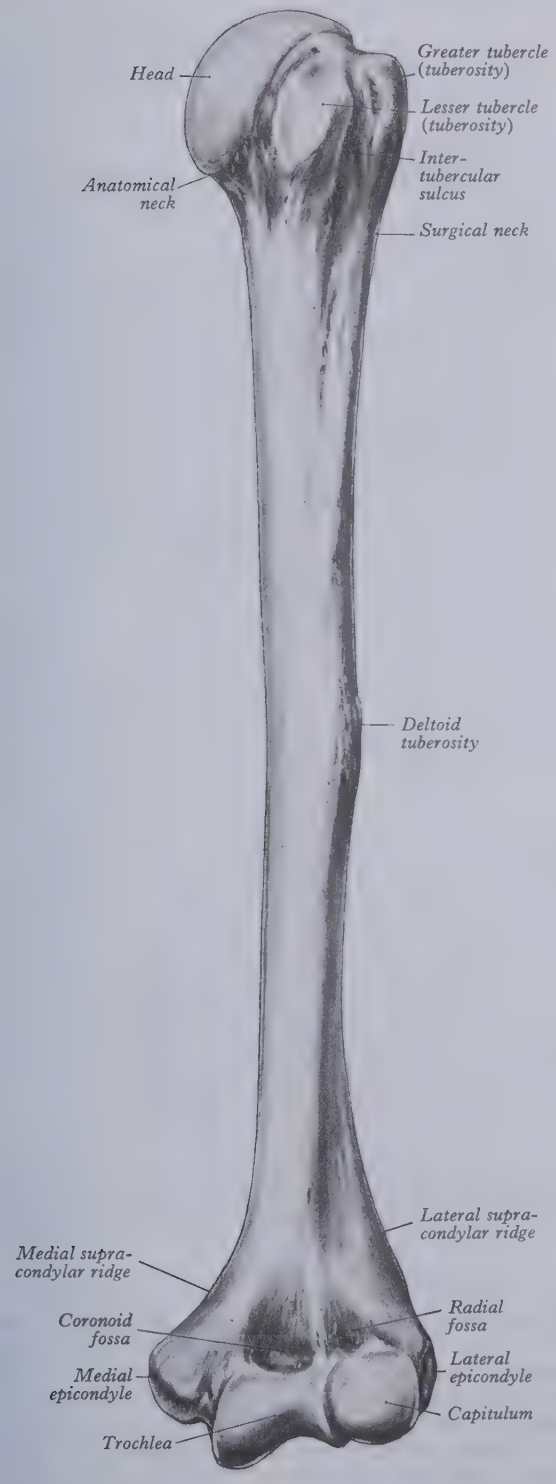
The *anterior border* descends from the front of the greater tubercle almost to the distal end of the bone. Its proximal third is the lateral edge of the intertubercular sulcus, marked by muscular attachments. Beyond this, as the anterior edge of the deltoid tuberosity, it is also rough but smoothly rounded in its distal half.

The *lateral border* is distally sharp and rough along its anterior aspect; its proximal two-thirds are barely discernible, although sometimes traceable to the posterior aspect of the greater tubercle. Centrally it is interrupted by a wide, shallow groove, descending obliquely laterally and forwards, the *sulcus for the radial nerve*.

The *medial border*, rounded in its distal half, bears a roughened strip just below its midpoint; proximal to this it is indistinct but reappears as the medial lip of the intertubercular sulcus, where it is again rough and reaches the lesser tubercle.

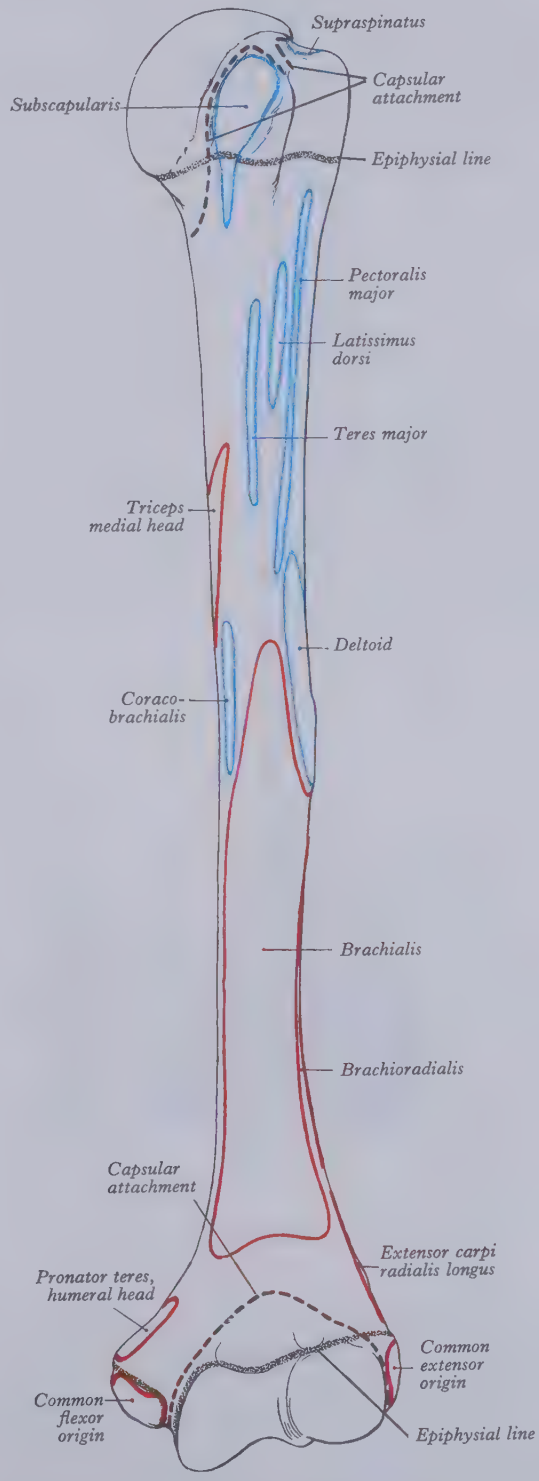
The *anterolateral surface* is between the anterior and lateral borders; just proximal to its midpoint is the rough *deltoid tuberosity*, tapering to a distal apex. Behind this the radial sulcus descends, fading distally when it reaches the lateral border a little beyond the tuberosity. The *anteromedial surface*, between the anterior and medial borders, forms in its proximal third the rough floor of the intertubercular sulcus, but the rest is smooth. Near its midpoint a nutrient foramen opens, its canal directed distally. The *posterior surface*, between medial and lateral borders, is the most extensive. A ridge, sometimes rough, descends laterally across its proximal third. The middle third is crossed by the commencement of the radial sulcus. The distal third is an extensive, flat surface, which widens distally.

The distal end of the humerus (**3**.176–178), basically a modified *condyle*, is wide transversely and has articular and non-articular parts. The *articular part* joints with the radius and ulna at the elbow and is divided into a lateral, convex *capitulum* and a medial, pulley-shaped *trochlea*.



The capitulum, less than half a sphere, includes anterior and inferior surfaces of the condyle laterally, but not its posterior surface. It articulates with the discoid radial head, which abuts the inferior surface in full extension but slides on to the anterior surface during flexion.

The trochlea is like part of a pulley, occupying anterior, inferior and posterior surfaces of the humeral condyle medially; it is separated laterally from the capitulum by a faint groove; all aspects of its medial margin project. It articulates with the trochlear notch of the ulna. In extension the inferoposterior trochlear circumference contacts the ulna, but in flexion the trochlear notch slides on to the anterior aspect, the posterior being uncovered. The projecting medial trochlear edge is a main determinant of angulation between the long axes of humerus and ulna when the forearm is extended and supinated (p. 506).



The *non-articular* condyle includes medial and lateral epicondyles, olecranon, coronoid and radial fossae. *The medial epicondyle*, a blunt projection on the condyle's medial, is subcutaneous and usually visible in passive flexion. Its smooth posterior surface is crossed by the ulnar nerve in a shallow sulcus as

it enters the forearm, and here the nerve can be rolled against bone. If it is jarred against the epicondyle, characteristic tingling sensations result. Distally the anterior epicondylar surface is marked by the attachment of superficial forearm flexors.

The lateral epicondyle, lateral non-articular part of the condyle, does not project beyond the lateral border. It has an anterolateral impression for superficial forearm extensors. Its posterior surface, slightly convex, is easily felt in a depression visible behind the extended elbow. The lateral humeral border ends at the *lateral epicondyle*, from which, extending proximally, is its distal part, the *lateral supracondylar ridge*. The medial border ends at the *medial epicondyle* and is, distally, the *medial supracondylar ridge*. A deep hollow, the *olecranon fossa*, on the condyle's posterior surface, proximal to the trochlea, contains the apex of the olecranon in the extended elbow. Its floor is always thin and may be deficient. A smaller *coronoid fossa*, immediately proximal to the trochlea on the anterior surface, accommodates the margin of the ulnar coronoid process in full flexion. A shallow *radial fossa*, proximal to the capitulum and lateral to the coronoid fossa, is related to the margin of the radial head in full flexion.

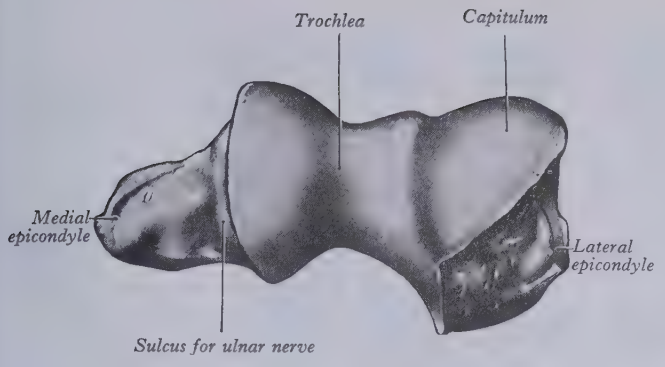
3.177A The left humerus: posterior aspect.



3.177B Key to 3.177A. The interrupted lines indicate the attachment of the capsular ligaments; the stippled lines mark the position of the epiphysial lines.

In lower mammals the longest axes of proximal and distal humeral articular surfaces make an angle with each other of a little more than 90°. But the proximal human humerus appears to have rotated laterally, so that the angle has been increased to about 164° (3.179), the *angle of 'humeral torsion'*. It is greater in males and adults, and less in anthropoid apes. Krahl (1976) claims that the angle increases with age until fusion of the epiphysis (p. 399).

The head's articular cartilage is thick centrally, and thins peripherally; in sectional profile it is spheroidal (strictly ovoidal, see p. 501).

To the *anatomical neck* is attached the *capsular ligament* of the shoulder joint (3.176,177), except at the intertubercular sulcus, where the long tendon of biceps emerges. But medially the attachment descends 1 cm or more on the shaft. To the *lesser tubercle* the subscapularis is attached (3.176A) and to its lateral margin the transverse ligament of the shoulder joint. The *greater tubercle* shows three impressions for tendons, the uppermost for supraspinatus, the middle for infraspinatus and the lowest for teres minor (3.177B). Its projecting lateral surface has many vascular foramina and is covered by the deltoid; a subacromial bursa may

3.178 The lower end of the left humerus: distal (inferior) aspect.

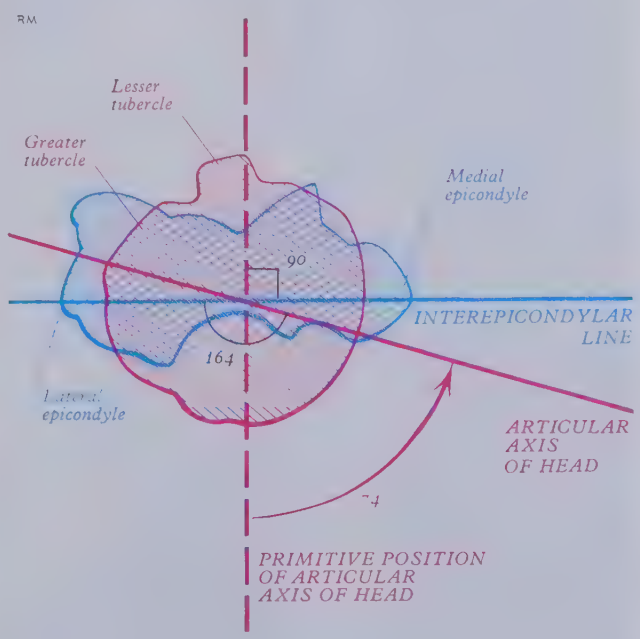
separate the deltoid from the tubercle. The attachments of subscapularis and teres minor are not confined to their respective tubercles, but extend for varying distances on to adjacent metaphysis.

The *intertubercular sulcus* (bicipital groove) contains the long tendon of biceps, its synovial sheath, and an ascending branch from the anterior circumflex humeral artery. The groove's lateral lip is marked by the tendon of pectoralis major, its floor by that of the latissimus dorsi and its medial lip by that of the teres major. Attachment of the pectoralis major extends beyond teres major's, that of latissimus dorsi being least extensive. Distal to the sulcus a small area of anteromedial surface is devoid of muscular attachment, but its distal half is occupied by the medial part of the brachialis (3.176B). The rough strip on the medial border is for the coracobrachialis. Near its distal end the medial supracondylar ridge has a narrow area for the humeral part of the pronator teres, and the ridge itself for the medial intermuscular septum.

To the oblique ridge across the *posterior surface* the lateral head of triceps is attached; proximal to this axillary (circumflex) nerve and posterior circumflex humeral vessels curve round the 'surgical neck' deep to the deltoid; distally the radial groove, containing the nerve and profunda vessels, descends laterally to the anterolateral surface. The medial head of the triceps occupies much of the posterior surface in a long triangular area, its apex medial on this surface and *proximal* to the distal limit of the teres major, widening distally over the whole dorsal surface almost to its distal end (3.177B).

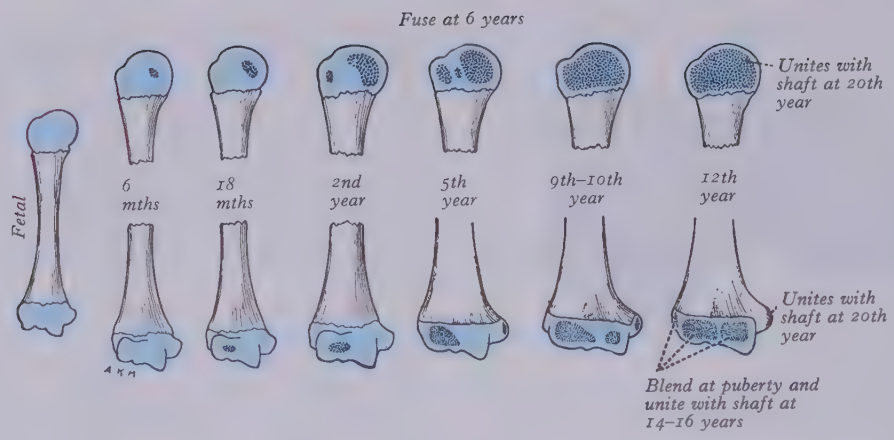
Proximally the *anterolateral surface* is smooth and covered by the deltoid, which is attached to its tuberosity; distally it is occupied by part of the brachialis, ascending into the floor of the radial groove (3.177B). The lateral supracondylar ridge, in its proximal two-thirds, is for the brachioradialis and in its distal third for the extensor carpi radialis longus. Behind these, the lateral intermuscular septum is attached to the ridge.

The articular region of the humeral condyle is so curved that anterior and posterior surfaces are anterior in plane to corresponding surfaces of the shaft. The trochlear groove spirals posterolaterally from the anterior to the posterior surface; posteriorly it is wider, deeper and more symmetrical; anteriorly its medial flange is longer and the convex surface adjoining its projecting medial margin is adapted to the medial arc of the coronoid articular surface. These asymmetries entail varying angulation between the humeral and ulnar axes, together with some conjunct rotation (p. 502).



The *cubital capsular ligament* (3.176B,177B) is attached to the proximal limits of the radial and coronoid fossae—which are intracapsular and covered by synovial membrane—and also to the medial aspect of the trochlear rim and root of the medial epicondyle. Posteriorly it ascends almost to the upper margin of the olecranon fossa, which is also intracapsular and covered by synovial membrane. Laterally it skirts the borders of the trochlea and capitulum, lying medial to the lateral epicondyle.

The common superficial flexor tendon springs from the medial epicondylar epiphysis, being wholly extracapsular. The common superficial extensor tendon is attached to the lateral epicondyle, also outside the articular capsule; to its posterior surface the anconeus is attached (3.177B). The medial epicondyle turns slightly backwards, the lateral slightly forwards.

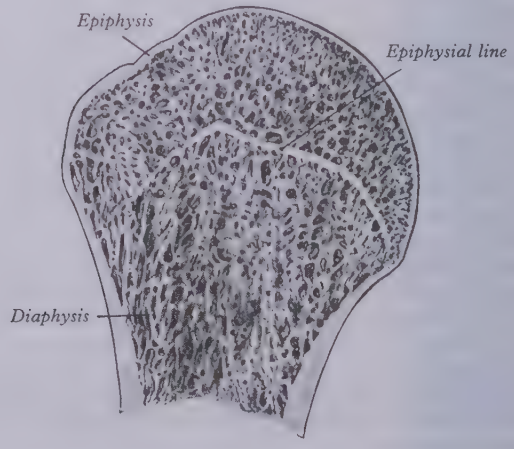


With the humerus pendent, the medial epicondyle is posteror in plane to the lateral; the humeral head is directed almost equally *backwards* and *medially*, the posterior surface of the shaft facing posterolaterally. Since the glenoid cavity faces anterolaterally, the humerus is not rotated medially *relative to the scapula* in this position of rest; but it *is* so rotated relative to the *conventional anatomical position*. This must be remembered when movements of arm and forearm are considered (pp. 503 and 509; see also *Introduction*).

A hook-shaped *supracondylar process*, from 2 to 20 mm in length, occasionally projects from the shaft's anteromedial surface, about 5 cm proximal to the medial epicondyle. It curves distally and forwards, its apex connected to the medial border, proximal to the epicondyle, by a fibrous band, to which part of the pronator teres is attached. The foramen so formed usually encloses the median nerve and brachial artery, but sometimes only the nerve or perhaps nerve plus the ulnar artery in a high division of the brachial artery. A groove for the artery and nerve usually exists behind the process. It is the homologue of the *entepicondylar foramen* of many animals and may protect the nerve and artery from compression by muscles. These skeletal features may aid in assessing racial affinities (p. 273).

Ossification (3.180). The humerus is ossified from eight centres, in shaft, head, greater and lesser tubercles, capitulum and lateral trochlea, medial trochlea and both epicondyles. The shaft begins to ossify centrally in the eighth week with gradual extension to its ends, and the humeral head usually during the first six months after birth, but just before it in 20% of individuals. The greater and lesser tubercles begin to ossify in the second and fifth years in males, about a year earlier in females. By the sixth year head and tubercles have become a single epiphysis, *hollow* inferiorly (3.182) to fit the conical end of the diaphysis and fusing with it about the twentieth year in males, two years earlier in females. Some deny a centre in the lesser tubercle, perhaps because it is often obscured in the usual anteroposterior

3.179 This diagram illustrates the concept of humeral 'torsion'. The left humerus is viewed distally along its length, with its proximal end (magenta) superimposed upon the distal (blue). The 'axes' of the two extremities are shown at right angles, as in early tetrapods and most quadrupedal mammals. In primates, including mankind, the axis of the head is directed medially, and the angle which this now makes with the 'primitive' anteroposterior position of the axis is the so-called angle of torsion. This is on average 74° in man: some authorities add to this the original angle of 90°, giving a total of 164°. See text for more detailed explanation.



3.180 Stages in the ossification of the humerus (not to scale).

radiological views (3.181). In the distal end, during the first year, ossification begins in the capitulum and extends to form most of its articular surface; a centre for the medial region of the trochlea appears in the ninth year in females and tenth in males. Ossification begins in the medial epicondyle in the fourth year in females, sixth in males, and in the lateral epicondyle about the twelfth year. Centres for lateral epicondyle, capitulum and trochlea fuse around puberty and the composite epiphysis unites with the shaft in the fourteenth year in females, sixteenth in males. The medial epicondyle is a separate epiphysis, entirely extracapsular (3.176B,177B), from a centre posteromedial in it. It is separated from the distal epiphysis by a downgrowth of shaft, with which it unites about the twentieth year.

The proximal epiphysis joins the shaft later than the distal, and growth in length is predominantly due to the proximal growth cartilage. Hence, after amputation through the arm in youth, the humerus continues to grow, its lower end progressively moulding the soft tissues and making the stump conical. Fractures are comparatively common and at almost any level. Muscular action is more often the cause than in any other long bone; it is usually the shaft, below attachment of the deltoid, which is broken. Hence the radial nerve may be injured in its groove and is sometimes involved later in the growth of callus. Non-union is commoner than in any other bone except the tibia. Fractures at the proximal end may damage the axillary nerve, and at the medial epicondyle the ulnar nerve. Late fusion of this epicondyle may be misdiagnosed as a fracture.

The Radius

The radius (3.183–186), lateral in the forearm, has expanded proximal and distal ends, the distal much the broader. The shaft widens rapidly towards its distal end, is convex laterally and concave anteriorly in its distal part. **The proximal end** includes a head, neck and tuberosity. *The head* is discoid, its proximal surface a shallow cup for the humeral capitulum. Its smooth *articular*

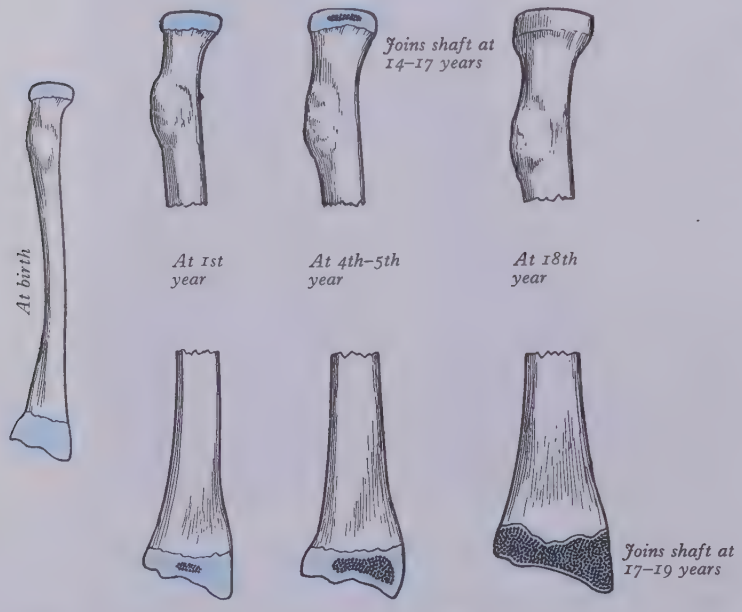
3.183 The bones of the left forearm: anterior aspect.

3.184 The bones of the left forearm: posterior aspect.

periphery is vertically deepest medially, where it contacts the ulnar radial notch. Its posterior surface is palpable in a small depression on the lateral side of the back of the extended elbow. The *neck* is the constriction distal to the head, which overhangs it, especially on the lateral side. *The tuberosity* is distal to the medial part of the neck; it is posteriorly rough but anteriorly usually smooth.

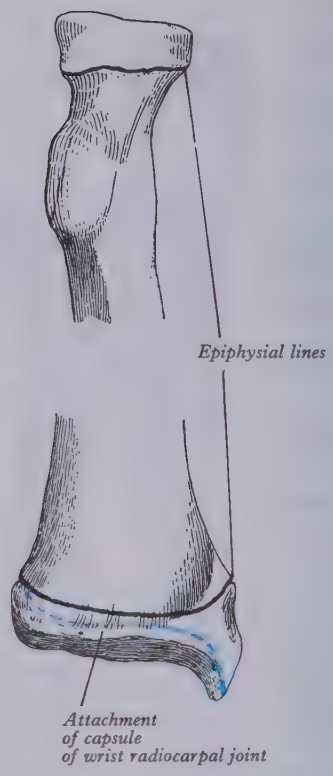
The shaft has a lateral convexity, in section triangular (3.188), but only its *interosseous border* is sharp, except proximally, near the tuberosity; distally it is the posterior margin of a small, elongated, triangular area, proximal to the ulnar notch (vide infra), the two areas forming a so-called *medial* surface. To its distal three-fourths the interosseous membrane is attached, connecting radius to ulna. The *anterior border* is obvious at both ends but rounded and indefinite between them. It descends laterally from the anterolateral part of the tuberosity as the *anterior oblique line*, distally a sharp, palpable crest along the lateral margin of the anterior surface. The *posterior* border is well-defined only in its middle third; proximally it ascends medially towards the postero-inferior part of the tuberosity; distally it is merely a rounded ridge. The *anterior surface*, between anterior and interosseous borders, is concave transversely and shows a distal forward curvature. Near its midpoint is a proximally directed nutrient foramen and canal. The *posterior surface*, between interosseous and posterior borders, is largely flat but may be slightly hollow in the proximal area. The *lateral surface* is gently convex; proximally, due to the

obliquity of anterior and posterior borders, it encroaches on the anterior and posterior aspects and is here slightly rough. A finely irregular oval area occurs near mid-shaft; beyond this the surface is smooth.



The distal end, the widest part, is four-sided in section. Its *lateral surface* is slightly rough, projecting distally as a *styloid process* palpable when tendons around it are slack. Distal (**3**.189) is the smooth *carpal articular surface*, divided by a ridge into medial and lateral areas, the medial quadrangular, the lateral triangular and curving on to the styloid process. The *anterior surface* is a thick, prominent ridge, palpable even through overlying tendons, 2 cm proximal to the thenar eminence. The *medial surface* is the *ulnar notch*, smooth, antero-posteriorly concave for articulation with the ulna's head. The *posterior surface* displays a palpable dorsal tubercle, limited medially by an oblique groove and in line with the cleft between the index and middle fingers. A wide, shallow groove, lateral to it, is divided by a faint vertical ridge. A similar but undivided groove is medial to the tubercle.

The *proximal articular surface* of the radial head and its *circumference* are covered by hyaline cartilage, the upper rim (margin) of the latter fitting the groove between capitulum and trochlea and invading the radial fossa in flexion. The articular circumference joints with the ulnar radial notch and annular ligament, within which it rotates in pronation and supination. The radial *neck* is enclosed by the ligament's narrower, distal part, separated by a synovial protrusion from the superior radio-ulnar joint.



The posterior area of the *tuberosity* is marked by the biceps tendon, but the latter is separated from a smooth anterior area by a bursa, distal to which the oblique cord is attached.

Proximally on the *anterior border* the thin, wide radial head of the flexor digitorum superificialis is attached, and to its conspicuous distal part the lateral edge of the extensor retinaculum. The small, triangular area proximal to the ulnar notch is for the deepest part of the pronator quadratus.

The proximal two-thirds of the *anterior surface* is an extensive area for the flexor pollicis longus, which conceals the nutrient foramen, the distal quarter is for the pronator quadratus. A rough area on the *lateral surface*, midway at its maximal curvature, is for the pronator teres. Proximally, the lateral surface widens, encroaching on the anterior and posterior, into a long V-shaped area (**3**.183,184) for the supinator. Distal to the pronator teres, the lateral surface is covered by tendons of radial extensors. Proximally on the *posterior surface* the abductor pollicis longus is attached and, more distally, the extensor pollicis brevis. The remaining surface is devoid of attachments but covered by the long and short pollicial extensors.

3.185 Stages in the ossification of the radius (not to scale).

3.186 The epiphysial lines of the left radius in adolescence: anterior aspect. The line of attachment of the articular capsule of the wrist joint is in blue.

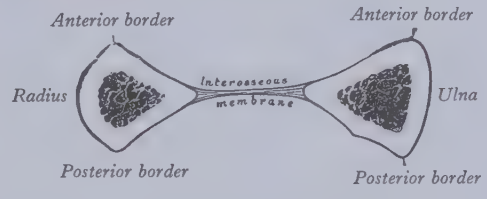
The radial *styloid process* projects beyond that of the ulna, its apex concealed by tendons of the abductor pollicis longus and extensor pollicis brevis. The carpal lateral ligament is attached to its tip. The *lateral surface*, near the styloid, receives the brachioradialis and is crossed obliquely, down and forwards, by tendons of the abductor pollicis longus and extensor pollicis brevis. The terminal ridge on the *anterior surface* of the lower end is an attachment for the palmar radiocarpal ligament. To a smooth ridge distal to the ulnar notch the base of the triangular articular disc of the inferior radio-ulnar joint is attached. From the latter, a narrow protrusion of synovial membrane extends proximally anterior to the lower end of the interosseous membrane (p. 508). The lateral part of the *carpal articular surface* joints with the scaphoid and the medial part of the surface with the lateral part of the lunate bone; in full adduction the latter's proximal surface is wholly in contact with the radius.

The radial *dorsal tubercle* receives a slip from the extensor retinaculum and is grooved medially by the tendon of the extensor pollicis longus. The wide groove lateral to the tubercle contains tendons of the extensor carpi radialis longus laterally, extensor carpi radialis brevis medially and their synovial sheaths. Medially the dorsal surface is grooved by the tendons of extensor digitorum, but extensor indicis and the posterior interosseous nerve separate these from the bone. Attached to the distal margin of this surface is the dorsal radiocarpal ligament.

Ossification (**3**.185,186). The radius ossifies at three centres, in the shaft, appearing centrally in the eighth week, and in each end. Near the end of the first postnatal year ossification begins in the distal epiphysis, and in the proximal at the fourth year in females, fifth in males. The proximal fuses in the fourteenth year in females, seventeenth in males, the distal in the seventeenth and nineteenth years respectively. A fourth centre sometimes appears in the tuberosity about the fourteenth or fifteenth year.

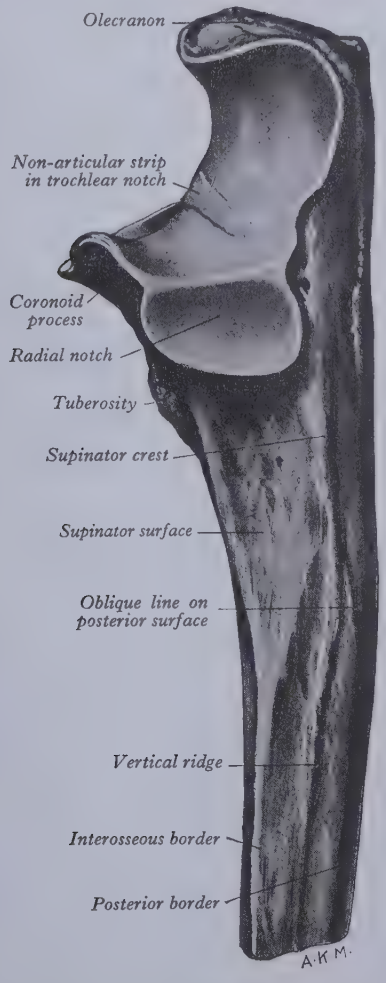
The Ulna

The ulna (**3**.183–192) is medial to the radius in the supinated forearm. Its proximal end is a massive hook (**3**.187), concave



forwards. The shaft's lateral border is a sharp (interosseous) crest. The bone diminishes progressively from its proximal mass throughout almost its whole length, but at its distal end expands into a small rounded head and styloid process. The shaft is triangular in section and has an appreciable double curve. In its whole length it is slightly convex dorsally; but mediolaterally its profile is sinuous; the proximal half has a slight laterally concave curvature, the distal half a medially concave curvature.

The proximal end (**3**.187) has large olecranon and coronoid processes and trochlear and radial notches articulating with the humerus and radius. The *olecranon*, more proximal, is bent forwards at its summit like a beak, which enters the humeral olecranon fossa in extension. Its posterior surface is smooth, triangular and subcutaneous, its proximal border being the elbow's 'point'. In extension it can be felt near a line joining the humeral epicondyles, but in flexion it descends, the three osseous points forming an isosceles triangle. Its anterior, articular surface forms the proximal area of the trochlear notch. Its base is slightly constricted where it joins the shaft and narrowest part of the proximal ulna. The *coronoid process* projects anteriorly distal to the olecranon, its proximal aspect forming the distal part of the trochlear notch, distal to which, on the lateral surface, is a shallow smooth, oval *radial notch* for articulation with the radial head. Distal to this the surface is hollow to accommodate the radial tuberosity during pronation and supination. The coronoid's anterior surface is triangular, its distal part the *tuberosity of the ulna*. Its medial border is sharp and proximally bears a small tubercle.

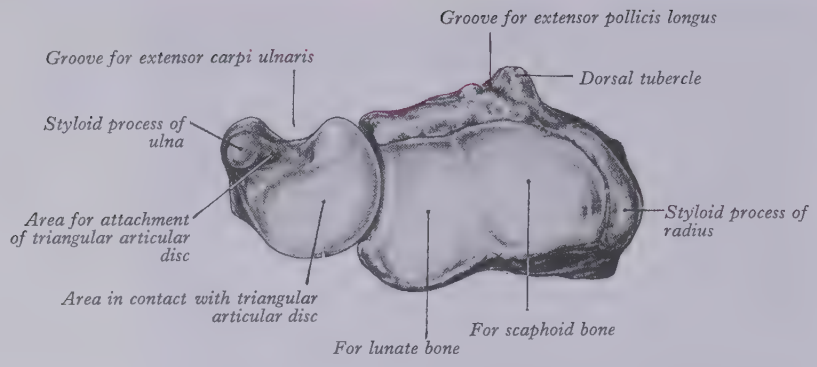


The *trochlear notch* articulates with the humeral trochlea. It is constricted at the junction of the olecranon and coronoid processes, where their articular surfaces may be separated by a narrow, rough non-articular strip. A smooth ridge, adapted to the humeral trochlea's groove, divides the notch into medial and lateral parts, the medial fitting to the trochlear flange. The *radial notch* (**3**.187), an oval or oblong proximal depression on the lateral aspect of the coronoid, joints with the radial head's periphery, separated from the trochlear notch by a smooth ridge.

The distal end, a little expanded, has a head and styloid process. The *ulnar head* is visible in pronation on the posteromedial carpal aspect and can be gripped when the supinated hand is flexed. Its lateral convex articular surface fits the radial ulnar notch. Its smooth distal surface (**3**.189) is separated from the carpus by an articular disc, the apex of which is attached to a rough area between the articular surface and *styloid process*. The latter, a short, round, posterolateral projection of the ulna's distal end, is palpable (most readily in supination) about 1 cm proximal to the plane of the radial styloid. A dorsal vertical groove is present between the head and styloid process.

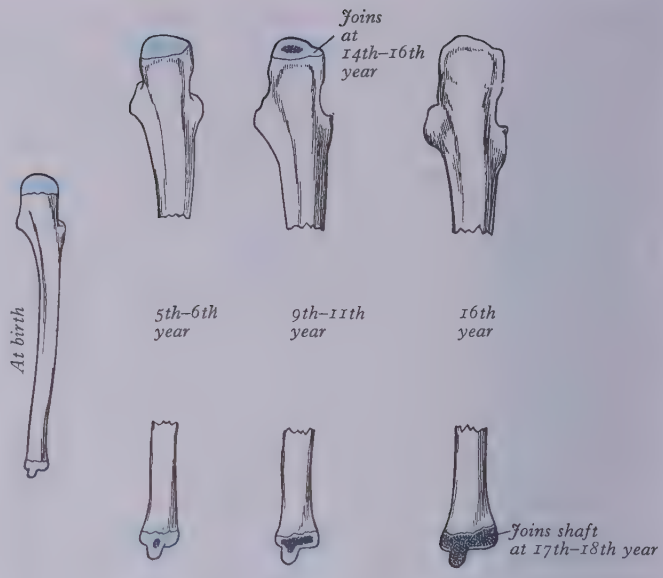
The shaft is triangular in section (**3**.188) in its proximal three-fourths, but distally almost cylindrical. It has anterior, posterior and medial surfaces and interosseous, posterior and anterior borders. The *interosseous border* is a conspicuous lateral crest in its middle two-fourths. Proximally continuous with the posterior border of a depression distal to the radial notch as the *supinator crest*, it disappears distally. The rounded *anterior border* commences medial to the ulnar tuberosity, descending backwards and

3.188 Transverse section through the left radius and ulna, showing the attachment of the antebrachial interosseous membrane: superior aspect.



3.187 The proximal part of the left ulna: lateral aspect.

usually traceable to the styloid process's base. The *posterior border*, also rounded, descends from the apex of the olecranon's posterior aspect, curving laterally to reach the styloid process. It is *palpable throughout* in a longitudinal furrow most obvious with the elbow in full flexion.



The *anterior surface* (**3**.183), between interosseous and anterior borders, is longitudinally grooved, sometimes deeply. Proximal to its midpoint is a nutrient foramen, directed proximally and containing a branch of the anterior interosseous artery. Distally, it is crossed obliquely by a rough, variable prominence, descending from the interosseous to the anterior border. The *medial surface*, between anterior and posterior borders, is transversely convex and smooth. The *posterior surface* (**3**.184), between posterior and interosseous borders, is divided into three areas, the most proximal limited by a sometimes faint oblique line ascending laterally from the junction of the middle and upper thirds of the posterior border to the posterior end of the radial notch (**3**.187). The region distal to this line is divided into a larger medial and narrower lateral strip by a vertical ridge, usually distinct only in its proximal three-fourths.

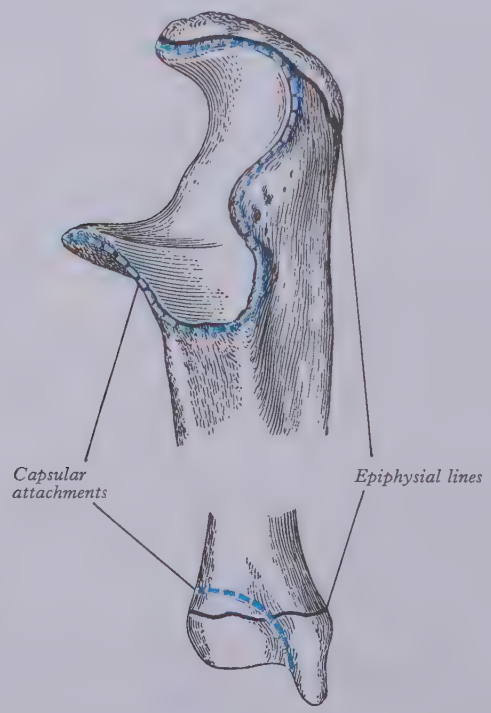
Further details. To the proximal *olecranon* surface, anteriorly, is attached the cubital capsular ligament, and to its rough posterior two-thirds the tendon of triceps; these may be separated by a smooth bursal area. Its medial surface is marked proximally by attachment of the posterior and oblique bands of the the ulnar collateral ligament and ulnar part of the flexor carpi ulnaris. The smooth area distal to this is the most proximal attachment of flexor digitorum profundus. To the lateral olecranon surface, and the adjoining posterior surface of the ulnar shaft as far as its oblique line (**3**.184,187), the anconeus is attached. Its posterior surface is separated from the skin by a subcutaneous bursa.

To the anterior surface of the *coronoid process*, including the ulnar tuberosity, the brachialis is attached. Its medial border is sharp; to a small tubercle at its proximal end are attached oblique and anterior bands of the ulnar collateral ligament and the distal part of the humero-ulnar slip of flexor digitorum superficialis. Distal to this the margin is for the ulnar part of the pronator teres. An ulnar part of the flexor pollicis longus may be attached to the

3.189 The distal ends of the right radius and ulna: distal (inferior) aspect.

3.191 Stages in the ossification of the ulna. The diagram is simplified in relation to the epiphysial ossification of the olecranon, which is held to have two centres (see Porteous 1960 and the description in the text).

lateral or, more rarely, the medial border of the coronoid process (Martin 1958); to its medial surface are attached fibres of the flexor digitorum profundus. To the anterior rim of the radial notch the annular ligament is attached and posteriorly to a ridge at or just behind the notch's posterior margin. The depressed area distal to the notch is limited behind by the *supinator crest*, both providing attachment for the supinator.



The olecranonic area of the *trochlear notch* is usually divided into three areas: the most medial faces ventromedially, and is grooved to fit the medial flange of the humeral trochlea with which it makes increasing contact during flexion; a flat intermediate area fits the lateral flange and the most lateral, a narrow strip, abuts the trochlea but only in extension (p. 504). The articular surface is narrower than the olecranon's base; resulting non-articular parts are related to the synovial processes (4.44). The coronoid area of the trochlear notch is also divided, its medial and lateral areas corresponding to medial and intermediate olecranonic areas. The medial is hollower, conforming to the convex medial trochlear flange (p. 505); to its medial and anterior borders, medial and anterior parts of the capsular ligament are attached.

To the subcutaneous *posterior border* is attached the forearm's deep fascia, which is also, in its proximal three-quarters, an aponeurotic attachment for the flexor digitorum profundus; in its proximal half it is another attachment for the flexor carpi ulnaris and, in its middle third, for the extensor carpi ulnaris. These muscles thus connect with the posterior border through a common blended aponeurosis. To the *interosseous border*, except proximally, is attached the interosseous membrane. To the proximal three-fourths of the *anterior border* the flexor digitorum profundus is attached.

The *anterior surface*, in its proximal three-fourths, is for the flexor digitorum profundus, as are the anterior border and *medial surface*, ascending medial to the coronoid process and olecranon. The rough strip across the distal fourth of the anterior surface is an attachment of the pronator quadratus. The anconeus is attached to the *posterior surface* proximal to the oblique line and lateral to the olecranon. The narrow strip between interosseous border and vertical ridge is for three deep muscles: the abductor pollicis longus from the proximal fourth, and (with a ridge sometimes interposed) from the succeeding fourth for the extensor pollicis longus; the extensor indicis is attached to the third quarter. The broad strip medial to the vertical ridge is merely covered by the extensor carpi ulnaris, whose tendon grooves the posterior aspect of the ulna's distal end. The ulnar collateral ligament is attached to the apex of the *styloid process*.

For an account of ulnar vascularization consult Fischer et al (1974).

Ossification (3.190,191). The ulna ossifies from four main centres, one each in the shaft and distal end and two in the olecranon. Ossification begins in mid-shaft about the eighth fetal week, extending rapidly. In the fifth (females) and sixth (males) years a centre appears in the distal end, extending into the styloid process. The distal olecranon is ossified as an extension from the shaft, the remainder from two centres, one for the proximal trochlear surface, and a thin scale-like proximal epiphysis on its summit (Porteous 1960). The latter appears in the ninth year in females, eleventh in males; the whole proximal epiphysis has joined the shaft by the fourteenth year in females, sixteenth in males. The distal epiphysis unites with the shaft in the seventeenth year in females, eighteenth in males.

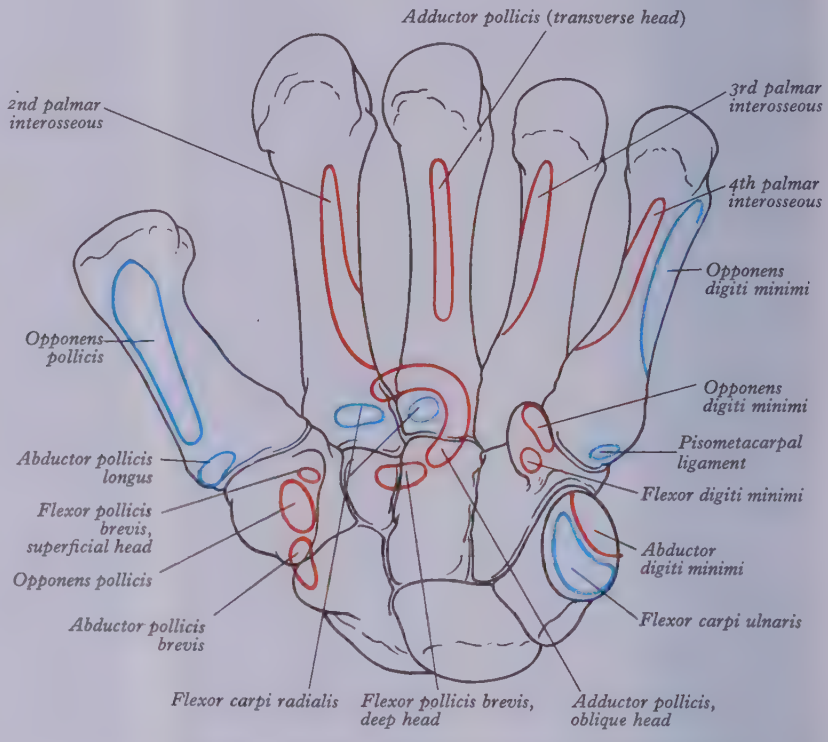
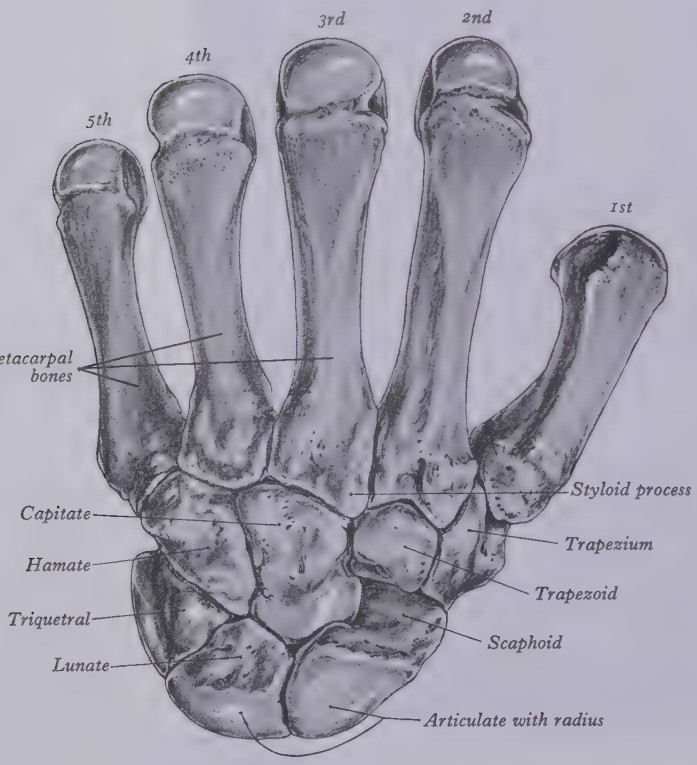
THE SKELETON OF THE HAND

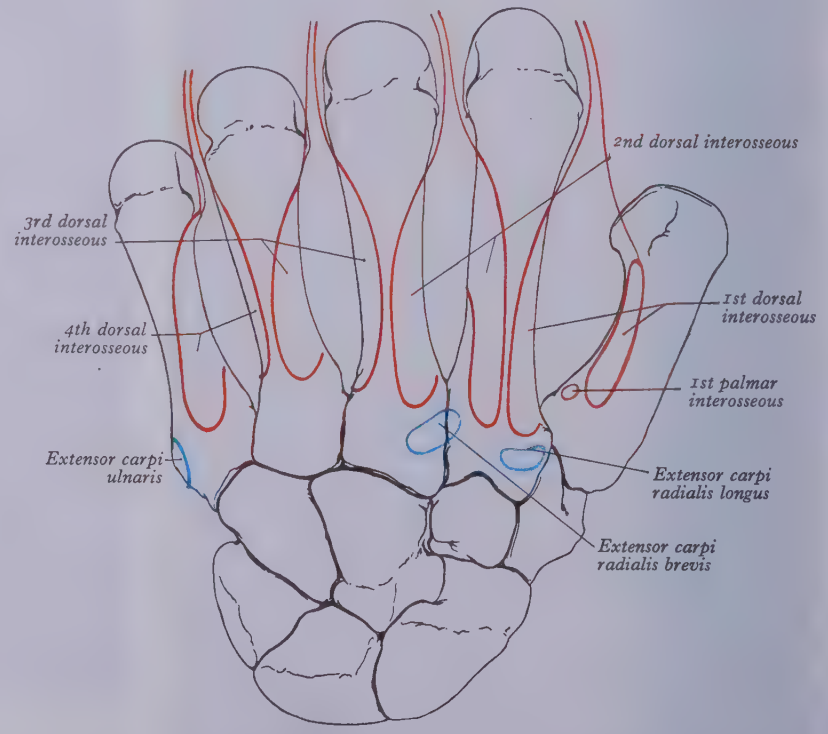


The hand's skeleton has three regions: (1) the carpus, (2) the metacarpus and (3) the phalanges. In the following description *proximal* and *distal* are used in preference to *superior* and *inferior*, and *palmar* and *dorsal*, which are self-explanatory, rather than *anterior* and *posterior*.

The Carpus



General features. The carpus (**3**.194A,B,195A,B) contains eight bones in proximal and distal rows of four. Proximally, in lateral to medial order, are the *scaphoid, lunate, triquetral* and *pisiform*

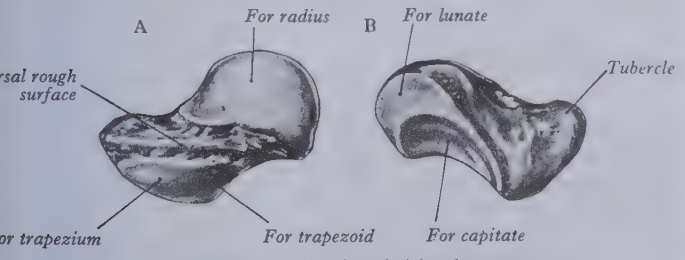


3.194A The carpal and metacarpal bones of the left hand: palmar aspect.

3.194B Muscle attachments to the carpal and metacarpal bones of the left hand: palmar aspect. Dorsal interossei not shown.

3.195A The carpal and metacarpal bones of the left hand: dorsal aspect.

3.195B Muscle attachments to the carpal and metacarpal bones of the left hand: dorsal aspect.



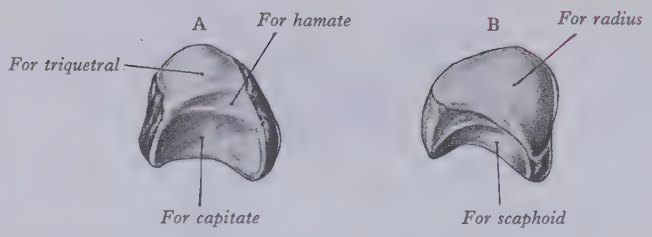
bones; in the distal row are the *trapezium, trapezoid, capitate* and *hamate bones*. The pisiform articulates with the palmar surface of the triquetral, thus separated from other carpal bones, all of which articulate with their neighbours. The other three proximal bones form an arch proximally convex, articulating with the radius and articular disc of the inferior radio-ulnar joint. The arch's concavity is a distal recess embracing, proximally, the projecting aspects of capitate and hamate bones; the two rows are thus mutually and firmly adapted without any loss of movement.

The dorsal carpal surface is convex and the palmar forms a deeply concave *carpal groove*, accentuated by the palmar projection of the lateral and medial borders. The medial projection is formed by the *pisiform bone* and the *hamulus*, an unciform palmar process of the *hamate* bone. The pisiform is at the proximal border of the hypothenar eminence, medial in the palm; it is easily felt in front of the triquetral. The hamulus is concave laterally, its tip palpable 2.5 cm distal to the pisiform, in line with the radial border of the ring finger. The ulnar nerve's superficial division can be rolled on it. The lateral border of the carpal groove is formed by the *tubercles of the scaphoid and trapezium*. The former is distal on the anterior scaphoid surface and palpable, sometimes also visible, as a small medial knob at the proximal border of the palmar thenar eminence, lateral to the tendon of the flexor carpi radialis. The trapezial tubercle is a vertically rounded ridge on the bone's anterior surface, slightly hollow medially and just distal and lateral to the scaphoid tubercle; it is difficult to palpate. (Both the scaphoid and trapezium may be grasped individually and moved passively, by firm pressure between an opposed index finger and thumb applied to the palmar surface and anatomical snuff-box simultaneously.) The carpal groove is made into an osseofibrous *carpal tunnel* by a fibrous retinaculum attached to its margins; the tunnel carries flexor tendons and the median nerve into the hand (see p. 1133). The retinaculum strengthens the carpus and augments flexor efficiency. Palmar and dorsal surfaces of carpal bones, apart from the triquetral and pisiform, are attachments of the radiocarpal, intercarpal and carpometacarpal ligaments.

The Individual Carpal Bones

The Scaphoid Bone

The scaphoid (**3**.196A,B), largest element in the proximal carpal row, has a long axis which is distal, lateral and slightly palmar in direction. Its round tubercle on the distolateral part of its *palmar surface* is directed anterolaterally (**3**.194A), and is an attachment of the flexor retinaculum and abductor pollicis brevis; it is crossed by the tendon of the flexor carpi radialis. The rough *dorsal surface* is slightly grooved, narrower than the palmar, and pierced by small nutrient foramina, often restricted to the distal half (13%) (Obletz & Halbstein 1938), an observation of clinical significance.

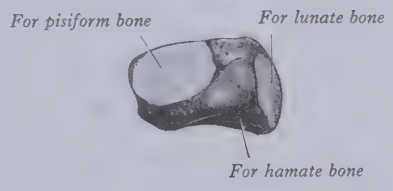


3.196 The left scaphoid bone: (A) dorsal, (B) palmar aspects.

The *lateral surface*, also narrow and rough, has the radial collateral ligament attached to it. The remaining surfaces are articular: the *radial surface* is convex, proximal and directed proximolaterally; the *lunate* surface is flat, semilunar, facing medially; the *capitate* surface is large, concave and distal, directed distomedially. The surface for *trapezium and trapezoid bones* is continuous, convex and distal.

The Lunate Bone

The lunate (**3**.197A,B), approximately semilunar, articulates between the scaphoid and triquetal in the proximal carpal row. Its



3.197 The left lunate bone: A. distomedial; B. proximolateral aspects.

rough *palmar surface*, almost triangular, is larger and wider than the rough *dorsal surface*. Its smooth convex *proximal surface* articulates with the radius and articular disc of the distal radio-ulnar joint. Its narrow *lateral surface* bears a flat semilunar facet for the scaphoid. The *medial surface*, almost square, articulates with the triquetral and is separated from the distal surface by a curved ridge, usually somewhat concave (**3**.197A) for articulation with the edge of the hamate bone in adduction. The *distal surface* is deeply concave to fit the medial part of the capitate's head.

The Triquetral Bone

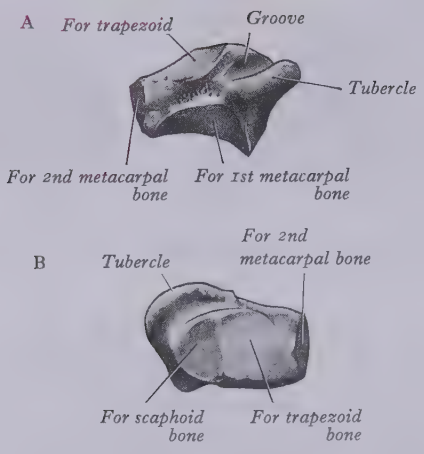
The triquetral (**3**.198), somewhat pyramidal, bears an oval isolated facet for articulation with the pisiform on its distal *palmar* surface. Its *medial* and *dorsal surfaces* are confluent, marked distally by attachment of the ulnar collateral ligament but smooth

3.198 The left triquetral bone: palmar aspect.

proximally for the articular disc of the distal radio-ulnar joint in full adduction. The *hamate surface*, lateral and distal, is concavoconvex, broad proximally, narrow distally. The *lunate surface*, almost square, is proximal and lateral.

The Pisiform Bone

The pisiform (**3**.199), as its name implies, is shaped like a pea, with a dorsal flat articular facet for the triquetral; it has a distolateral long axis. The palmar non-articular area, surrounding and projecting distal to the articular surface, has the tendon of the

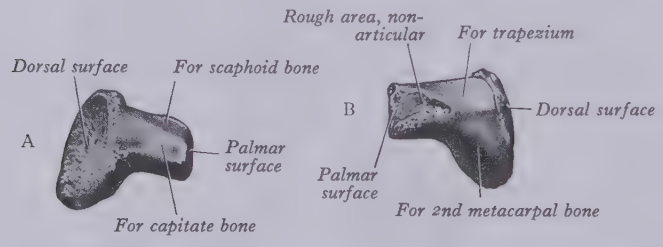


3.199 The left pisiform bone: dorsal aspect.

flexor carpi ulnaris attached to it and also the tendon's distal continuations, the pisometacarpal and pisohamate ligaments. Hence the pisiform has attributes of a sesamoid bone (see p. 457), which it almost certainly is, being unrepresented in primitive carpalia (p. 400).

The Os Trapezium

The os trapezium (**3**.200A,B) has a tubercle and groove on its rough *palmar surface*. The groove is medial and contains the tendon of the flexor carpi radialis; to its margins are attached two layers of the flexor retinaculum (**5**.73 and p. 625). The *tubercle* is obscured by attached thenar muscles, opponens pollicis between flexor pollicis brevis distally and abductor pollicis brevis proximally (**3**.194B). The elongate, rough *dorsal surface* is related to the radial artery. The large *lateral surface* is rough for attachment of the radial collateral ligament and capsular ligament of the pollicial carpometacarpal joint. A large *sellar surface* faces disto-laterally

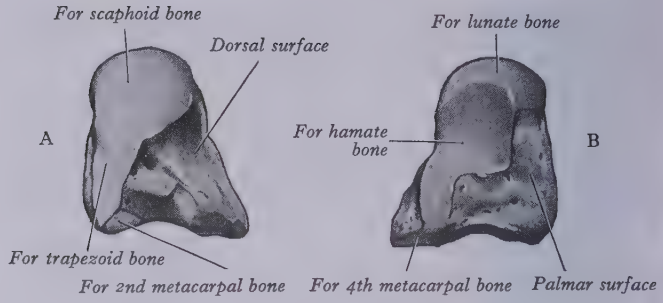


3.200 The left trapezium: A. palmar; B. proximomedial aspect.

for the base of the pollicial metacarpal bone. Most distally it projects between bases of the first and second metacarpal bones and carries a small, quadrilateral, distomedially directed facet articulating with the second metacarpal base. The large medial surface is gently concave for articulation with the trapezoid. The proximal surface is a small, slightly concave facet for the scaphoid. Due to its contribution to mobility of the pollex, the metacarpal articular surface has attracted much attention. Its ridge or 'summit', fitting the concavity of the first metacarpal base, extends in a palmar and lateral direction, at an angle of about 60° with the plane of the second and third metacarpals (Kuczynski 1974, p. 514 and 634). Abduction and adduction occur in the plane of the ridge, which is shorter than the corresponding metacarpal groove; contours of both vary reciprocally, being more curved near the second metacarpal base, with a longer radius of curvature away from this. The two surfaces are not completely congruent, the area of close contact probably moving towards the palm in adduction and dorsally in abduction (see p. 514).

The Trapezoid Bone

The trapezoid (3.201A,B), small and irregular, has a rough *palmar surface* narrower and smaller than its rough *dorsal surface*, the former invading the lateral aspect. The *distal surface*, articulating

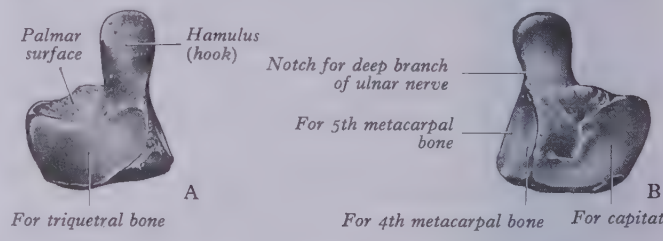


3.201 The left trapezoid bone: A. proximomedial; B. distolateral aspects.

with the grooved second metacarpal base, is triangular, convex transversely and concave at right angles to this. The *medial surface* articulates, by a concave facet, with the distal part of the capitate, the *lateral surface* with the trapezium and the *proximal* with the scaphoid bone.

The Capitate Bone

The capitate (3.202A,B), the central and largest carpal bone, articulates with the third metacarpal base, its triangular *distal surface* concavoconvex for this. Its lateral border is a concave strip for the medial side of the second metacarpal base; its dorsomedial angle usually bears a facet for the fourth metacarpal base. The *head* projects into the concavity formed by the lunate and scaphoid bones, its *proximal surface* articulating with the lunate and the *lateral* with the scaphoid. The scaphoid and trapezoidal facets, usually continuous on the distolateral surface, may be separated by a rough interval. The *medial surface* has a large facet



3.202 The left capitate bone: A. lateral; B. medial aspects.

for the hamate, deeper proximally where it is partly non-articular. *Palmar* and *dorsal surfaces* are roughened for carpal ligaments; the dorsal is larger.

The Hamate Bone

The hamate (3.203A,B) is cuneiform with an unciform *hamulus* projecting from the distal part of its rough *palmar surface;* the hamulus is curved with a lateral concavity and its tip inclines laterally contributing to the medial wall of the carpal tunnel. To the hamular apex is attached the flexor retinaculum. Distally, on the hamular base, a slight transverse groove may be in contact with the ulnar nerve's terminal deep branch. The remaining *palmar surface*, like the *dorsal*, is rough for ligaments. A faint ridge divides the *distal surface* into a smaller lateral facet articulating

3.203 The left hamate bone: A. medial; B. lateral aspects.

with the fourth metacarpal base and a medial facet for the fifth. The *proximal surface*, the thin margin of the wedge, usually bears a narrow facet contacting the lunate in adduction. The *medial surface* is a broad strip, convex proximally, concave distally, articulating with the triquetral; distally a narrow medial strip is non-articular. The *lateral surface* articulates with the capitate by a facet covering all but its distal palmar angle.

The Metacarpus

The metacarpus (Singh 1959) consists of five metacarpal bones, conventionally numbered in lateromedial order. These are miniature long bones, with a distal head, shaft and expanded base. The rounded *heads* articulate with the proximal phalanges. Their articular surfaces are convex, less so transversely, and extend further on palmar surfaces, especially at their margins. The familiar knuckles are produced by metacarpal heads. The metacarpal bases articulate with the distal carpal row and with each other, excepting the first and second. The *shafts* have longitudinally concave palmar surfaces, forming hollows for palmar muscles. Their dorsal surfaces have a distal triangular area, continued proximally as a round ridge. These flat areas are palpable proximal to the knuckles.

The *medial four metacarpal bones* are sometimes described as parallel; strictly they diverge somewhat, radiating gently proximodistally. However, *the first metacarpal*, relative to the others, is more anterior and *rotated medially* on its axis through a right angle, so that its morphologically *dorsal* surface is *lateral*, its radial border palmar, its palmar surface medial and its ulnar border dorsal. Hence the pollex flexes medially across the palm and

can be rotated into opposition with each finger. Such opposition depends on medial rotation and is the prime factor in manual dexterity; when an object is grasped, fingers and thumb encircle it from opposite sides, greatly increasing the power and skill of the grip. Lewis (1977) has made an extended study of human metacarpals and their articulations with the carpus and phalanges, in an explanation of evolving human skills.

Individual Metacarpal Bones

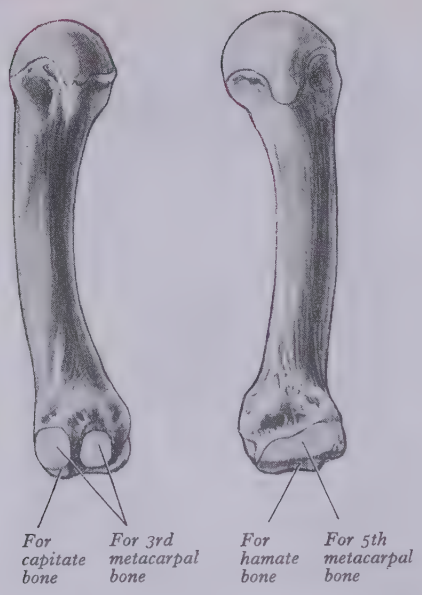
The first metacarpal bone (3.204) is short and thick. (Caution should be exercised when considering descriptions of this bone; here, morphological terms are used supplemented, in places, by their topographical equivalents.) Its dorsal (lateral) surface can be felt to face laterally; its long axis diverges distolaterally from its neighbour. The *shaft* is flattened, dorsally broad and transversely convex. The palmar (medial) surface is concave in long axis and divided by a ridge into a larger lateral (ventral) and smaller medial

3.204 The first right metacarpal bone: palmar and lateral aspects.

(dorsal) part. Opponens pollicis is attached to the radial border and adjoining palmar surface, the first dorsal interosseous muscle (radial head) is attached to its ulnar border and adjacent palmar surface. The *base* is concavoconvex and articulates with the trapezium (p. 514). On its lateral (palmar) side abductor pollicis longus is attached, to its ulnar side the first palmar interosseous muscle (p. 632). The *head* is less convex than in other metacarpals and contrasts in being transversely broad. On its palmar aspect ulnar and radial angles form two articular eminences, on which glide sesamoid bones.

The second metacarpal bone (3.205) has the longest shaft and largest *base*, which is grooved in dorsopalmar direction for the trapezoid bone; medial to the groove a deep ridge articulates with the capitate bone; laterally, nearer the base's dorsal surface, is a quadrilateral trapezial facet, and just dorsal to this a rough impression marks attachment of the extensor carpi radialis longus. On the palmar surface a small tubercle or ridge receives flexor carpi radialis. The base's medial side articulates with the third metacarpal base by a long facet, centrally narrowed. The *shaft* is prismatic in section and longitudinally curved, convex dorsally, concave towards the palm. Its dorsal surface is distally broad but proximally narrows to a ridge and is covered by extensor tendons of the index finger; its converging borders begin at the tubercles, one on each side of its head for the attachment of collateral ligaments (p. 515). Proximally the *lateral surface* inclines dorsally for the ulnar head of the first dorsal interosseous muscle. The *medial surface*, inclining similarly, is divided by a faint ridge into a palmar strip for the second palmar interosseous and a dorsal for the radial head of the second dorsal interosseous muscle.

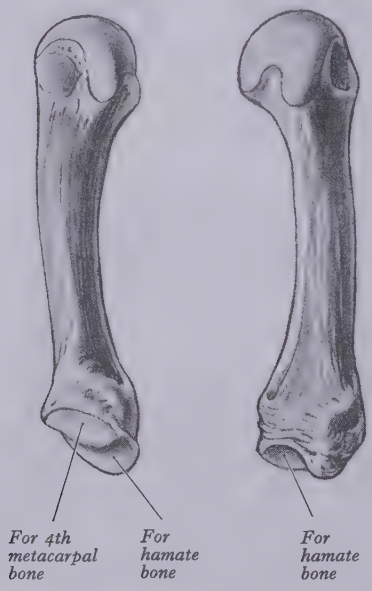
The third metacarpal bone (3.206) has a short *styloid process*, projecting proximally from the radial side of the dorsal



3.205 The left second metacarpal bone: dorsolateral and medial aspects.

surface. Its *base* articulates with the capitate bone by a facet ventrally convex but dorsally concave where it invades the styloid process on the lateral aspect of its base. A strip-like facet, constricted centrally, articulates with the second metacarpal base (laterally) and the fourth metacarpal base (medially), the latter by two oval facets. The palmar facet may be absent; less frequently the facets are connected proximally by a narrow bridge. The base's palmar surface receives a slip from the flexor carpi radialis tendon; to its dorsal surface, beyond the styloid process, extensor carpi radialis brevis is attached. The *shaft* resembles that of the second metacarpal. To its lateral surface the ulnar head of the second dorsal interosseous muscle is attached, to its medial surface the radial head of the third dorsal interosseous and to the intervening palmar ridge in its distal two-thirds the transverse

3.206 The left third metacarpal bone: lateral and medial aspects.

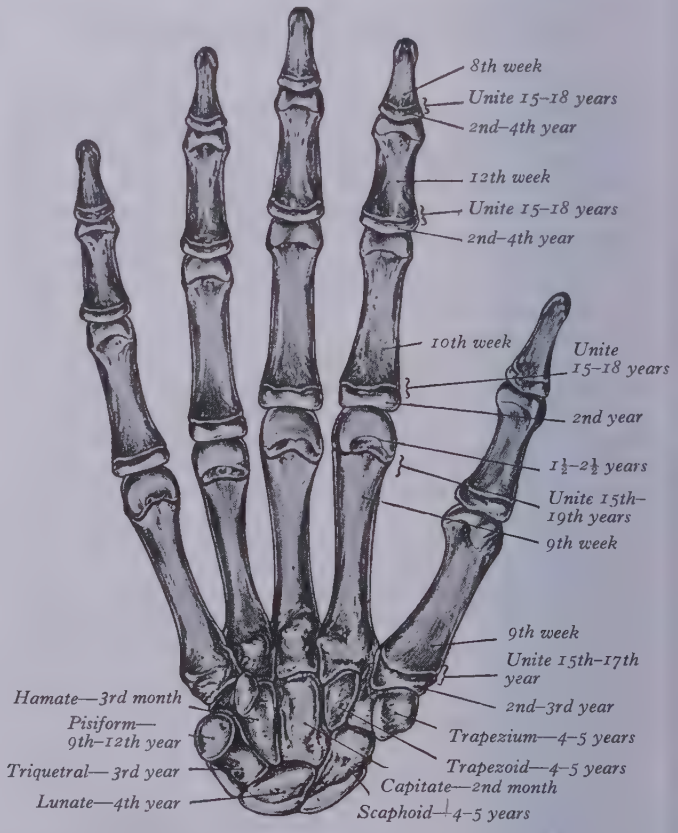


3.207 The left fourth metacarpal bone: lateral and medial aspects.

head of adductor pollicis. Its dorsal surface is covered by the extensor tendon.

The fourth metacarpal bone (3.207), shorter and thinner than second and third, displays on its *base* two lateral oval facets for the third metacarpal base (vide supra), the dorsal usually larger and proximally in contact with the capitate. A single medial elongate facet is for the fifth metacarpal base. The proximal, quadrangular surface articulates with the hamate bone, being ventrally convex, dorsally concave. The *shaft* is like the second, but a faint ridge on its lateral surface separates attachments of the third palmar interosseous and the ulnar head of the third dorsal interosseous muscles. To the medial surface the radial head of the fourth dorsal interosseous is attached.

The fifth metacarpal bone (3.208) differs in its medial basal surface, which is non-articular and bears a tubercle for extensor carpi ulnaris. The lateral basal surface is a facet, transversely concave, convex from palm to dorsum, for articulation with the hamate. A lateral strip articulates with the fourth metacarpal base. The *shaft* has a triangular dorsal area almost reaching the base; the lateral surface inclines dorsally only at its proximal end. To the medial surface opponens digiti minimi is attached; the lateral is divided by a ridge, sometimes sharp, into a palmar strip for the fourth palmar interosseous and a dorsal strip for the ulnar part of the fourth dorsal interosseous.



3.208 The left fifth metacarpal bone: lateral and medial aspects.

The Phalanges of the Hand

There are 14 phalanges, three in each finger, two in the pollex. Each has a head, shaft and proximal base. The *shaft* tapers distally, its dorsal surface transversely convex. The palmar surface is transversely flat but gently concave ventrally in its long axis. *Bases* of *proximal phalanges* carry concave, oval facets adapted to metacarpal heads, their own heads smoothly grooved like pulleys and encroaching more on palmar surfaces. Conforming to this, *bases* of *middle phalanges* carry *two* concave facets separated by a smooth ridge. Middle phalangeal *heads* are also pulley-like, to which the bases of distal phalanges are adapted; the latter's own heads are non-articular but carry a rough, crescentric *palmar tuberosity*, to which the pulps of finger tips are attached.

In addition to articular ligaments, phalanges afford attachment to numerous muscles: to the base of a distal phalanx on its palmar surface a corresponding tendon of flexor digitorum profundus and, on its dorsal surface, extensor digitorum; to the sides of a middle phalanx a tendon of flexor digitorum superficialis (p. 617) and its fibrous sheath; to the base dorsally, a part of extensor digitorum. To the sides of a proximal phalanx a fibrous flexor sheath is attached; to its base, laterally, part of the corresponding dorsal interosseous, and, medially, another dorsal interosseous muscle are attached (p. 631).

Phalanges of the minimus and pollex differ: attached to the medial side of the base of the former's proximal phalanx are abductor and flexor digiti minimi; to the base of the proximal pollicial phalanx are attached, dorsally, the tendon of extensor pollicis brevis and the oblique head of adductor pollicis and, medially, oblique and transverse heads of the adductor, sometimes conjoined with the first palmar interosseous (p. 631).

3.209 The bones of the hand of a child, indicating the general plan of ossification.

Margins of the proximal pollicial phalanx are not sharp, the fibrous sheath being less strongly developed than in other digits.

Ossification of the Bones in the Hand (3.209–213)

Carpal bones are cartilaginous at birth, but ossification may have started by then in the capitate and hamate. Each carpal is ossified from one centre, capitate first, pisiform last; but the order in others varies. The capitate begins to ossify in the second *month*, the hamate at the end of the third, triquetral in the third *year*, lunate during the fourth and scaphoid, trapezium and trapezoid in the fourth in females, fifth in males; the pisiform begins in the ninth or tenth year in females, twelfth in males. The order varies according to sex (Garn & Rohmann 1960), nutrition and, possibly, race (Shakir & Zaini 1974, Wingerd et al 1974). Occasionally an *os centrale* (p. 400) occurs between the scaphoid, trapezoid and capitate bones; during the second prenatal month it is a cartilaginous nodule usually fusing with the scaphoid. Sometimes the styloid process of the third metacarpal is a separate ossicle. Occasionally, lunate and triquetral elements may fuse; other fusions and accessory ossicles have also been described (O'Rahilly 1953, 1956).

Each **metacarpal bone** ossifies from a primary centre for the shaft and a secondary in the *base* of the first and *heads* of the other four. Ossification begins in mid-shaft about the ninth week. Centres for second to fifth metacarpal heads appear in that order in the second year in females, and between one and a half to two and a half years in males. They unite with shafts about the fifteenth or sixteenth year in females, eighteenth or nineteenth in males. The first metacarpal base begins late in the second year in females, early in the third in males; it unites before the fifteenth year in females, seventeenth in males (Joseph 1951). For wider assessments of range of variability consult Modi (1957) and Krogman (1962).

The pollicial metacarpal bone ossifies like a phalanx; some therefore consider the pollicial skeleton to consist of three *phalanges*; others believe the distal to represent fused middle and distal phalanges, a condition occasionally observed in the fifth toe (Broom 1930). (When the pollex has *three* phalanges, the metacarpal has a distal *and* a proximal epiphysis. It occasionally bifurcates distally, the medial branch, with no distal epiphysis, bearing *two* phalanges, the lateral showing a distal epiphysis, and *three* phalanges—Nicholson 1937.) The existence of only a *distal* metacarpal epiphysis may be associated with a greater range of movement at the metacarpophalangeal joint. In the pollex, it is the carpometacarpal joint which has the wider range, and a *basal* epiphysis in the first metacarpal may be attributable to this. However, a distal epiphysis may appear in the first, and a proximal in the second metacarpal.

Growth studies of 1700 children, aged one to 18 years, favour the view of the pollicial metacarpal as a proximal phalanx (as first suggested by Vesalius in 1543). But this ignores the observations that the so-called distal epiphysis of the first metacarpal is usually (if not always) a diaphysial prolongation into terminal cartilage, rather than a separate centre. A review of the data concerning such 'pseudo-epiphyses' corroborates this description (Haines 1974).

Phalanges are ossified from a primary centre for the shaft and a proximal epiphysial centre. Ossification begins prenatally in shafts as follows: distal phalanges in the eighth or ninth week, proximal phalanges in the tenth, middle phalanges in the eleventh

3.210 Radiograph of a hand at 2½ years (male). Note early stages of ossification in epiphyses at proximal ends of phalanges and first metacarpal, at distal ends of remaining metacarpals and radius and in the capitate, hamate and lunate bones. The last is more usually preceded by the centre for the triquetral. Compare with 3.211-213.

3.211 Radiograph of a hand at 6½ years (male). Note the more advanced state of the centres of ossification already visible in 3.210, and additional centres in the distal ulnar epiphysis and in the triquetral, scaphoid, trapezium and trapezoid carpal bones.

3.212 Radiograph of a hand at 11 years (female). Note the maturing shapes of all the ossifications previously seen in 3.210 and 3.211, with the addition of the pisiform bone.

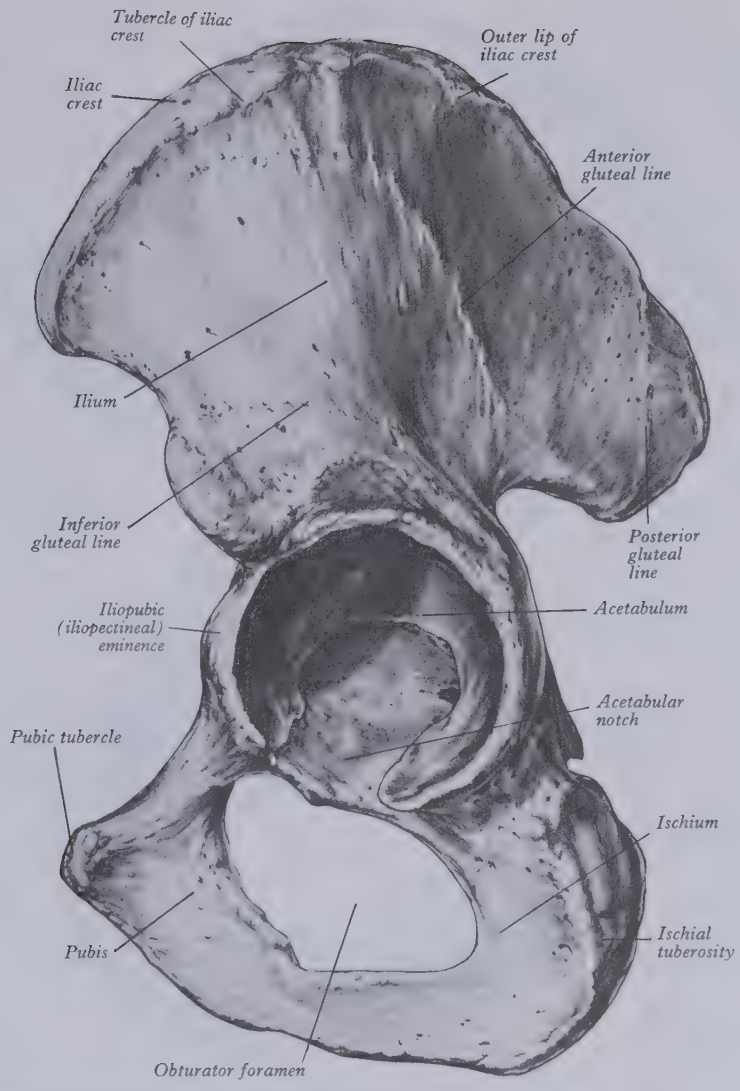
3.213 Radiograph of adult hand for comparison (male of 19 years). Note additional ossification in the sesamoid bones of the thumb.

week or later. Epiphysial centres appear in proximal phalanges early in the second year (females), and in its later months (males); in middle and distal phalanges in the second year (females), third or fourth (males). All epiphyses unite about the fifteenth to sixteenth year in females, seventeenth to eighteenth in males.

Applied anatomy. The scaphoid is the most frequently fractured carpal bone, the fracture usually crossing the long axis. Fractures of its proximal part or its 'waist' may fail to unite, possibly because the proximal fragment, devoid of nutrient foramina in about 13% (p. 417), has lost its blood supply. Ventral dislocation of the lunate bone is often associated with scaphoid fracture. The displaced lunate may compress the median nerve against the flexor retinaculum.

THE SKELETON OF THE LOWER LIMB

The Innominate Bone



The innominate or hip bone (3.214A,B,215A,B) is large, irregular, constricted centrally and expanded above and below. Its *lateral surface* has a deep, cup-shaped *acetabulum*, articulating with the femoral head. Distal (antero-inferior) to this is the large, oval or triangular *obturator foramen*. Above the acetabulum the bone widens into a plate with a sinuously curved *iliac crest*.

The bone articulates in front with its fellow, to form the pelvic girdle (p. 399). Each has three parts, **ilium, ischium** and **pubis**, connected by cartilage in youth but united as one bone in adults, the principal union being in the acetabulum (3.214B,215B). The *ilium* includes the upper acetabulum and expanded area above it; the *ischium* includes the lower acetabulum and bone postero-inferior to it; the *pubis* forms the anterior acetabulum, separating ilium from ischium, and the anterior median region where the pubes meet.

The Ilium

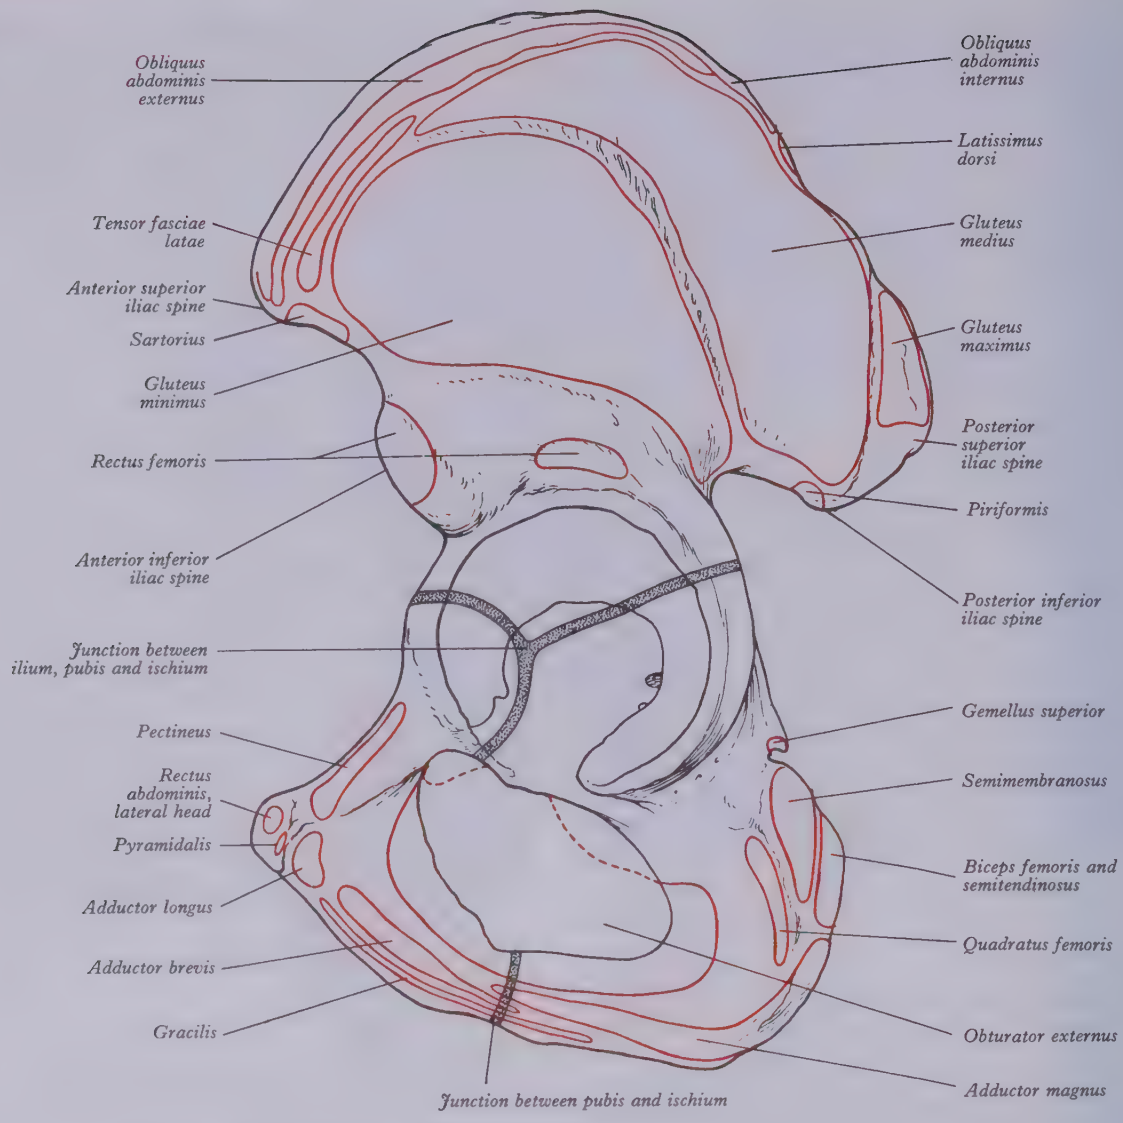
The ilium, so named because it supports the *flank*, may be described as having upper and lower parts and three surfaces. The smaller, lower part forms a little less than the upper two-fifths of the acetabulum, the upper part being much expanded, with gluteal, sacropelvic and iliac (internal) surfaces. The *gluteal surface*, posterolateral, is an extensive rough area; the anteromedial *iliac fossa* is smooth and concave; the *sacropelvic surface* is medial and is postero-inferior to the fossa, separated from it by the *medial border*.

The iliac crest, the ilium's superior border, is convex upwards but sinuously curved, internally concave in front, the reverse behind. Its ends project as anterior and posterior superior iliac spines. The *anterior superior iliac spine* is palpable at the lateral end of the inguinal fold; the *posterior superior iliac spine* is not palpable but often indicated by a dimple, about 4 cm lateral to the second sacral spine above the medial gluteal region (buttock). The crest has ventral and dorsal segments: the ventral is slightly more than the anterior two-thirds of the crest and its prominence is associated with changes in iliac form due to the emergence of the upright habit; the dorsal segment, about the posterior third in mankind, exists in all land vertebrates. The iliac crest's ventral segment has internal and external lips, the rough intermediate zone being narrowest centrally. The *tubercle of the crest* (3.214A) projects on the outer lip about 5 cm dorsosuperior to the anterior

3.214A The left innominate bone: lateral (external) aspect. Compare with Key, **3.214B**.

superior spine. The dorsal segment has two sloping surfaces separated by a longitudinal ridge ending at the posterior superior spine. The crest's *summit*, a little behind its midpoint, is level with the interval between the third and fourth lumbar spines. The lower part of the ilium will be described with the acetabulum (p. 428).

The *iliac anterior border* descends to the acetabulum from the anterior superior spine. Superiorly it is concave forwards; inferiorly is a rough *anterior inferior iliac spine*, immediately above the acetabulum.



The *iliac posterior border*, irregularly curved (**3.215A,B**), descends from the posterior superior spine at first forwards, with a dorsal concavity forming a small notch. At the lower end of the notch is a wide, low projection, the *posterior inferior iliac spine*; here the border turns almost horizontally forwards for about 3 cm and finally down and back to join the posterior ischial border. Together they form a deep *greater sciatic notch*, bounded above by ilium, below by ilium and ischium (**3.215B**).

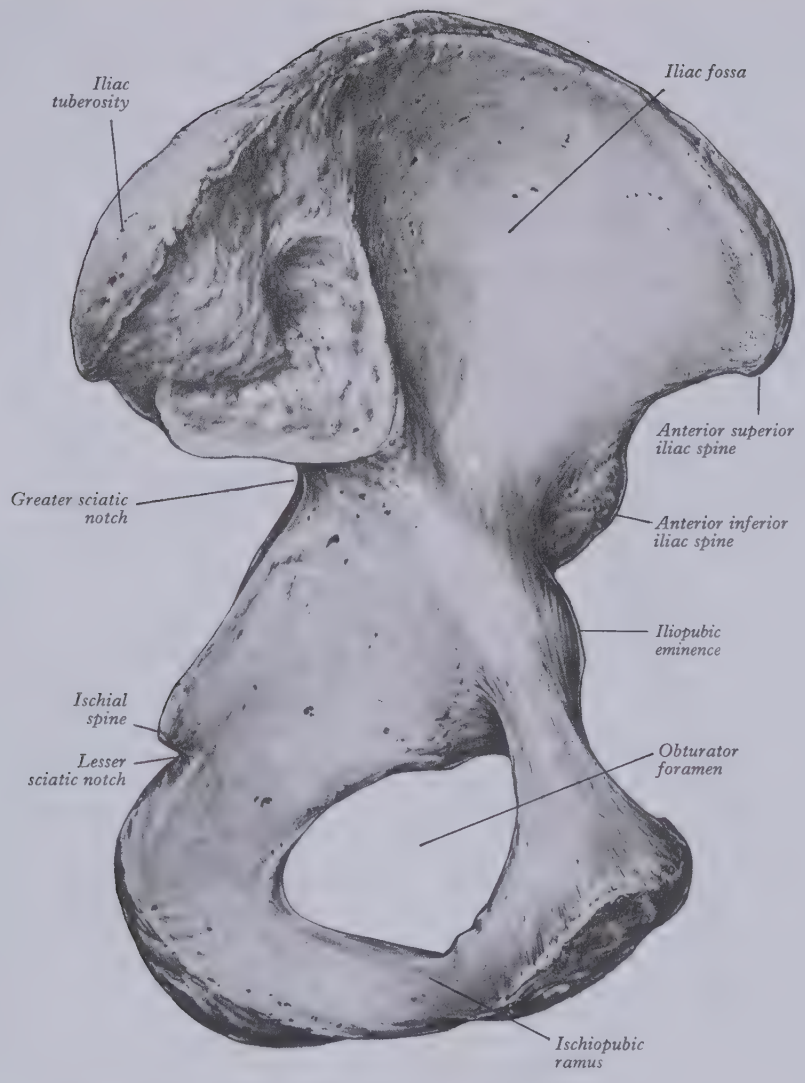
The *iliac medial border*, separating the iliac fossa and the sacropelvic surface, is indistinct near the crest, rough in its upper part, then sharp where it bounds an articular surface for the sacrum, and finally rounded. The latter part is the *arcuate line*, which inferiorly reaches the posterior part of the *iliopubic (iliopectineal) eminence*, marking the union of ilium and pubis.

The gluteal surface (**3.214A,B**), facing inferiorly in its dorsal part, laterally and slightly downwards in front, is bounded above by the iliac crest, below by the upper acetabular border and by anterior and posterior borders. It is rough and curved, convex in front, concave behind, and marked by three gluteal lines. The *posterior gluteal line* is shortest, descending from the external lip of the crest about 5 cm in front of its posterior limit and ending in front of the posterior inferior spine. Above, it is usually distinct, but inferiorly ill-defined and frequently absent. The *anterior gluteal line*, the longest, begins near the midpoint of the superior margin of the greater sciatic notch and ascends forwards into the crest's outer lip, a little anterior to its tubercle. The *inferior gluteal line*, rarely well-marked, begins posterosuperior to the anterior inferior spine, curving back and downwards to end near the apex of the greater sciatic notch. Between the inferior gluteal line and the acetabular margin is a rough, shallow groove. Behind the acetabulum the lower gluteal surface is continuous with the posterior ischial surface, the union marked by a low elevation.

The iliac fossa, the internal concavity of the ilium, facing anterosuperior, is limited above by iliac crest, in front by the anterior border, behind by the medial border, separating it from the sacropelvic surface. It forms the smooth and gently concave posterolateral wall of the greater pelvis. Below it is continuous with a wide shallow groove (**3.215A**), which is bounded laterally by the anterior inferior spine and medially by the iliopubic eminence.

The sacropelvic surface (**3.215A**), the postero-inferior part of the medial iliac aspect, is bounded postero-inferiorly by the posterior border, anterosuperiorly by the medial border, posterosuperiorly by the iliac crest and antero-inferiorly by the line of fusion of ilium to ischium. It is divided into iliac tuberosity,

3.214B Key to 3.214A the stippled bands indicate the limits of the iliac, pubic and ischial parts of the bone.



auricular and pelvic surfaces. The *iliac tuberosity*, a large, rough area below the dorsal segment of the iliac crest, shows cranial and caudal areas separated by an oblique ridge and connected to the sacrum by the interosseous sacroiliac ligament. The *auricular surface* (3.215A,B), immediately antero-inferior to the tuberosity, articulates with the lateral sacral mass. Shaped like an ear, its widest part is anterosuperior, its 'lobule' postero-inferior and on the medial aspect of the posterior inferior spine. Its edges are well-defined, but the surface, though articular, is rough and irregular. The *pelvic surface* is antero-inferior to the acutely recurved part of the auricular surface, contributing to the lateral wall of the lesser pelvis. Its upper part, facing down, is between the auricular surface and the upper limb of the greater sciatic notch; its lower region faces medially and is separated from iliac fossa by the arcuate line. Antero-inferiorly it extends to the line of union of ilium with ischium; this is usually obliterated, but passes from the depth of the acetabulum to, roughly, the middle of the inferior limb of the greater sciatic notch.

Further details. The iliac crest, approximating to the lower limit of the waist, is an attachment for lateral abdominal and dorsal muscles, fasciae and muscles of the lower limb (3.214B,215B). To the *outer lip* and *tubercle* of its ventral segment (p. 422) the fascia lata and iliotibial tract are attached, anterior to its tubercle tensor fasciae latae; to its anterior two-thirds, the lower fibres of the external oblique and, just behind its summit, lowest fibres of latissimus dorsi. A variable interval exists between the most posterior attachment of external oblique and most anterior attachment of latissimus dorsi, and here the crest is the base of the lumbar triangle. The crest's *intermediate area* receives the internal oblique. To the anterior two-thirds of its *inner lip* transversus abdominis is attached, and behind this the lumbodorsal fascia and quadratus lumborum. To the crest's dorsal segment (p. 422), on its lateral slope, the highest fibres of gluteus maximus are attached; from its medial slope erector spinae and, along its medial margin, interosseous and dorsal sacro-iliac ligaments arise.

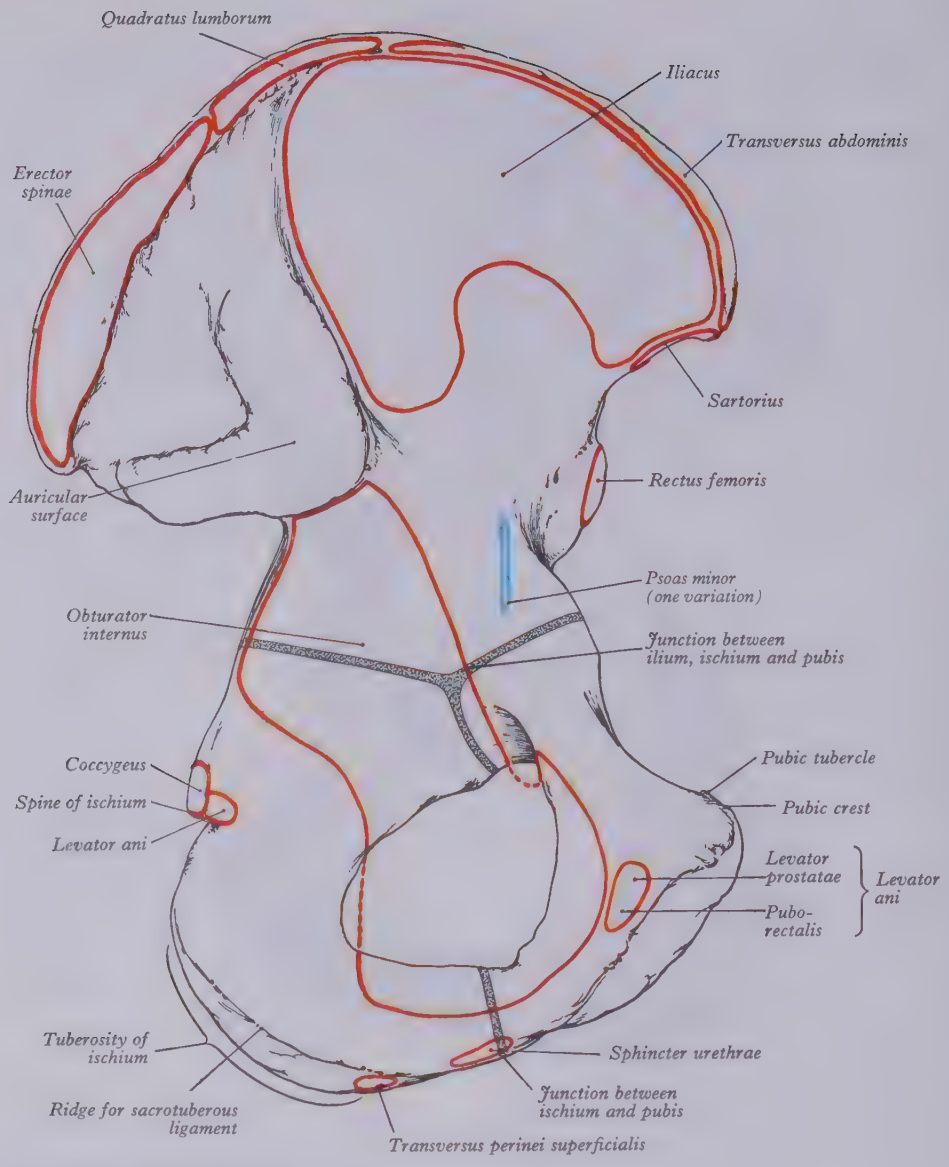
To the **anterior superior spine** is attached the lateral end of the inguinal ligament and, below it, the sartorius extends down the *anterior border*. The **anterior inferior spine** is divided indistinctly into an upper area for the straight part of rectus femoris and a lower area extending laterally along the upper acetabular margin to form a triangular impression for the iliofemoral ligament.

To the upper part of the **posterior border** upper fibres of the sacrotuberous ligament are attached and in front of the posterior inferior spine (i.e. on the upper border of the greater sciatic notch) fibres of piriformis. The superior rim of the notch is related to superior gluteal vessels and nerve. The lower part of the border (i.e. the lower margin of the greater sciatic notch) is covered by piriformis and related to the sciatic nerve, which, however, largely adjoins the ischium.

The gluteal surface is divided by the three gluteal lines into four areas (3.214A,B): (*a*) behind the posterior line, its upper

3.215A The left innominate bone: medial (internal) surface. Compare with Key, **3**.215B.

rough part being for upper fibres of the gluteus maximus and its lower, smooth region for part of the sacrotuberous ligament and iliac head of the piriformis; (*b*) between posterior and anterior lines, below the iliac crest, for the gluteus medius; (*c*) between anterior and inferior lines for the gluteus minimus; (*d*) below the inferior line, where there are many vascular foramina. Attached to a curved groove above the acetabulum is attached the reflected head of the rectus femoris and to an area adjoining the acetabular rim is the articular capsule; most of this area is covered by gluteus minimus. Postero-inferiorly, near the union of ilium and ischium, the bone is related to the piriformis. The vascular foramina on the iliac gluteal aspect may lead into large vascular canals in the bone (Sirang 1973).



The iliac fossa, in its upper two-thirds, provides attachment for the iliacus (**3**.215B), also related to the lower third; branches of the iliolumbar artery run between muscle and bone, one entering a large nutrient foramen often postero-inferior in the fossa. The wide groove between the anterior inferior spine and iliopubic eminence is occupied by converging fibres of iliacus laterally and the tendon of psoas major medially, the tendon separated from bone by a bursa. The right iliac fossa contains the caecum, and often the vermiform appendix and terminal ileum; the left one houses the end of the descending colon.

The iliac tuberosity (sacropelvic surface) gives attachment to dorsal sacroiliac ligaments and, behind the auricular surface, the interosseous sacroiliac ligament. To its anterior part is attached the iliolumbar ligament and above this is the medial part of the quadratus lumborum. **The auricular surface** articulates with the sacrum and is reciprocally shaped (p. 516). To its sharp anterior and inferior borders the ventral sacroiliac ligament is attached. The narrow part of the **pelvic surface**, between the auricular surface and the upper rim of the greater sciatic notch, often shows a rough *preauricular sulcus* for the lower fibres of the ventral sacro-iliac ligament, more apparent in females. However, its unreliability in determination of sex was shown in a study of 237 Indian pelves (Jit & Gandhi 1966), but consult also Finnegan & Faust (1974) and Finnegan (1978). Lateral to the sulcus, piriformis is sometimes, in part, attached and, to the more extensive remainder of the pelvic surface, is attached part of the obturator internus (**3**.215B).

The Pubis

The pubis is the ventral part of the innominate bone and forms a median cartilaginous *pubic symphysis* with its fellow. From its anteromedial body a superior ramus passes up and back to the acetabulum and an inferior ramus passes back, down and laterally to join the ischial ramus inferomedial to the obturator foramen.

The body, dorsoventrally compressed, has anterior, posterior and symphysial (medial) surfaces and an upper border, the *pubic crest*. The *anterior surface* also faces *inferolaterally*; it is rough superomedially and elsewhere smooth, affording attachment for medial femoral muscles. The smooth *posterior surface* faces

3.215B Key to **3.215A** the stippled bands indicate the limits of the iliac, pubic and ischial parts of the bone.

upwards and backwards as the oblique anterior wall of the minor pelvis and is related to the urinary bladder. The *symphysial surface* is elongate and oval, united by cartilage to its fellow at the pubic symphysis. Denuded of cartilage it has, in the elderly, an irregular surface of small ridges and furrows or nodular elevations, varying much with age (Todd 1920, 1921, Brooks 1955, McKern & Stewart 1957, Suchey et al 1979), features of obvious forensic value. Pal & Tamankar (1983), in a series of 60 male and 60 female pubes of Northern Indians, aged from 14 to 60 years, found that accepted data gave inaccurate values, some 'over-ageing' their specimens, some the reverse. The *pubic crest* is the rounded upper border of the body, which overhangs the anterior surface (**3.214A**), its lateral end the rounded *pubic tubercle*. Both crest and tubercle are palpable, the latter partly obscured in males by the spermatic cord, crossing above it from scrotum to abdomen. The *pubic rami* diverge posterolaterally from the lateral corners of the body.

The superior pubic ramus passes upwards, backwards and laterally from the body, superolateral to the obturator foramen to reach the acetabulum. Triangular in section, it has three surfaces and borders. Its anterior, *pectineal surface*, tilted slightly up, is triangular in outline and extends from the pubic tubercle to the iliopubic eminence (**3.215A**). It is bounded in front by the rounded *obturator crest* and behind by the sharp *pecten pubis (pectineal line)* which, with the crest, is the pubic part of the *linea terminalis* (i.e. anterior part of pelvic brim). The dorsosuperior, *pelvic surface*, medially inclined, is smooth and narrows into the posterior surface of the body, bounded above by the pecten pubis and below by a sharp *inferior border*. The *obturator surface*, directed down and back, is crossed by the *obturator groove* sloping down and forwards; its limit in front is the *obturator crest* and, behind, the inferior border.

The inferior pubic ramus, an inferolateral process of the body, descends inferolaterally to join the ischial ramus medial to, and below, the obturator foramen. The union may be locally thickened, but not obviously so in adults. The ramus has two surfaces and borders. The *antero-external surface*, continuous above with that of the pubic body, faces the thigh and is marked by muscles, its lateral limit being the margin of the obturator foramen and, medially, the rough anterior border. The *postero-internal surface* is continuous above with that of the body and transversely convex, its medial part often everted in males (**3.223**) and connected to the crus penis. This surface faces the perineum medially, its smooth lateral part tilted up towards pelvic cavity.

The pubic tubercle is a medial attachment of the inguinal ligament in the floor of the superficial inguinal ring and is crossed by the spermatic cord; ascending loops of cremaster are also attached to it. Lateral on the **pubic crest** are attached the lateral

part of the rectus abdominis and, below it, the pyramidalis. Medially the crest is crossed by the medial part of the rectus abdominis, ascending from ligamentous fibres interlacing in front of the pubic symphysis.

The *anterior surface* of the pubic body faces the femoral adductor region; on its medial part and to a rough strip, which is wider in females, the ventral pubic ligament is attached. In the angle between its upper end and the pubic crest the tendon of the adductor longus is attached and below this, to a line near the medial border extending down to the inferior ramus, is attached the gracilis. Lateral to the gracilis the adductor brevis is attached to the body and inferior ramus. Obturator externus is attached laterally to the anterior surface, spreading to both rami (3.214B).

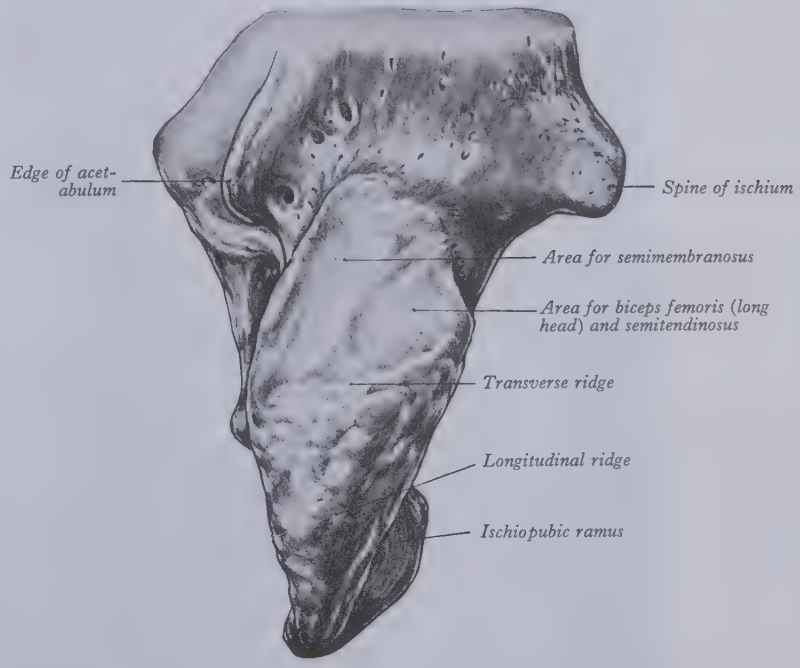
The *posterior pubic surface* is separated from the urinary bladder by the retropubic fat; near its centre anterior fibres of the levator ani are attached, more laterally the obturator internus, and this extends to both rami. Medial to the levator ani the puboprostatic ligaments are attached.

To the *pectineal surface of the superior ramus* along its upper part the pectineus is attached, covering the rest of the surface (3.214B).

The pecten pubis is the sharp, superior edge of the pectineal surface. Attached at its medial end are the conjoint tendon and lacunar ligament, along the rest of it a strong fibrous *pectineal ligament* (p. 597) and, near its centre, psoas minor when present. The smooth *pelvic surface* is separated from parietal peritoneum only by areolar tissue, in which the lateral umbilical ligament descends forwards across the ramus and, laterally, the ductus deferens passes backwards. The *obturator groove*, converted to a canal by the upper borders of the obturator membrane and obturator muscles, transmits obturator vessels and nerve from pelvis to thigh. To the lateral end of the *obturator crest* (3.215B) some fibres of the pubofemoral ligament are attached.

To the *external surface of the inferior ramus* are attached gracilis, adductor brevis and obturator externus, in medio-lateral order. Also, the adductor magnus usually extends from the ischial ramus on to the lower part of the inferior pubic ramus between adductor brevis and obturator externus. The *internal surface* is indistinctly divided into medial, intermediate and lateral areas. The medial area faces inferomedially in direct contact with the crus penis, limited above and behind by an indistinct ridge for attachment of the inferior fascia of the urogenital diaphragm (p. 606). To the intermediate area, related to the dorsal penile nerve, internal pudendal vessels and their fascial sheath, may be attached some inner fibres of sphincter urethrae, and to the lateral area, fibres of obturator internus. The *medial margin* of the ramus, strongly everted in males, is an attachment of the fascia lata and the membranous layer of the superficial perineal fascia.

The Ischium



The ischium, inferoposterior part of the innominate bone, has a body and ramus, the body having upper and lower ends and femoral, dorsal and pelvic surfaces (3.214–216). Above, it forms the inferoposterior part of the acetabulum; below, its ramus ascends anteromedially at an acute angle to meet the descending pubic ramus, completing the obturator foramen.

The *femoral surface*, facing down, forwards and laterally towards the thigh, is bounded in front by the margin of the obturator foramen and a lateral border, indistinct above but well-defined below, forming the lateral limit of the ischial tuberosity. The *dorsal surface*, facing superolaterally, is continuous above with the iliac gluteal surface, and here a low convexity follows the acetabular curvature. This surface is inferiorly the upper part of the ischial tuberosity, above which is a wide, shallow groove on its lateral and medial aspects. The *ischial tuberosity* (3.216) is a large, rough area on the ischium's lower dorsal surface and inferior extremity. Though obscured by gluteus maximus in extension, it is palpable in flexion. It is 5 cm from midline and about the same distance above the gluteal fold (p. 637). Elongate, widest above, tapering inferiorly, it is the attachment of the posterior femoral muscles. The ischial dorsal aspect is between the lateral and posterior borders. The *posterior border* blends above with that of the ilium, helping to complete the inferior rim of the *greater sciatic notch*, the posterior end of which has a conspicuous *ischial spine*. Below this the rounded border is the floor of the *lesser sciatic notch*, between ischial spine and tuberosity. The *pelvic surface* is smooth and faces the pelvic cavity; below this is part of the lateral wall of the ischiorectal fossa.

The ischial ramus has anterior and posterior surfaces continuous with those of the inferior pubic ramus; the former is really anteroinferior and roughened by the attachment of medial femoral muscles. The smooth *posterior surface* is partly divided into perineal and pelvic areas, like the inferior pubic ramus. The *upper border* completes the obturator foramen; the rough *lower border*, together with the medial border of the inferior pubic ramus, bounds the subpubic angle and pubic arch.

Further details. Attached below to the *femoral surface* of the **ischial body** is part of the obturator externus (3.214B) and along the upper part of the lateral border of the ischial tuberosity is the quadratus femoris. Below the acetabulum, to the lateral border, the ischiofemoral ligament is attached. Above the ischial tuberosity the *dorsal surface* is crossed by the tendon of obturator internus and the gemelli; between them and bone is the nerve to the quadratus femoris. At a higher level the femoral surface is covered by piriformis, partially separated by the sciatic nerve and the nerve to the quadratus femoris.

The ischial tuberosity is divided nearly transversely into upper and lower areas (3.216), the upper subdivided by an oblique line into a superolateral part for semimembranosus and an inferomedial for the long head of biceps femoris and semitendinosus; the lower region narrowing as it curves on to the inferior ischial aspect is subdivided by an irregular vertical ridge into lateral and medial areas. The larger lateral area is for part of the adductor magnus, the medial is covered by fibro-adipose tissue, usually containing the ischial bursa of gluteus maximus and supporting the body in sitting. Medially the tuberosity is limited by a curved ridge passing on to the ramus, to which the sacrotuberous ligament and its falciform process are attached (3.215B). Many fibres of biceps femoris pass into the ligament, an interesting fact, since the sacrum and posterior part of the ilium are primitive mammalian attachments of biceps femoris—the tuberosity being a secondary attachment, the ligament representing, at least in part, remains of primitive tendon.

3.216 The left ischial tuberosity: posterior aspect. The *transverse ridge* forms the lower boundary of the area for the hamstring muscles and separates it from the lower half of the tuberosity, which is divided into lateral and medial areas by the *longitudinal ridge*. To the lateral area is attached the adductor magnus; the medial area is covered with fibro-adipose tissue and supports the body in the sitting posture.

Superomedial to the tuberosity the posterior surface has a wide, shallow groove, usually covered by hyaline cartilage, with a bursa between it and the tendon of obturator internus. To the lower margin of the groove, near the tuberosity, the gemellus inferior is attached, and to the upper margin, near the ischial spine, gemellus superior.

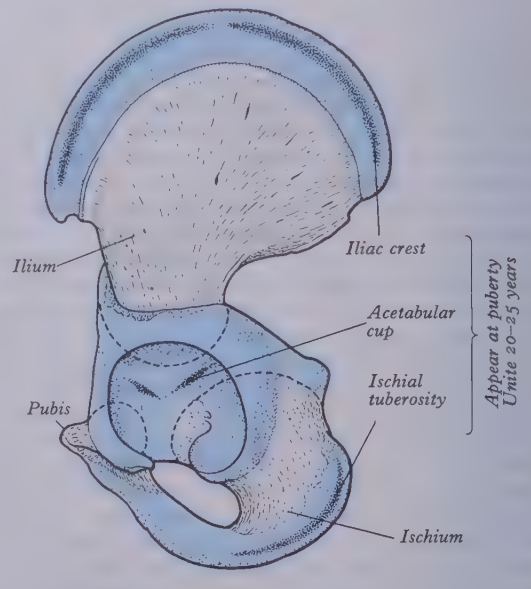
The ischial spine projects down and a little medially. To its margins is attached the sacrospinous ligament, separating the greater from the lesser sciatic foramen (4.56). It is crossed dorsally by internal pudendal vessels and nerve to the obturator internus. Its pelvic surface is an attachment of coccygeus (coextensive with the sacrospinous ligament) and the most posterior fibres of the levator ani. Various structures traverse these foramina (p. 517).

To the smooth *pelvic ischial surface*, in its upper part, is attached obturator internus, converging on the lesser sciatic notch (foramen) and covering the rest of this surface, except the pelvic aspect of the ischial spine. The muscle and its fascia separate bone from the ischiorectal fossa.

The *anterior surface* of the *ischial ramus* faces the adductor region. The obturator externus above, anterior fibres of the adductor magnus and, near the lower border, gracilis are all attached here. Between adductor magnus and gracilis the attachment of adductor brevis may descend from the inferior pubic ramus. The *posterior surface* is divided into pelvic and perineal areas; the former, facing back, has part of the obturator internus attached to it; the perineal area faces medially, its upper part related to crus penis or clitoridis, with sphincter urethrae attached to it, and below this ischiocavernosus and transversus superficialis perinei. The inferior fascia of the urogenital diaphragm is attached below the ridge between perineal and pelvic areas and above the areas for the penile crus and sphincter urethrae. The *lower border* of the ramus is an attachment of fascia lata and a membranous layer of the superficial perineal fascia.

The acetabulum (3.214A), an approximately hemispherical cavity central on the lateral aspect of the innominate bone, faces antero-inferiorly; it is surrounded by an irregular margin deficient *inferiorly* at the *acetabular notch*. The *acetabular fossa* is the cavity's central floor, which is rough and non-articular and has an articular *lunate surface*, widest above, where weight is transmitted to the femur. On this crescentic surface, covered with cartilage, the head of the femur slides. All three innominate elements contribute to the acetabulum in man, but unequally. The pubis forms the anterosuperior fifth of the articular surface, the ischium forms the fossa's floor and rather more than the postero-inferior two-fifths of articular surface, and the ilium the remainder. A linear defect may cross the acetabular surface from *superior* border to acetabular fossa, but does *not* follow any junction between the main morphologic parts of the innominate bone.

The obturator foramen, below and slightly anterior to the acetabulum, is between the pubis and ischium. It is rimmed above by the grooved obturator surface of the superior pubic ramus, medially by the pubic body and its inferior ramus, below by the ischial ramus, laterally by the anterior border of the ischial body, including the margin of the acetabular notch. The foramen is almost closed by the *obturator membrane* which is attached to its margins, except above, where a communication remains between pelvis and thigh; this free edge is attached to an *anterior obturator tubercle* at the anterior end of the the inferior border of superior pubic ramus, and a *posterior obturator tubercle* on the anterior border of the acetabular notch; these tubercles are sometimes indistinct. Since the tubercles lie in different planes and the obturator groove crosses the foramen's upper border, the acetabular rim is in fact a spiral. The foramen is large and oval in males, but smaller and nearly triangular in females.



Structure. The thicker parts of the innominate are trabecular, encased by two layers of compact bone; the thinner parts, e.g. in the acetabulum and central iliac fossa, are often translucent, consisting of one lamina of compact bone. In the upper acetabulum and along the arcuate line, i.e. the route of weight transmission from sacrum to femur, compact bone is increased and subjacent trabecular bone displays two sets of pressure lamellae. They start together near the upper auricular surface and diverge to impinge on two strong buttresses of compact bone, whence two similar sets of lamellar arches start and converge on the acetabulum (Wakeley 1929). Because of frequent use for biopsy puncture the ventral iliac crest has been much studied as regards distribution of cortical and trabecular bone. Whitehouse (1977) has surveyed these studies; his own observations, by scanning electron micrography, indicate that the cortical bone is very porous, being only 75% bone, and merely 35% near the anterior superior iliac spine; denser cortical bone commences at margins of the crest, thickening rapidly below it on both aspects of the iliac squama.

Ossification. This is by three primary centres, for ilium, ischium and pubis; the iliac appears above the greater sciatic notch prenatally about the eighth week, the ischial in its body in the fourth month, and the pubic in its superior ramus between the fourth and fifth months. At birth some parts are still cartilaginous: the whole iliac crest, the acetabular floor and inferior margin (3.217); the acetabulum is still a cartilaginous cup with a triradiate stem extending medially to the pelvic surface as a Y-shaped epiphysial plate between ilium, ischium and pubis (Harrison 1957), including also the anterior inferior iliac spine. Cartilage along the inferior margin also covers the ischial tuberosity, forms (temporarily) conjoined ischial and pubic rami and continues to the pubic symphysial surface and along the pubic crest to its tubercle.

The ossifying ischium and pubis fuse to form a continuous ramus at the seventh or eighth year (3.218). Secondary centres appear about puberty and join between fifteenth and twenty-fifth years. There are usually two for the iliac crest, but these rapidly fuse, and two for the acetabular cartilage, occurring between ilium and pubis, and ilium and ischium. These two centres fuse (*os acetabuli*) as ossification spreads to include the whole stem of triradiate cartilage, forming a substantial part of the articular surface along the junction of the triradiate stem, cartilage cup and around its periphery. The anterior inferior iliac spine may be ossified from the triradiate centre or a separate one. Cartilage at the inferior acetabular margin begins to ossify over the ischial tuberosity, spreading forwards. The part ossifying first fuses almost at once, before more anterior parts have ossified, and fusion also extends forwards. The pubic tubercle, crest and symphysial surface may have separate centres.

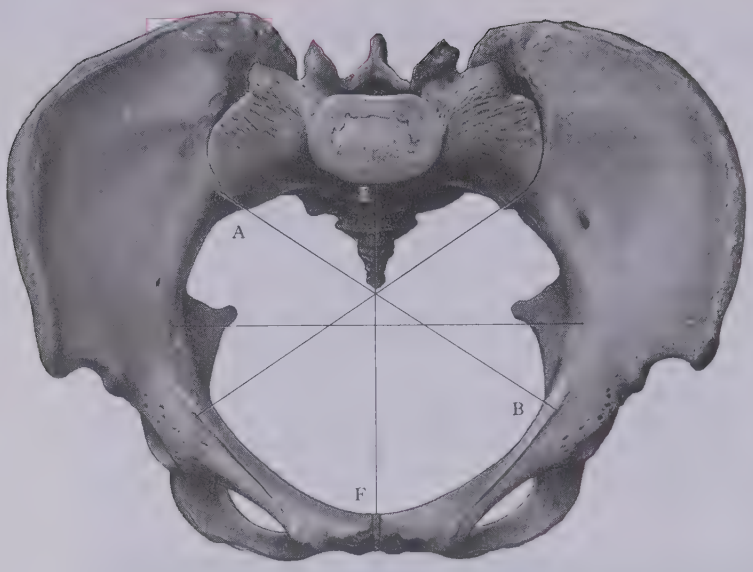
The Skeletal Pelvis

The term *pelvis*, 'a basin', is vaguely applied to the skeletal ring formed by innominate bones and sacrum, the cavity within them and even the entire region where trunk and lower limbs meet. It

3.217 The innominate bone at birth. More heavily stippled areas indicate the secondary centres of ossification and the Y-shaped medial extension of the cartilaginous acetabular cup is indicated by interrupted lines. The ossified part of the ischium is shown in the floor of the acetabulum.

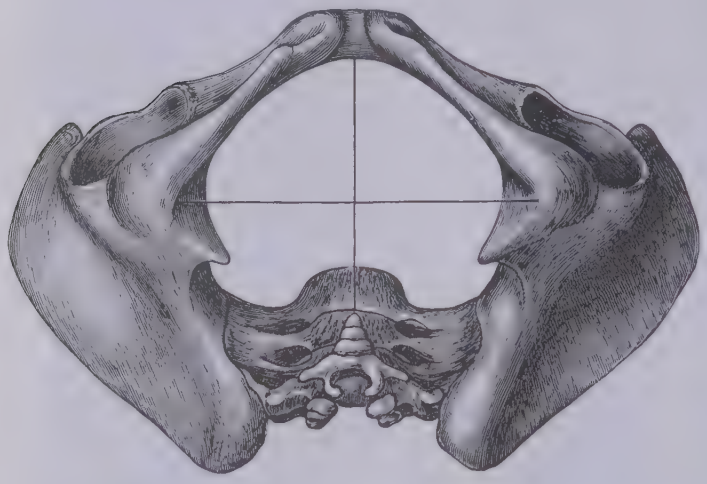
is used here in the skeletal sense, for the irregular osseous girdle between femoral heads and fifth lumbar vertebra. It is massive, because its primary function is to withstand compression and other forces due to body weight and powerful musculature, mechanisms considered elsewhere (p. 518). Here, we are concerned with metrical and other features of sexual significance, and hence of obstetric, forensic and anthropological application.

The pelvis can be regarded as having greater and lesser segments, the true and false pelves, arbitrarily divided by an oblique plane, passing through the sacral promontory behind and *lineae terminales* elsewhere. Each linea terminalis includes the iliac arcuate line (p. 423), pecten (iliopectineal line) and pubic crest. But the segments are continuous, and parts of the body cavity which they enclose are also continuous through the superior pelvic aperture or pelvic inlet (3.219).



The greater pelvis consists of iliac flanges above the lineae terminales and the sacral base. Structure of this junctional zone is massive, forming powerful arches from acetabular fossae to vertebral column around the visceral cavity which is, of course, part of the abdomen; because of the pelvic inclination (vide infra) it has little anterior wall.

The lesser pelvis encloses a true basin when soft tissues of the pelvic floor are in place. Skeletally it is a narrower continuation of greater pelvis, with irregular but more complete walls around its cavity. Naturally of great obstetric importance, it has a *median curved axis*. It has superior and inferior openings, the superior occupied in life by viscera, the inferior largely closed by the pelvic floor and its sphincters.



The superior pelvic aperture (pelvic inlet), variable in contour—round or oval—is encroached upon by the sacral promontory. Its boundary, described as *pelvic brim*, is obstetrically important (3.219 and vide infra) and has also long been measured for anthropological reasons, as has the pelvic cavity; much information is available, especially for females. Data of different observers vary, being founded on differing racial and economic groups. Data cited here are merely approximate samples of values in Europeans (Martin 1928). Three dimensions of the *pelvic inlet* have become conventional:

3.218 Anteroposterior radiograph of the pelvis of a boy aged seven. 1. Ilium. 2. Pubis. 3. Ischium. 4. Part of triradiate growth cartilage. 5. Cartilage between pubic and ischial rami. 6. Superior femoral epiphysis. 7. Ossifying greater trochanter. 8. Cartilaginous growth plates.

3.219 The diameters of the superior aperture of the lesser pelvis (female). A. sacroiliac joint; B. iliopubic eminence; C,D. middle of pelvic brim; E. sacral promontory; F. pubic symphysis.

3.220 The diameters of the inferior aperture of the lesser pelvis (female). The oblique diameter is not shown.

A. *Anteroposterior diameter* (true conjugate) is measured between midpoints of the sacral promontory and upper border of symphysis pubis (male 100 mm, female 112 mm).
B. *Transverse diameter* is the maximum distance between similar points (assessed by eye) on opposite sides of the pelvic brim (male 125 mm, female 131 mm).
C. *Oblique diameter* is measured from iliopubic eminence to opposite sacroiliac joint (male 120 mm, female 125 mm).

The cavity of the lesser pelvis, short and curved, is markedly longer in its posterior wall. Antero-inferiorly it is bounded by pubic bones, their rami and symphysis; posteriorly by the concave anterior sacral surface and coccyx; and on each side by the smooth quadrangular pelvic aspect of fused ilium and ischium. The region thus enclosed is the pelvic cavity proper, through which pass, in all land vertebrates, the ends of the alimentary canal and urogenital ducts. Thus in humans its contents are rectum, bladder and parts of the reproductive organs. The rectum is posterior, bladder anterior, uterus intermediate. The cavity must also permit passage of the fetal head.

Pelvic diameters are often measured and while this can be done at many levels, measurements are usually chosen at approximately midlevel.

A. *Anteroposterior diameter* is measured between midpoints of the third sacral segment and posterior surface of symphysis pubis (male 105 mm, female 130 mm).
B. *Transverse diameter* is the widest transverse distance between side walls of the cavity, and often the greatest transverse dimension in the whole cavity (male 120 mm, female 125 mm).
C. *Oblique diameter* is the distance from lowest point of one sacroiliac joint to midpoint of contralateral obturator membrane (male 110 mm, female 131 mm).

The inferior pelvic aperture (pelvic outlet) (3.220), less regular in outline than the superior, is indented behind by coccyx and sacrum and bilaterally by ischial tuberosities. Its perimeter thus consists of three wide arcs; anterior is the *pubic arch*, between the converging ischiopubic rami; between the sacrum and coccyx posteriorly and the ischial tuberosities laterally are two large sciatic notches, divided, on both sides, by sacrotuberous and sacrospinous ligaments into *greater* and *lesser sciatic foramina* (p. 517). With ligaments included, the inferior aperture is rhomboidal, its anterior limbs being ischiopubic rami (joined by the inferior pubic ligament), its posterior the sacrotuberous ligaments, with the coccyx median. The outlet is thus not rigid in its posterior half, being limited by ligaments and coccyx, all slightly yielding. Even with the sacrum taken as the posterior midline limit (more reliable for measurement), there remains slight mobility at the sacroiliac joints. Note also that a plane of the inferior aperture is merely conceptual: the anterior, ischiopubic part has a plane inclined down and back to a transverse line between the lower limits of the ischial tuberosities, and the posterior half has a plane approximating to sacrotuberous ligaments, sloping down and forwards to the same line. Dimensions of the inferior aperture are measured as follows:

A. *Anteroposterior diameter* is usually measured from coccygeal apex to the midpoint of the lower rim of the symphysis. The lowest sacral point may also be used (male 80 mm, female 125 mm).
B. *Transverse diameter* is measured between ischial tuberosities at the lower borders of their medial surfaces. Hence the term *bituberous diameter* (male 85 mm, female 118 mm).
C. *Oblique diameter* extends from the midpoint of sacrotuberous ligament on one side to the contralateral ischiopubic junction (male 100 mm, female 118 mm).

Apart from these main measurements, by consensus the basis of pelvic osteometry, other planes and measurements are used in obstetric practice. *Plane of greatest pelvic dimensions*, an obstetrical concept, represents the most capacious pelvic level, between pelvic brim and midlevel plane, corresponding with the latter anteriorly (midsymphysis) but ascending slightly to the disc between second and third sacral segments. *Plane of least pelvic dimensions* is said to be at about midpelvic level; its transverse diameter is between apices of ischial spines; most difficulty in parturition occurs here. *Posterior median diameter* is the part of any anteroposterior diameter behind its intersection with transverse diameter, and thus assessable at any level or plane as an indicator of capacity of the posterior pelvic segment. Because direct measurement of osseous dimensions is impracticable in living patients, except by radiological methods, indirect measurements may be used.

The *diagonal (oblique) conjugate* is the distance from the sacral promontory to the lower symphysial border, measured *per vaginam*, and a guide to the 'true' conjugate. This, like all pelvic diameters described anatomically, largely disregards soft tissues. The *intercristal* and *interspinous diameters*, respectively the greatest widths between iliac crests and anterior superior iliac spines, are sometimes compared in females. Average values are (intercristal) 250 mm and (interspinous) 275 mm, the difference between them being an indication of width of pelvic cavity; iliac crests do not turn medially at their anterior ends to the same extent in females as males. The method's value is dubious and correlation between such sexual characteristics in the pelvis is uncertain.

Morphological Classification of Pelves

Interest in the above dimensions is primarily obstetric and, less frequently, forensic. All pelvic measurements display, as others elsewhere, individual variation; values quoted are means from

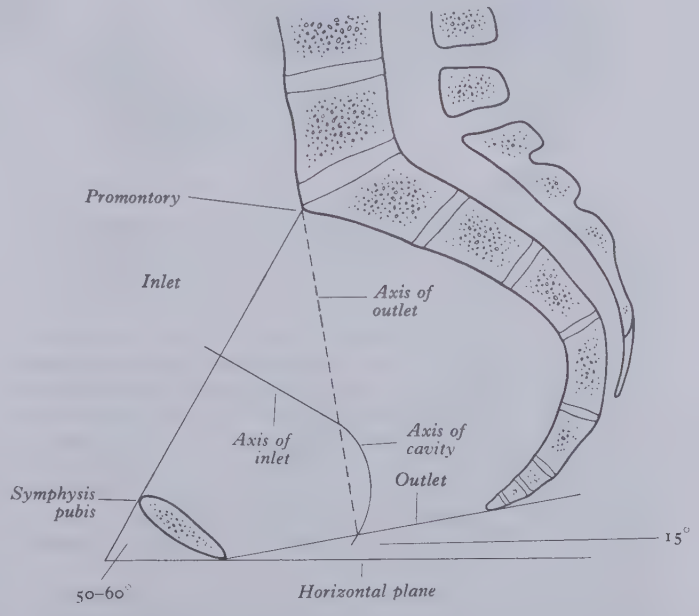
limited surveys. Sexual and racial differences also occur. The range in any group, for both sexes, is large when adequately assessed. Measurements are on skeletonized pelves in the most extensive studies; such data are not only of anthropological interest but also the basis of attempts to define clinically identifiable forms of the pelvis without resort to the full range of measurements, which are not all possible in the living, although radiological pelvimetry has become a refined technique (Borell & Fernström 1960). In the female patient it is *her* measurements which are significant, not average values; comparison between her dimensions and a fetal head are the principal concern. These values can satisfactorily be assessed only by radiographic techniques. Hence modern pelvimetry and fetal cephalometry have replaced obstetric measurement by calipers whenever requisite expertise is available (Clyne 1963, Lewis 1964).

Pelvic measurements, however obtained, have been analysed by many anatomists, anthropologists, obstetricians and radiologists in attempts to classify human pelves, especially the female. *Pelvic brim index*—(ant-post./trans. diameters) × 100—was an early attempt to define the shape of the pelvic cavity (Turner 1886). Like the cephalic index (p. 396) its range is divided into steps, by which pelves are classified as *platypellic* (transversely flat), *mesatipellic* (intermediate) and *dolichopellic* (anteroposteriorly long); on anatomical and radiological data a *brachypellic* form is added, also known as *android* and responsible for most cases of severe obstruction in childbirth (Greulich & Thoms 1938, 1939, Thoms 1940). Such classification is equally applicable to both sexes and various ages, e.g. in one large series, children and males were predominantly dolichopellic, females mostly mesati- and brachypellic. Platypellic pelves are comparatively rare in all series. Another classification depends jointly on anatomical and radiological data, the latter including qualitative and metrical observations (Caldwell & Moloy 1933, Caldwell et al 1940). This divides the superior pelvic aperture by its transverse diameter into an anterior *forepelvis* and a *hindpelvis*, the latter more variable in shape and capacity. The slope of pelvic walls, whether radiographically straight, convergent or divergent, pelvic depth and shape and size of the greater sciatic notch (lateral radiographs) and shape of the subpubic arch are all considered. This study led to wide acceptance of four pelvic types (shown in the table below and 3.225) depending fundamentally on skeletal measurement, although frequently applied somewhat subjectively in clinical practice. Though intermediate forms exist, the classification is claimed to embrace all but a very small percentage. Basic skeletal mean values in the original study were as follows:

PELVIC TYPE	CONJUGATE DIA. (mm)	TRANSVERSE DIA. (mm)	WHITE FEMALES (%)	NEGRO FEMALES (%)
Gynaecoid (=mesatipellic)	108·5	137·6	41·4	42·1
Android (=brachypellic)	105·9	135·6	32·5	15·7
Anthropoid (=dolichopellic)	117·5	129·4	23·5	40·5
Platypelloid (=platypellic)	85·5	144·5	2·6	1·7

Apart from racial differences (e.g. high rate of anthropoid pelves in Negro women), such observations emphasize the low incidence of the platypelloid form. Children (under nine years) and adult males show a high incidence of dolichopelly, perhaps indicating a paedomorphic trait in males. The platypelloid pelvis has been described as 'ultrahuman'.

Correlation of pelvic type with general bodily physique is uncertain (Smout et al 1969). It has been claimed, e.g. that women with the dangerous android pelvis are stout, short-necked and broad-shouldered (Kenny 1944), views regarded as unreliable by others (Ince & Young 1940).



Pelvic Axes and Inclination

The axis of the superior pelvic aperture traverses its centre at right angles to its plane, directed down and backwards; when prolonged (projected) it passes through the *umbilicus* and *midcoccyx*. An axis is similarly established for the inferior aperture; projected up it impinges on the *sacral promontory*. Axes can likewise be constructed for any plane, and one for the whole cavity is a concatenation of an infinite series of such lines. It follows the cavity's curvature, indicated by the profile of sacrum and coccyx in lateral views (3.221). The form of this *pelvis axis* and disparity in depth between anterior and posterior contours of the cavity are prime factors in the mechanism of fetal transit in the *pelvic canal*.

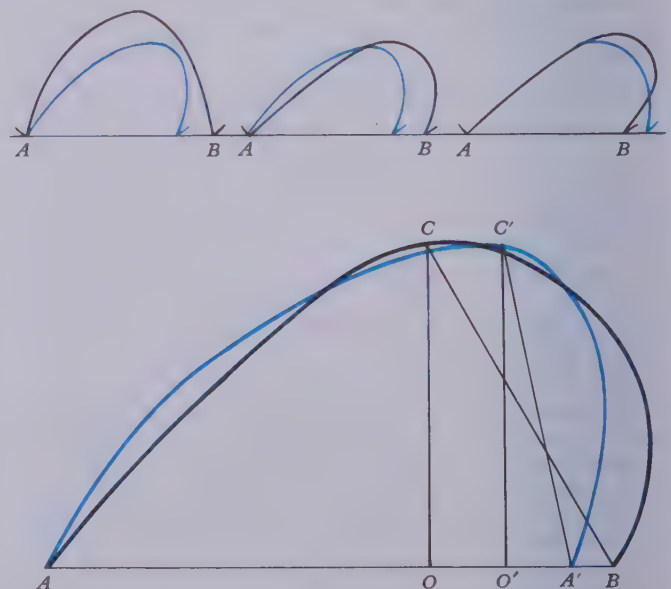
In the standing position the pelvic canal curves obliquely back relative to trunk and abdominal cavity (3.221). The whole pelvis is tilted forwards, the plane of the pelvic brim making an angle of 50 to 60° with the horizontal. The plane of the inferior aperture is tilted likewise to about 15°, dorsal parts of both planes being thus above ventral. Strictly, the pelvic outlet has two planes, an anterior passing back from pubic symphysis and a posterior passing forwards from the coccyx, both descending to meet at the intertuberous line. In standing, the pelvic aspect of the symphysis pubis faces as much up as back and the sacral concavity is directed antero-inferiorly. The front of the symphysis and anterior superior iliac spines are in the same vertical plane. In sitting, body weight is transmitted through inferomedial parts of the ischial tuberosities, with variable soft tissues intervening, and anterior superior spines are in a vertical plane through the acetabular centres, the whole pelvis being tilted back and the lumbosacral angle somewhat diminished at the sacral promontory.

SEXUAL DIFFERENCES IN THE PELVIS

The pelvis obviously provides the most marked skeletal differences between male and female (3.222–225); surprisingly, distinction can be made even during fetal life, particularly in the subpubic arch (Boucher 1957). Radiographic pelvic studies in American children during their first postnatal year show that male infants exceed females in dimensions of the whole pelvis, but usually females exceed males in the size of pelvic cavity (Reynolds 1945). From two to nine years a similar distinction prevails; but the difference is said to be maximal at 22 months, decreasing in later childhood (Reynolds 1947). Sexual differences in adults, which have been much assessed (Genovese 1959), are divisible

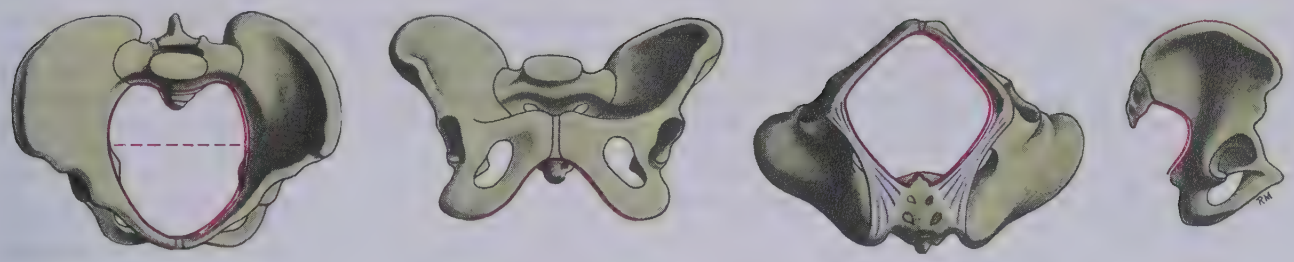
3.221 Median sagittal section through the female pelvis to show the planes of inlet and outlet and their relation to each other and the horizontal plane. The curved axis of the pelvic cavity is also shown. It should be observed that, as depicted in this section, the curve of the sacrum affects the lower part of the third and the upper part of the fourth sacral vertebrae. In many cases the curve is restricted to the fourth vertebra only. Difficulties in defining the plane of the outlet are mentioned in the text.

3.222 The female pelvis: anterior aspect. (From a specimen in the museum of the Royal College of Surgeons of England.)



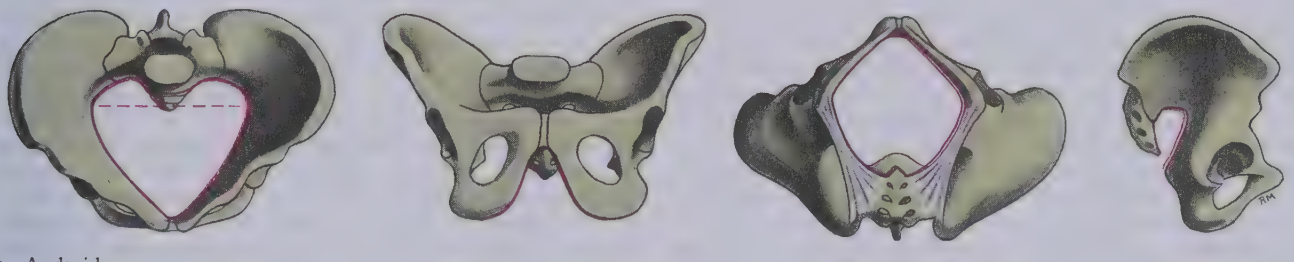
3.223 The male pelvis: anterior aspect.

into metrical and non-metrical features, the range of most, overlapping between sexes.

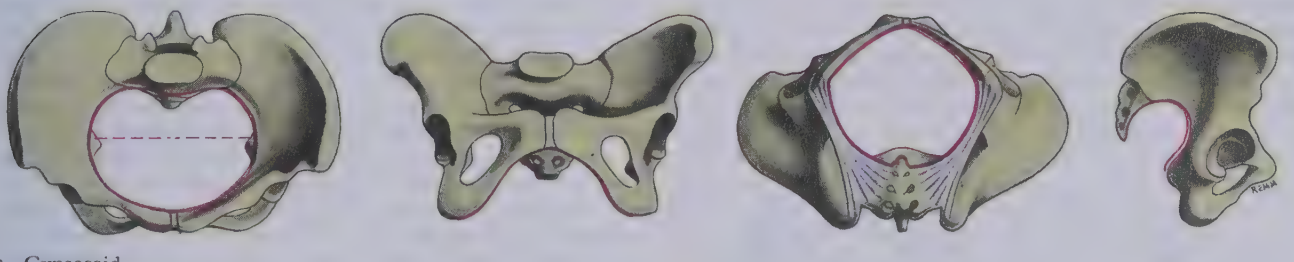


Differences are inevitably linked to function. While primary pelvic function in *both* sexes is locomotor, the pelvis is adapted to parturition in females, particularly the lesser pelvis, changes in which variably affect proportions and dimensions of the greater pelvis. Since males are distinctly more muscular and therefore more heavily built, overall pelvic dimensions, such as intercristal measurement, are greater, markings for muscles and ligaments more pronounced and general architecture heavier. The male iliac crest is more rugged and more medially inclined at its anterior end; in females crests are less curved in all parts. The iliac blades are more vertical in females, but do not ascend so far; iliac fossae are therefore shallower and each iliopectineal line more vertical. These iliac peculiarities probably account for the greater prominence of female hips.

The male is relatively and absolutely more heavily built *above* the pelvis, with consequent differences at lumbosacral and hip joints. The sacral basal articular facet for the fifth lumbar vertebra and intervening disc is more than a third of the total sacral basal width in males but less than a third in females, whose sacrum is also relatively broader, accentuating this difference. Thus the female has relatively broader alae. The male acetabulum is absolutely larger and its diameter about equal to the distance between its anterior rim and symphysis pubis. But in females acetabular diameter is usually less than this distance, not only because it is absolutely smaller but also because the anterolateral wall of the cavity is comparatively and often absolutely wider. Female symphysis and adjoining parts of pubis and ischium, forming the anterior pelvic wall, are also absolutely less in height, producing a somewhat triangular obturator foramen, which is more ovoid in males. Differing pubic growth is also expressed in the subpubic arch below symphysis and between inferior pubic rami. It is more angular in males, being 50 to 60°; in females it is rounded, less easy to measure and usually 80 to 85°. Associated with pubic width in females is greater separation of pubic tubercles. Ischiopubic rami are also much more lightly built and narrowed near the symphysis. In males they bear a distinctly rough, everted area for attachment of penile crura, the corresponding attachment for the clitoris being poorly developed. Ischial spines are closer in males, being more inturned. The greater sciatic notch is usually wider in females; comparisons of its width and angle yield mean values for males and females of 50.4° and 74.4° (Hanna & Washburn 1953); greater female values for angle and width are associated with increased backward sacral tilt and greater anteroposterior pelvic diameter, especially at lower levels. A method for comparing *depth* of the notch is reported by Jovanović & Živanović (1965). More recently, detailed analysis of dimensions and derived indices in relation to sex determination at the greater sciatic notch has been made by Singh & Potturi (1978), based on a study of 200 adult hip bones (120 males and 80 females). Using defined points (Jit & Singh 1966) they assessed maximal width and depth, posterior segment of width, total angle, and posterior angle. Two indices were also assessed (3.224). Width and depth of the notch per se were found valueless for determining sex: the posterior angle was the best single parameter, the length of the posterior segment and index II were also highly effective, especially in females.



The sacrum displays metrical sexual differences, in addition to orientation. Female sacra are less curved, curvature being most marked between the first and second segments and the third and fifth, with an intervening flatter region. Male sacra are more evenly curved, relatively long and narrow and more often exceeding five segments (by addition of a lumbar or coccygeal vertebra). The *sacral index* compares sacral breadth (between most anterior



3.224 (*Above*) three common profiles of the greater sciatic notch in males (blue) and females (black). (*Below*) points, axes and angles utilized in mensuration of the greater sciatic notch. AB = *maximal width*, i.e. distance between the tip of the ischial spine and a tubercle marking attachment of the piriformis muscle. OC = *maximal depth* (perpendicular to AB). OB = *posterior segment* of width. Index I = OC × 100/AB. Index II = OB × 100/AB. ACB = *total angle*. BCO = *posterior angle*. (Modified, with permission, from Singh & Potturi 1978.)

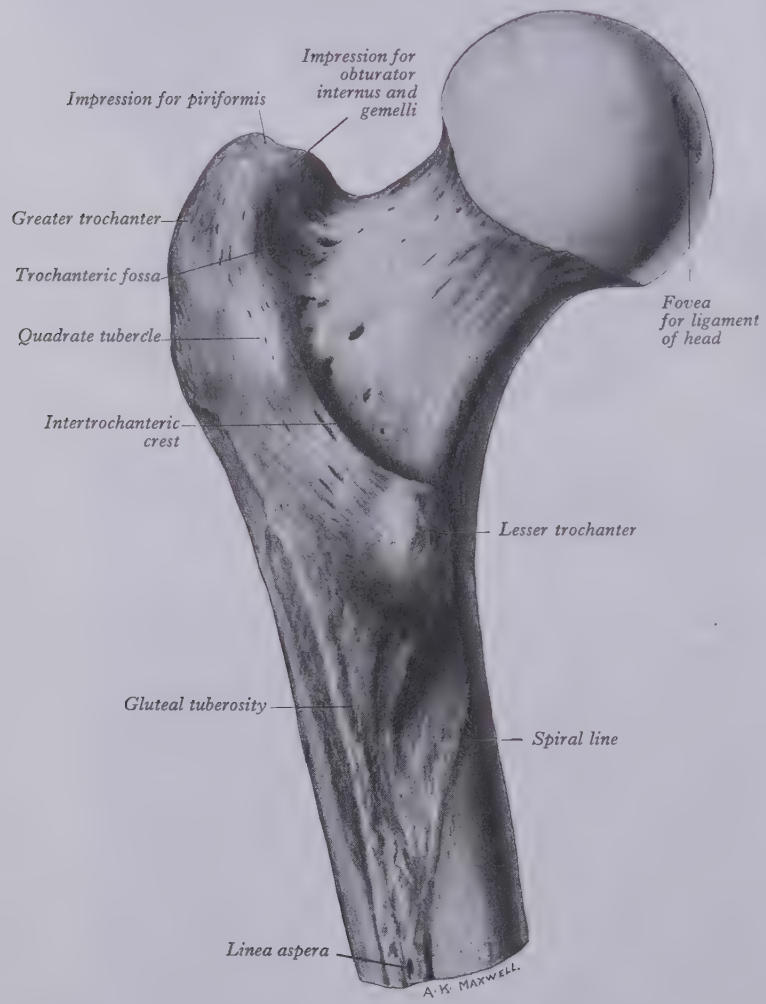
3.225 The major differences between the four types of pelvis in the most widely accepted classification. Types shown in A and B are commonest in males, B and C in females, while D is rare, even in females. Note the variations in superior and inferior apertures, greater sciatic notch, and subpubic arch. Note varying proportion between fore-and hind-pelvis, anterior and posterior to transverse diameter of the inlet. (Caldwell and Moloy's Classification, after Clyne 1963.)

points on the auricular surfaces) with length (between midpoints on the anterior margins of promontory and apex); average values for males and females are 105 and 115%. Auricular surfaces are relatively smaller and more oblique in females; contrary to a common statement, they extend on the upper *three* sacral vertebrae in *both* sexes. The dorsal auricular border is more concave in females (Weisl 1954). Many differences are summarized in the generalization that the pelvic cavity is longer and more conical in males, shorter and more cylindrical in females; but in both the axis is curved. Differences are greater at the inferior aperture than the brim, where in absolute measurements males are not as different from females as sometimes stated. But the superior aperture is more likely to be anthropoid or android in males, gynaecoid or android in females, the sexes overlapping to this extent.

In forensic practice identification of human skeletal remains (sometimes fragmentary) usually involves diagnosis of sex, and this is most certainly established from the pelvis. Even parts of the pelvis may be useful. Several studies of metrical characteristics in various pelvic regions have been made, leading to various indices. The ilium has received particular attention, e.g., one index essentially compares the pelvic and sacro-iliac parts of the bone (Derry 1923). A line is extended back from the iliopectineal eminence to the nearest point on the anterior auricular margin and thence to the iliac crest. The auricular point divides this *chilotic line* into anterior (pelvic) and posterior (sacral) segments, each expressed as a percentage of the other. Such *chilotic indices* display reciprocal values in the sexes, the pelvic part of the chilotic line being predominant in females, the sacral part in males. The most detailed metrical study of the ilium, involving several indices, indicates its limited reliability in 'sexing' pelves (Straus 1927). However, the higher incidence and definition of the female preauricular sulcus was confirmed (p. 425). A *puboischial index*, based on maximum lengths of ischium and pubis, measured from their acetabular junction, produced values of 83.7% and 100.0%

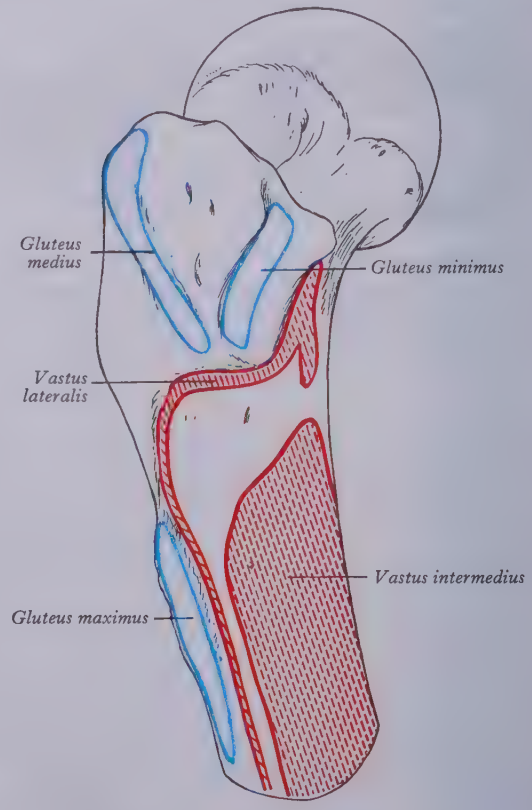
for American males and females (Washburn 1949); when this was correlated with the angle of the sciatic notch, it was claimed that sex of 98% of pelves could be deduced. The desirability of correlation of all available metrical data is to be emphasized; when a range of pelvic data can be combined, especially if they are metrical, 95% accuracy should be achieved. Complete accuracy has been claimed when the rest of the skeleton is available. Nevertheless, assessment of sex in isolated and often incomplete human remains cannot always be absolutely certain.

The Femur



The femur is, of course, the longest and strongest bone (**3**.226–233). Its length is associated with striding gait, its strength with weight and muscular forces. Its *shaft*, almost cylindrical in most of its length and bowed forward, has a proximal round, *articular head* projecting mainly medially on its short *neck*, a medial curvature of the proximal shaft. The distal extremity is more massive, being a double 'knuckle' or *condyle* articulating with the tibia. In standing, the femora are oblique (**3**.1–3), their heads separated by the pelvic width, their shafts converging down and medially to where the knees almost touch. Since the foreleg bones descend vertically from the knees, the femoral obliquity approximates the feet, bringing them under the line of body weight in standing or progression. The narrowness of this base detracts from stability but facilitates forward movement by increasing speed and smoothness. Femoral obliquity varies but is greater in women, due to relatively greater pelvic breadth and shorter femora. Proximally the femur (**3**.226,227) comprises a head, neck, and greater and lesser trochanters.

The femoral head, slightly more than half a 'sphere' (but see pp. 478, 518), faces up and anteromedially to articulate with the acetabulum. (More precisely, the head is not part of a true sphere, but rather it is sphenoidal and part of the surface of an ovoid.) Its smoothness is interrupted postero-inferior to its centre by a small, rough *fovea*.



The femoral neck, about 5 cm long, connects head to shaft at an angle of about 125°. This facilitates movement at the hip joint, enabling the limb to swing clear of the pelvis. The neck is narrowest in its midpart, widest laterally. Its contours are rounded, the upper almost horizontal and slightly concave above, the lower straighter but oblique, directed inferolaterally and backwards to the shaft near the lesser trochanter. On all aspects the neck diverges as the capitular articular surface is approached. The neck's anterior surface is flat and marked at the junction with the shaft by a rough *intertrochanteric line* (**3**.228A). The posterior surface, facing back and up, is transversely convex, and concave in its long axis; its junction with the shaft is marked by the rounded *intertrochanteric crest* (**3**.226,229A).

The greater trochanter, large and quadrangular, projects up from the junction of the neck and shaft. Its posterosuperior region projects superomedially (**3**.226,229A) to overhang the adjacent posterior surface of the neck and here its medial surface presents the rough *trochanteric fossa*. The trochanter's proximal border is a hand's breadth below the iliac tubercle, level with the centre of the femoral head. It has an anterior rough impression, its lateral surface being divided by an oblique, flat strip, wider above, crossing it down and forwards; this aspect is palpable and, with the muscles (**3**.227) relaxed, can be gripped. The trochanteric fossa occasionally presents a tubercle or exostosis, a useful non-metrical racial characteristic (p. 273). **The lesser trochanter** (**3**.226) is a conical posteromedial projection of shaft at the postero-inferior aspect of its junction with the neck. Its summit and anterior surface are rough, but its posterior surface, at the distal end of the intertrochanteric crest, is smooth. It is not palpable.

The intertrochanteric line, at the junction of the anterior surfaces of neck and shaft (**3**.228), is a prominent ridge, descending medially from a tubercle, superomedial on the anterior aspect of the greater trochanter to the neck's lower border, level with but

3.226 The proximal part of the left femur: posterior aspect.

3.227 The proximal part of the right femur: lateral aspect.

in front of the lesser trochanter, often ending in a second tubercle. Distally it is continuous with the *spiral line* (vide infra). **The intertrochanteric crest** (3.226,229A), at the junction of the *posterior* surface of neck with shaft, is a smooth ridge, descending medially from the posterosuperior angle of the greater to the lesser trochanter. A little above its centre is a low, rounded *quadrate tubercle*.

Relations and Attachments

The femoral head is intracapsular, encircled lateral to its equator by the acetabular labrum. Its periphery is distinct, except anteriorly, where the articular surface extends to the neck. To its fovea (3.226) is attached the ligament of the head; the head's anterior surface is separated inferomedially by the tendon of psoas major, the subpsoas bursa, and the articular capsule from the femoral artery. Its blood supply is from a vascular circle around the neck, near the attachment of the fibrous capsule, supplied by medial and lateral circumflex arteries; from this rami pierce the capsule (under its zona orbicularis, p. 519) to ascend the neck beneath the reflected synovial membrane. These divide into metaphysial branches entering the neck and epiphysial rami to peripheral non-articular parts of the head to supply the epiphysis. During growth, territories of the two groups are separated by the epiphysial plate; after osseous union of head and neck, they anastomose freely. A small supply reaches the head along its ligament (pp. 439 and 783) by the acetabular branches of obturator and medial femoral circumflex arteries; these anastomose with the epiphysial vessels (Crock 1965). Observations on developmental patterns of this supply in late fetal and early postnatal periods modify the above description: though medial and lateral circumflex arteries at first contribute equally, two major branches of the medial are the final supply, both related posterior to the neck (Ogden 1974). Supply from the lateral circumflex diminishes and the arterial circle is interrupted. As the femoral neck elongates, the extracapsular circle becomes more distant from the epiphysial part of the head.

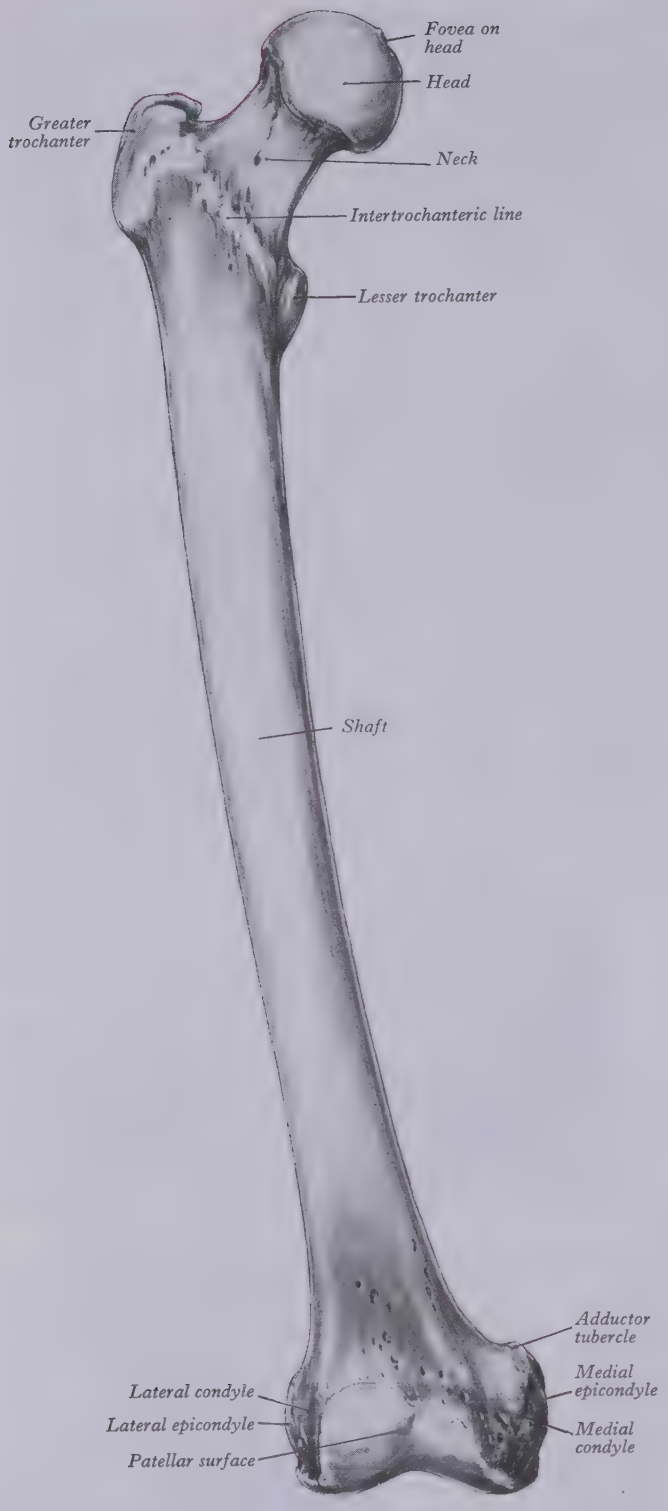
The neck has numerous vascular foramina, especially anterior and posterosuperior. Its angle with the shaft is widest at birth and diminishes until adolescence; it is less in females. Its *anterior surface* is intracapsular; the capsular ligament extends laterally attaching to the intertrochanteric line. Facets, often covered by extensions of articular cartilage, and various imprints frequently occur here; though attributed to squatting habits, they are not always so associated; their cause is uncertain (Kostick 1963). One such feature, the *cervical fossa* (of Allen), may be racial (p. 273). On the *posterior surface* the capsule does not reach the intertrochanteric crest (3.229A,B); little more than the medial half of the neck is intracapsular. The anterior surface adjoining the head and covered by cartilage is related to the iliofemoral ligament. A groove spirals across the neck's posterior surface in a proximolateral direction, produced by the tendon of obturator externus approaching the trochanteric fossa. The neck is *not* in the plane of the shaft, but inclined forwards. Hence the head's transverse axis makes an angle with the transverse condylar axis, the *angle of femoral torsion* (approximately 15°).

The greater trochanter (3.227,228B,229B) provides attachment for most gluteal muscles: gluteus minimus to its rough anterior impression, gluteus medius to its lateral oblique strip, the area anterior to this separated from its tendon by a trochanteric bursa; the area behind is covered by deep fibres of gluteus maximus, with part of its trochanteric bursa interposed. To the trochanter's upper border is attached the tendon of piriformis, to its medial surface the common tendon of obturator internus and the gemelli; at their attachment these two tendons are often variably fused. The trochanteric fossa receives the tendon of obturator externus.

The lesser trochanter has psoas major attached to its summit and anteromedial surface. To the medial or anterior surface of its base iliacus is attached, descending a little behind the spiral line. Adductor magnus (upper part) plays over its posterior surface, with sometimes an interposed bursa.

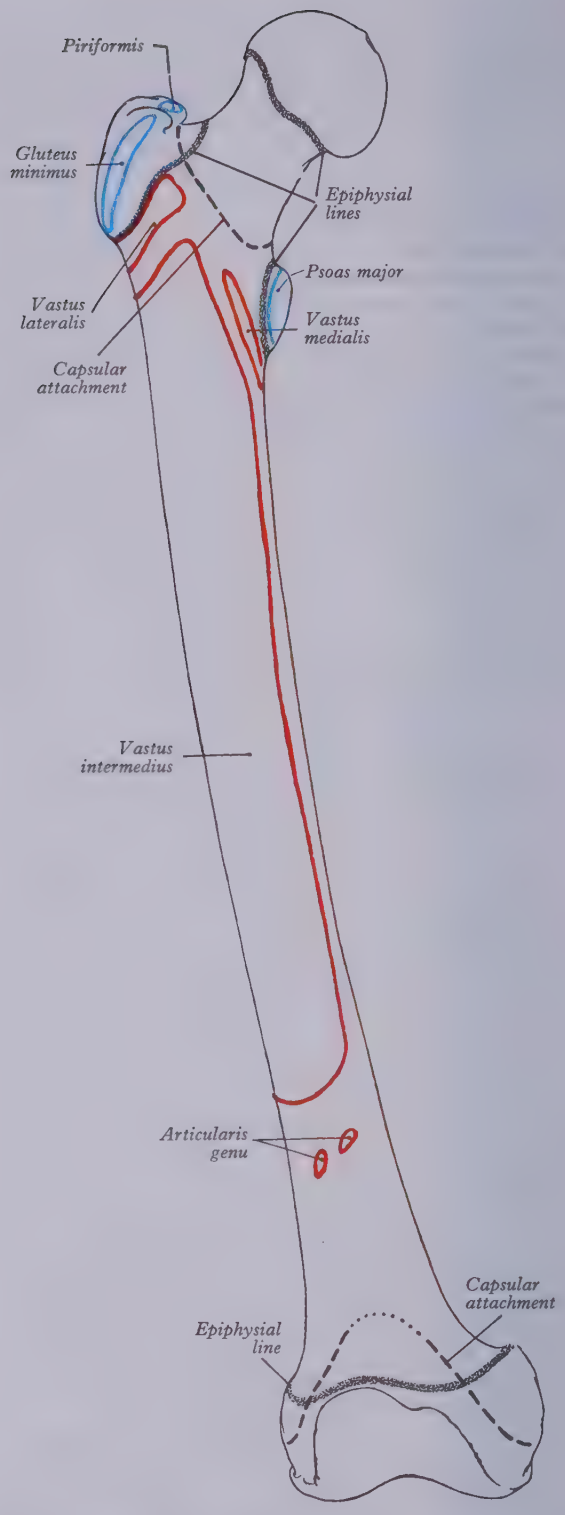
To the *intertrochanteric line*, lateral limit of the coxal capsular ligament, at its proximal and distal parts with their tubercles, are attached the upper and lower bands of the iliofemoral ligament. The most proximal fibres of the vastus lateralis are attached to its proximal end, those of vastus medialis distally. The *intertrochanteric crest*, above the *quadrate tubercle*, is covered by gluteus maximus, separated distally from the muscle by quadratus femoris and the upper border of adductor magnus. To the tubercle and the bone distal to it quadratus femoris is attached (3.229B).

The shaft (3.228,229), narrowest centrally, expands a little upwards, but more so towards its distal end. Its long axis diverges about 10° from the tibia's. Its *middle third* has three surfaces and borders. The extensive *anterior surface*, smooth and gently convex, is between lateral and medial borders, both round and indistinct. The *lateral surface*, really posterolateral, is bounded behind by the posterior border, the broad, rough **linea aspera**, usually a crest with lateral and medial edges; its subjacent compact bone is augmented to withstand compressive forces concentrated here by the shaft's anterior curvature. The *medial surface* is posteromedial, smooth like the others, bounded in front by the indistinct medial border and behind by linea aspera. In its *proximal third* the shaft has a fourth, *posterior surface*, bounded medially by a narrow, rough *spiral line*, continuous proximally with the intertrochanteric line, distally with the medial edge of linea aspera. Laterally this surface is limited by the broad, rough, *gluteal tuberosity*, ascending a little laterally to the greater trochanter and descending to the lateral edge of linea aspera; this surface is triangular. In its *distal third* the shaft also has a fourth, *posterior surface*, between *medial* and *lateral supracondylar ridges*, continuous above with corresponding edges of the linea aspera; the lateral is the more distinct. Proximally the medial ridge is partly obliterated where the femoral artery is close to bone, slanting back to the popliteal fossa. This *popliteal surface* (3.229A) is also triangular, in its distal medial part rough and slightly elevated.



Further details. The shaft (3.228B,229B) is surrounded by muscles and is impalpable. Its *anterior* and *lateral surfaces* are attachments in its proximal three-fourths for vastus intermedius and distal to this for slips of articularis genus. The distal anterior surface, for 5 to 6 cm above the patellar articular surface, is covered by a suprapatellar bursa, between bone and muscle. The distal lateral surface is covered by vastus intermedius. The *medial surface*, devoid of attachments, is covered by vastus medialis.

Vastus lateralis has a linear attachment from in front of the greater trochanter's base to the proximal end of the gluteal tuberosity, and along the latter's lateral margin to the proximal half of the lateral edge of the linea aspera. Similarly, the vastus medialis is attached from the distal end of the intertrochanteric line along the spiral line to the medial edge of the linea aspera and thence to the medial supracondylar line; it receives many fibres from the aponeurotic attachments of adductor magnus (vide infra).

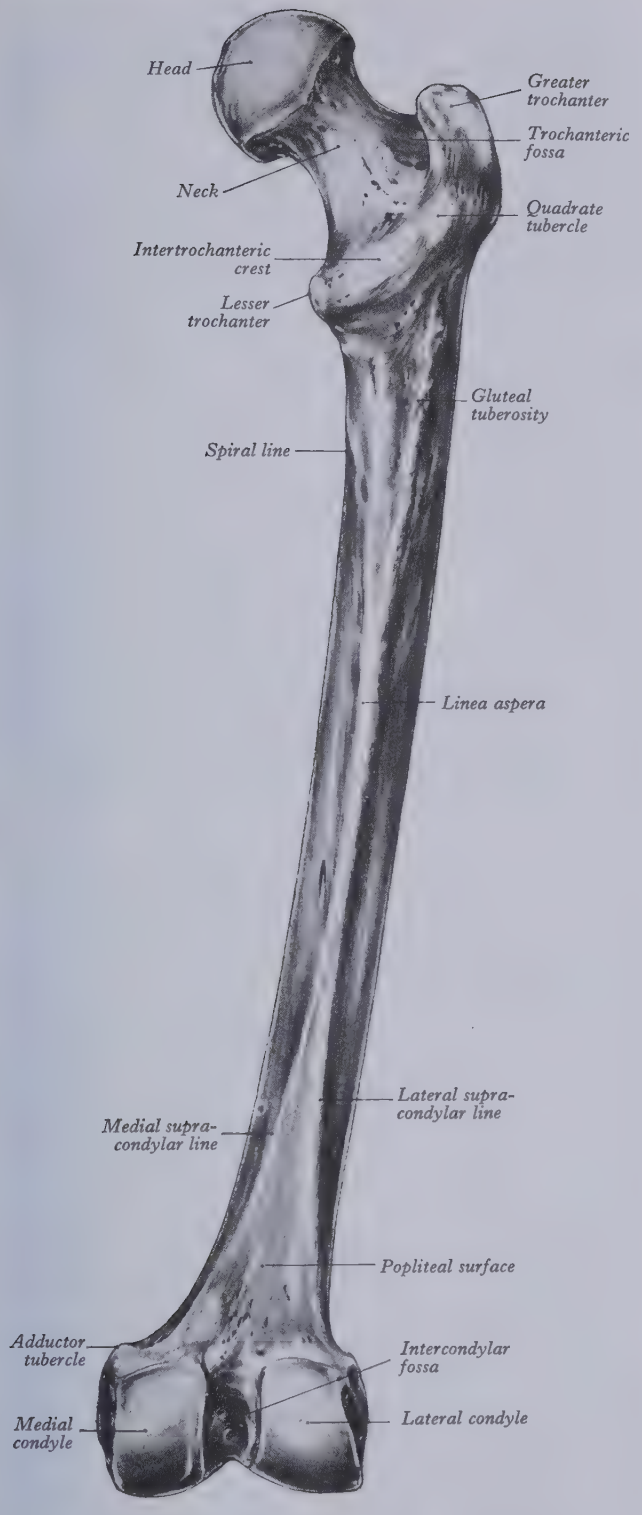


The gluteal tuberosity may be an elongate depression or a ridge. It may in part be prominent enough to be dubbed a *third trochanter*. It receives the deeper fibres of the distal half of the gluteus maximus and, at its medial edge, pubic fibres of adductor magnus, distal to which the adductor magnus is attached to the linea aspera and aponeurotically to the proximal part of the medial supracondylar ridge, remaining fibres forming a large tendon attached to the adductor tubercle (p. 438), with an aponeurotic expansion to the distal part of the medial supracondylar ridge. Lozanoff et al (1985) have devised a metrical technique associating various femoral dimensions with the incidence of a third trochanter in human femora, finding that increased incidence is associated with short femora bearing large epiphyses. Though this series is limited, the metrical technique applied is commendable.

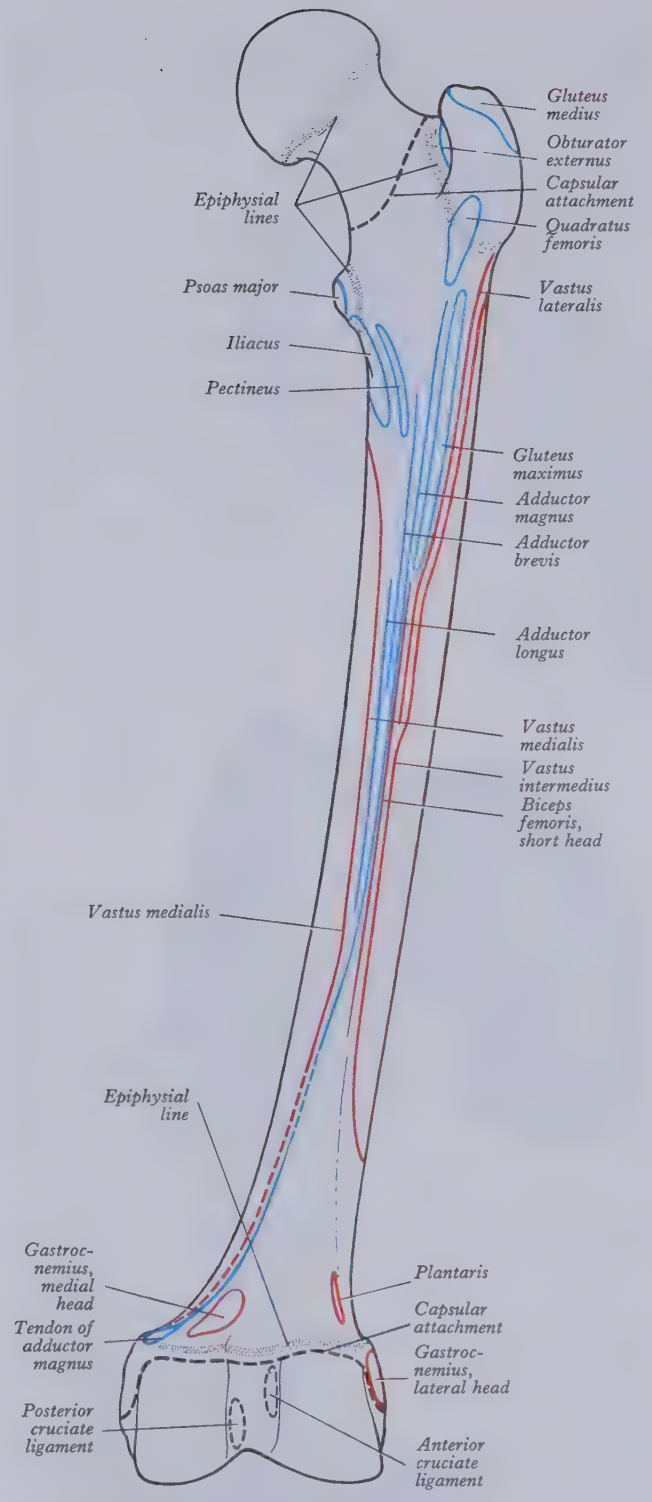
Between gluteal tuberosity and spiral line, the posterior femoral surface receives pectineus and adductor brevis, the former at a line, sometimes slightly rough, from the lesser trochanter's base to the linea aspera. The adductor brevis is attached lateral to the pectineus and beyond this to the proximal part of the linea aspera, medial to the adductor magnus.

In addition, the **linea aspera** receives adductor longus, intermuscular septa and the short head of the biceps femoris, inseparably blended at their attachment. The perforating arteries cross the linea laterally under tendinous arches in the adductor magnus and biceps. Nutrient foramina appear in the linea aspera, varying

3.228A The right femur: anterior aspect. Compare with Key, 3.228B.



3.228B Key to 3.228A. The epiphysial lines are stippled. The interrupted lines correspond to the attachments of the capsular ligaments. The dotted part of the interrupted line indicates the site of communication between the cavity of the knee joint and the suprapatellar synovial bursa.



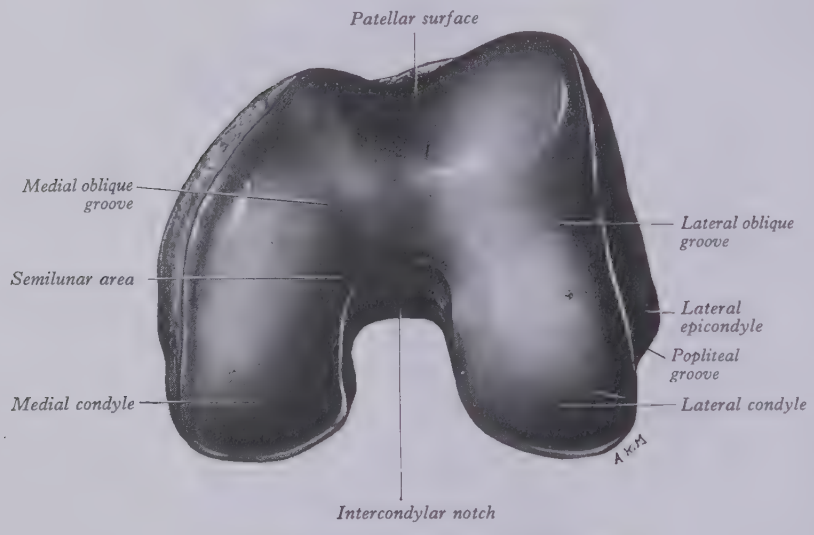
in number and site, one usually near its proximal end, usually a second near its distal end. They are directed proximally.

The popliteal surface, proximal floor of the popliteal fossa, is covered by variable amounts of fat separating the popliteal artery from bone. The superior medial genicular artery, from the popliteal artery in the intercondylar notch, arches medially above the medial condyle. It is separated from bone by the medial head of gastrocnemius, attached a little above the condyle, distal to which may be a smooth facet underlying a bursa for the medial head of the gastrocnemius. More medially, proximal to the articular surface, is often an imprint which in flexion is close to a rough tubercle on the medial tibial condyle for attachment of the semimembranosus (Kostick 1963). The superior lateral genicular artery arches up laterally proximal to the lateral condyle but separated from the bone by attachment of the plantaris to the distal part of the lateral supracondylar line.

The lateral supracondylar line is most distinct in its proximal two-thirds, where the short head of the biceps femoris

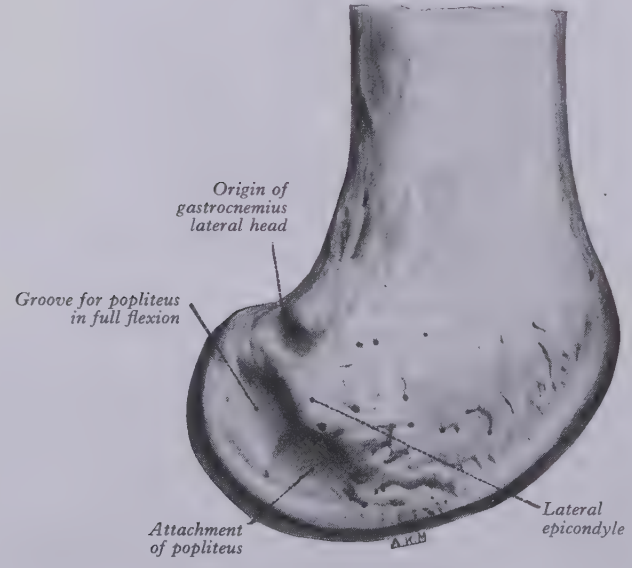
3.229A The right femur: posterior aspect. Compare with Key, 3.229B.

3.229B Key to 3.229A. The epiphysial lines are stippled; the interrupted lines indicate the attachments of the capsular ligaments.



and lateral intermuscular septum are attached. Its distal third has a small rough area for the plantaris, often encroaching on the popliteal surface. The **medial supracondylar line** is indistinct in its proximal two-thirds, where there is attachment of the vastus medialis. Proximally it is crossed by femoral vessels entering the popliteal fossa from the adductor canal. It is often sharp for 3 or 4 cm proximal to the adductor tubercle, and here the lower membranous expansion from the tendon of adductor magnus is attached.

The femur's distal end, widely expanded as a bearing surface for transmission of weight to the tibia, has two massive *condyles*, partly *articular*. Anteriorly the condyles unite and continue into the shaft, posteriorly separated by a deep *intercondylar fossa* and projecting beyond the plane of the popliteal surface. The *articular surface* is a broad area, like an inverted U, for the patella above and the tibia (3.230). The *patellar surface* extends anteriorly on both condyles, but largely the lateral; transversely concave, it is vertically convex and grooved for the posterior patellar surface. The *tibial surface* is divided by the intercondylar fossa but is anteriorly continuous with the patellar surface; its medial part is a broad strip on the convex inferoposterior surface of the medial condyle, gently curved with a medial convexity; its lateral part covers



similar aspects of the lateral condyle but is broader and passes straight back. Heiple & Lovejoy (1971) regarded a deep patellar groove as a hominid feature, concerned with bipedal gait; others disagreed. The role of the groove in preventing lateral patellar subluxation is often repeated, but remains uncertain.

The lateral condyle (3.230,231), laterally flat and less prominent than the medial, is more massive and more directly in line with the femoral shaft, hence transmits more weight to the tibia. Its most prominent point is the *lateral epicondyle*; its whole lateral aspect is palpable. A short groove, deeper in front, separates lateral epicondyle posteriorly from the articular margin. The medial surface is the lateral wall of the intercondylar fossa. Its lateral surface projects beyond the shaft. To its lateral epicondyle is attached the fibular collateral ligament and, to an impression posterosuperior to this, part of the lateral head of the gastrocnemius. Attached anteriorly in the groove is the popliteus (3.231), whose tendon is in it in full flexion; in extension it crosses the articular margin and may groove it. Adjoining the margin a strip of condyle, 1 cm broad, is intracapsular, covered by synovial membrane except for attachment of the popliteus.

The medial condyle has a bulging, convex medial aspect, easily palpable. Proximally its *adductor tubercle* (3.229A) receives the tendon of adductor magnus, an important surgical landmark most readily identified from above, but often a facet. The condyle's summit, the *medial epicondyle*, is antero-inferior to the tubercle. The medial condyle's lateral surface is the medial wall of the intercondylar fossa. The condyle projects distally so that, despite the shaft's obliquity, the profile of the distal end is almost horizontal. A curved strip, about 1 cm wide, adjoining the medial articular margin, is covered by synovial membrane and is inside the joint's capsule. The medial epicondyle, proximal to this, receives the tibial collateral ligament.

3.230 The distal end of the left femur: inferior aspect.

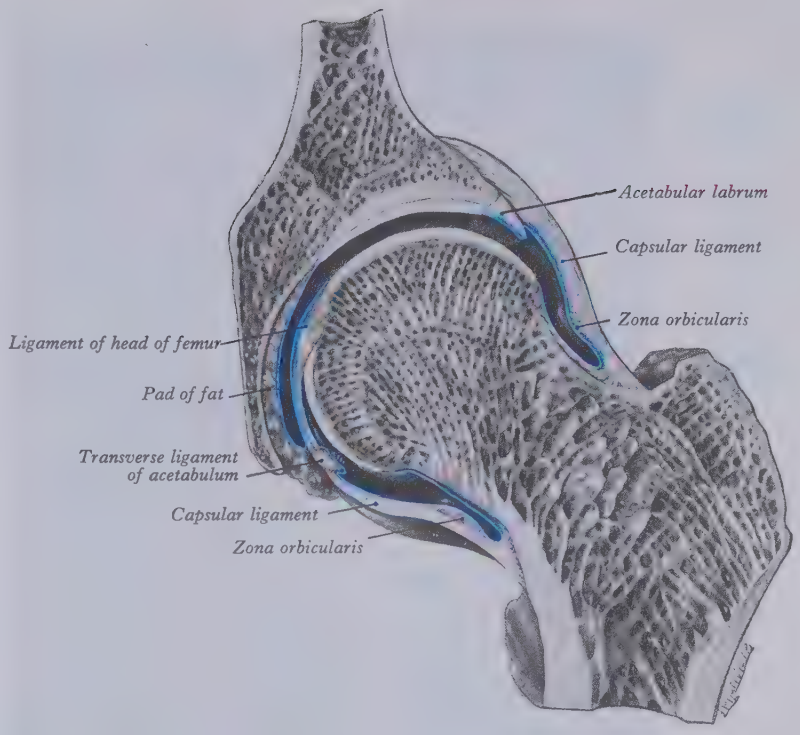
3.231 The distal end of the right femur: lateral aspect.

The intercondylar fossa separates the two condyles distally and behind. In front it is limited by the distal border of the patellar surface, behind by an *intercondylar line*, separating it from the popliteal surface. It is within the capsular ligament but covered by synovial membrane over a very limited area.

The patellar surface extends proximally more on the lateral side; its proximal border is hence oblique and runs distally and medially (3.228A,230), separated from tibial surfaces by two faint grooves, which cross the condyles obliquely. The lateral groove is more distinct (3.230); it runs laterally and slightly forwards from the front of the intercondylar fossa and expands to form a faint triangular depression, resting on the anterior edge of the lateral meniscus with the knee fully extended. The medial groove is restricted to the medial part of the medial condyle and rests on the anterior edge of the medial meniscus in full extension; where it ceases, the patellar surface continues back to the lateral part of the medial condyle as a semilunar area adjoining the anterior region of the intercondylar fossa; this area articulates with the patella's medial vertical facet in full flexion; it is not distinct in outline in most femora. In habitual squatters articular cartilage may extend to the lateral aspect of the lateral condyle under vastus lateralis.

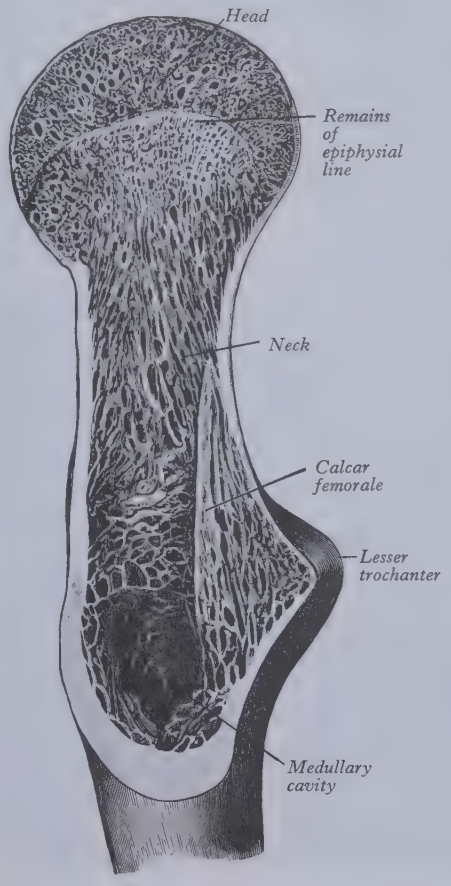
The tibial surfaces are transversely convex in all directions. Anteroposterior curvature of both surfaces is not uniform, with a shorter radius posteriorly; the medial surface is longer anteroposteriorly, and has a slight laterally concave profile. These differences are important determinants of rotatory movements, adjunct and conjunct (p. 481), at the knee joint (p. 530).

The intercondylar fossa, between projecting parts of condyles, is intracapsular but largely extrasynovial. Its lateral wall, the medial surface of the lateral condyle, has a flat, posterosuperior impression spreading to the fossa's floor near the intercondylar line for proximal attachment of the anterior cruciate ligament. The fossa's medial wall, lateral surface of the medial condyle, bears a similar larger area for proximal attachment of the posterior cruciate ligament, sited anteriorly and extending to the fossa's anterior floor. Both impressions are smooth, and largely devoid of vascular foramina like most attachments of tendons or ligaments; the rest of the fossa is rough and pitted by vascular foramina, but a bursal recess between the ligaments may ascend to it. To the *intercondylar line* is attached the capsular ligament and, laterally, the oblique popliteal ligament, and to the fossa's anterior border, the infrapatellar synovial fold (p. 527).



Structure. The femoral shaft is a cylinder of compact bone, with a large medullary cavity. The wall is thick in its middle third, where the femur is narrowest and the medullary cavity most capacious; but proximally and distally the compact wall is progressively thinner, the cavity gradually filling with trabecular bone; the extremities, especially where articular, consist of trabecular bone within a thin shell of compact bone; their trabeculae are disposed along lines of greatest stress (p. 524). In the proximal end (3.232,233) the main trabeculae form a series of plates orthogonal to the articular surface, converging to a central dense wedge, which is supported by strong trabeculae passing to the sides of the neck, especially along its upper and lower profiles. Force applied to the femoral head is hence transmitted to the wedge and thence to the junction of neck and shaft. This junction is strengthened by dense trabeculae extending laterally from the lesser trochanter to the end of the neck's superior aspect, thus resisting tensile or shearing forces applied to the neck through the head. A smaller bar across the junction of the greater trochanter with the neck and shaft resists shearing due to muscles attached to it. These two bars are proximal layers of arches between the sides of the shaft, transmitting to it forces applied to the proximal end. A thin vertical plate, *calcar femorale* (3.233), ascends from the compact wall near the linea aspera into the trabeculae of the neck. Medially it joins the posterior wall of the neck, laterally it continues into the greater trochanter, dispersing into general trabecular bone. It is thus in a plane anterior to the trochanteric

crest and base of the lesser trochanter. Scanning electron microscopy of the proximal femoral end, in a small series of specimens, has partly confirmed these details (Whitehouse & Dyson 1974). Wide variation in metrical parameters of trabecular pattern in the femoral head and neck was nevertheless observed. Tensile and compressive tests of 40 human femora also indicate that axial trabecular tissue of the femoral head withstands much greater stresses than do peripheral trabeculae. In the distal femoral end trabeculae spring from the entire internal surface of compact bone, descending perpendicular to the articular surface; proximal to condyles these are strongest and most accurately perpendicular. Horizontal planes of trabecular bone, arranged like crossed girders, form a series of cubical compartments.



Ossification (3.228B,229B,234) of the femur is from five centres: in the shaft, head, greater and lesser trochanters and the distal end. Excepting the clavicle, it is the first long bone to ossify, this beginning in midshaft in the seventh prenatal week and extending to produce a miniature shaft largely ossified at birth. Secondary centres appear in the distal end during the ninth month (from which condyles and epicondyles are formed), in the head during the first six months after birth, in the greater trochanter during the fourth year and in the lesser between twelfth and fourteenth. Note that the centre in the cartilaginous head is restricted to it until the tenth year, so that the epiphysial line (3.218) is horizontal and the inferomedial part of the articular surface is on the neck (3.234). The medial epiphysial margin later grows over this part of the articular surface. Thus, the mature epiphysis is a *hollow cup* on the neck's summit. The epiphysial line follows the articular margin except where separated superiorly from the articular surface by a non-articular area; here blood vessels enter the head (Trueta 1957, Smith 1962a). The epiphyses fuse independently, the lesser trochanter soon after puberty, then the greater, the head at the fourteenth year in females, seventeenth in males, and the distal end at the sixteenth year in females, eighteenth in males. Note that the distal epiphysial plate traverses the adductor tubercle (3.228B).

Applied Anatomy. The distal femoral end is the only epiphysis in which ossification constantly starts just before birth, a most reliable indicator that a dead newborn child was viable. Since the epiphysial plate is level with the adductor tubercle, the epiphysis does not form all the distal end covered by synovial membrane; hence operations here may damage the distal epiphysial cartilage in children and entail subsequent shortening of the leg. Fractures of the femoral neck are usually due to transmitted stress, as in tripping over obstructions. The trunk continues to advance and, overbalancing, twists and imposes excessive medial rotation on thigh and leg. Before 16 years the usual injury is a spiral fracture of the shaft, but between 16 and 40 a crescentic tear of the medial meniscus is frequent. Between 40 and 60, a common result is fracture of the foreleg, but over 60, fracture of the femoral neck is common, because of osteoporotic changes in ageing bones. Women are more liable, their bones being lightly built.

Normally, with lower limb aligned with trunk, the greater trochanter's apex is on the line joining the anterior superior iliac spine and the most prominent part of the ischial tuberosity (Nelaton's line). In displacements due to fracture of the neck the trochanter may be above this line.

The Patella

The patella (3.235–237), the largest sesamoid bone, is embedded in the tendon of quadriceps femoris anterior to the knee joint. Flat, distally triangular, proximally curved, it has anterior and posterior surfaces, three borders and an apex. In the living, when standing, its distal apex is a little proximal to the line of the knee joint.

The convex *anterior surface*, subcutaneous, is perforated by nutrient vessels. It is longitudinally striated, separated from skin by a prepatellar *bursa* and covered by an expansion from the tendon of quadriceps femoris, which blends distally with superficial fibres of the so-called patellar *ligament*, strictly the continued *tendon* of quadriceps. The *posterior surface* has a proximal smooth, oval, articular area, crossed by a smooth vertical ridge, which fits the

3.234 Stages in the ossification of the femur. Note how the neck, which is ossified as an extension from the shaft, invades, and is partly enclosed by, the cartilaginous head (not to scale).

groove on the femoral patellar surface and divides the patellar articular area into medial and lateral facets, the lateral being larger. The 'ridge' and flanking facets are, of course, continuously covered by articular cartilage. (Degenerative changes in this cartilage, associated with ageing, have been reported by Meachim 1982.) A narrow strip, proximally broader, is marked off medially from the medial facet; this contacts the medial femoral condyle in extreme flexion. Distal to the articular surface the *apex* is roughened by attachment of ligamentum patellae and, proximal to this, the area between the roughened apex and articular surface is covered by an infrapatellar pad of fat.

The thick *superior border* slopes down and forwards; except near its posterior margin, it is an attachment for quadriceps femoris (rectus femoris and vastus intermedius). The *medial* and *lateral borders* are thinner and converge distally, and to them are attached expansions of the tendons of vastus medialis and lateralis termed the *medial* and *lateral patellar retinacula* (p. 527). The lateral retinaculum receives accessions from the iliotibial tract. Near the superolateral angle is a shallow, circular depression for a distinct part of the tendon of vastus lateralis (vasti medialis and lateralis).

Structure. The patella consists of almost uniformly dense trabecular bone, covered by a thin compact lamina. Trabeculae beneath the anterior surface are parallel with it; elsewhere they radiate from the articular surface to other parts.

Ossification. Several centres appear during the third to sixth years and quickly coalesce. Accessory marginal centres appear later and fuse with the central mass (Hellmer 1935, Prakash et al 1979).

The Tibia

The tibia (3.238–240), medial to and much stronger than the fibula, is exceeded in length only by the femur. Its shaft is prismoid in section, with expanded ends, the smaller distal end having a strong *medial malleolus* projecting distally. The anterior border is sharp, curving medially towards this malleolus; the anterior, together with medial and lateral borders, defines three surfaces.

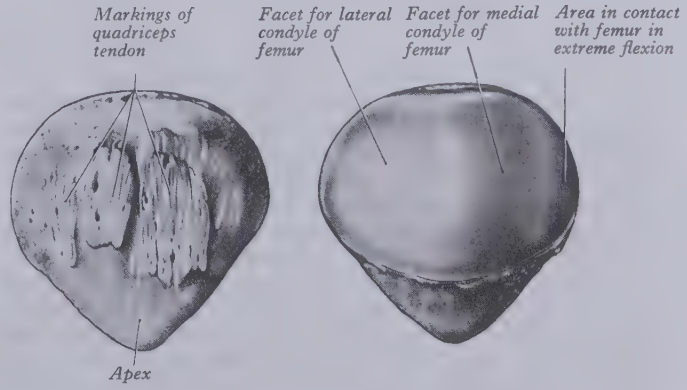
3.236 Anteroposterior (A) and lateral (B) radiographs of the knee in a boy aged 14. 1. Patella. 2. Intercondylar eminences. 3. Cartilaginous growth plates with adjacent epiphyses. 4. Prolongation of proximal tibial epiphysis and growth plate forming the tibial tuberosity.

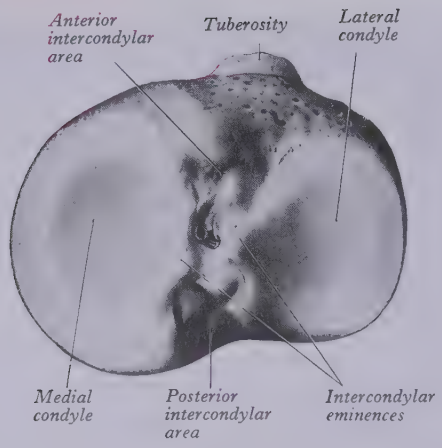
The proximal end, expanded especially transversely, is a bearing surface for body weight transmitted through the femur; it has massive *medial* and *lateral condyles*, an intercondylar area and tibial tuberosity. The condyles overhang the shaft's proximal posterior surface, and both have proximal articular surfaces separated by the irregular intercondylar area. The condyles are visible and palpable at the sides of the ligamentum patellae, the lateral being more prominent. In the passively flexed knee the anterior *margins* of the condyles are palpable in fossae flanking the patellar ligament.

The medial condyle is larger but projects less. Its *oval* articular surface (3.238A–C) is concave and its lateral border, deepening the concavity, extends on to a *medial intercondylar tubercle*. Its posterior surface, distal to the articular margin, has a horizontal, rough groove; its anteromedial surface is a rough strip, separated from the shaft's medial surface by an inconspicuous ridge.



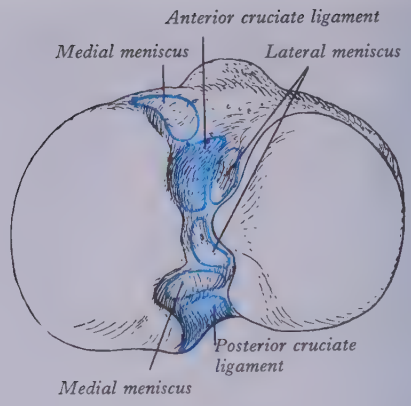
The lateral condyle overhangs the shaft posterolaterally above a small circular facet for articulation with the fibula. The proximal, articular surface (3.238A–C) for the lateral femoral condyle is almost *circular*, centrally concave, its medial border extending on a *lateral intercondylar tubercle*. Its posterior, lateral and anterior edges are rough.

Anterior condylar surfaces are continuous with a large triangular area; its apex is distal and formed by the tibial tuberosity, whose lateral edge is a sharp ridge between the lateral condyle and lateral surface of the shaft.

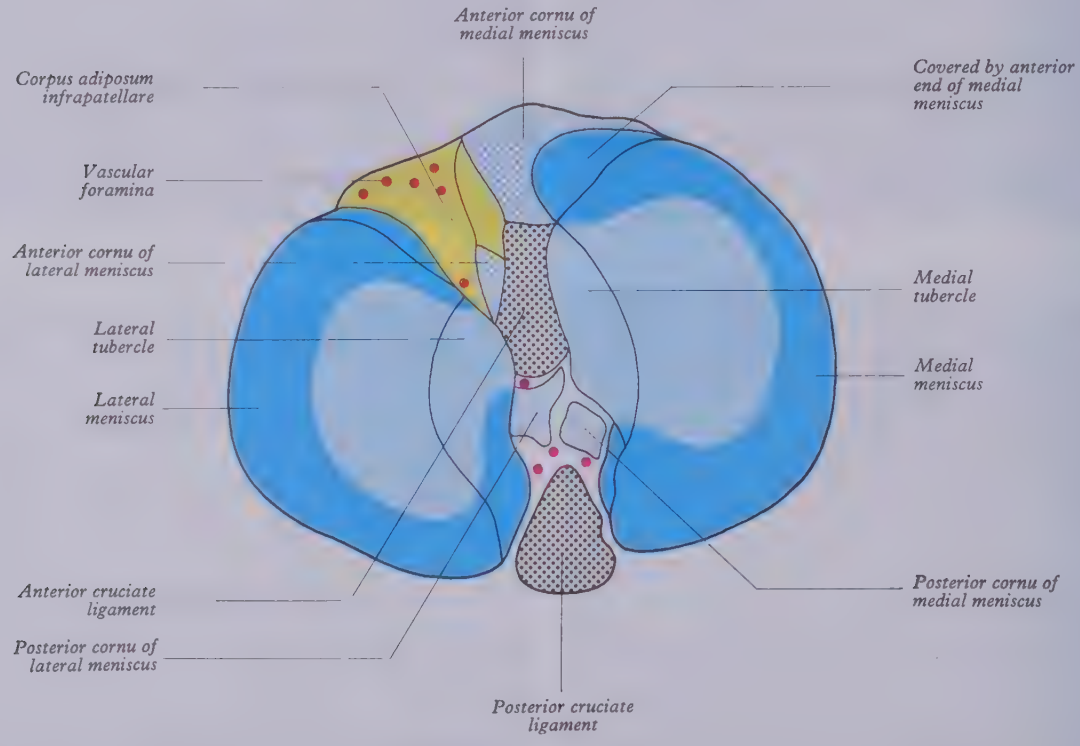


The intercondylar area (3.238A–C), between the condylar articular surfaces, is rough, narrowest centrally and here forms an *intercondylar eminence*, edges of which project slightly proximally as *lateral* and *medial intercondylar tubercles*. At the back and front of the eminence the intercondylar area widens as the articular surfaces diverge.

The tibial tuberosity, at the proximal end of the anterior border, is the truncated apex of a triangular area, mentioned above, where anterior condylar surfaces merge. It projects little, and is divided into a distal rough and a proximal smooth region. The former is palpable, separated from skin merely by a subcutaneous *infrapatellar bursa*; to the proximal part the ligamentum patellae is attached.



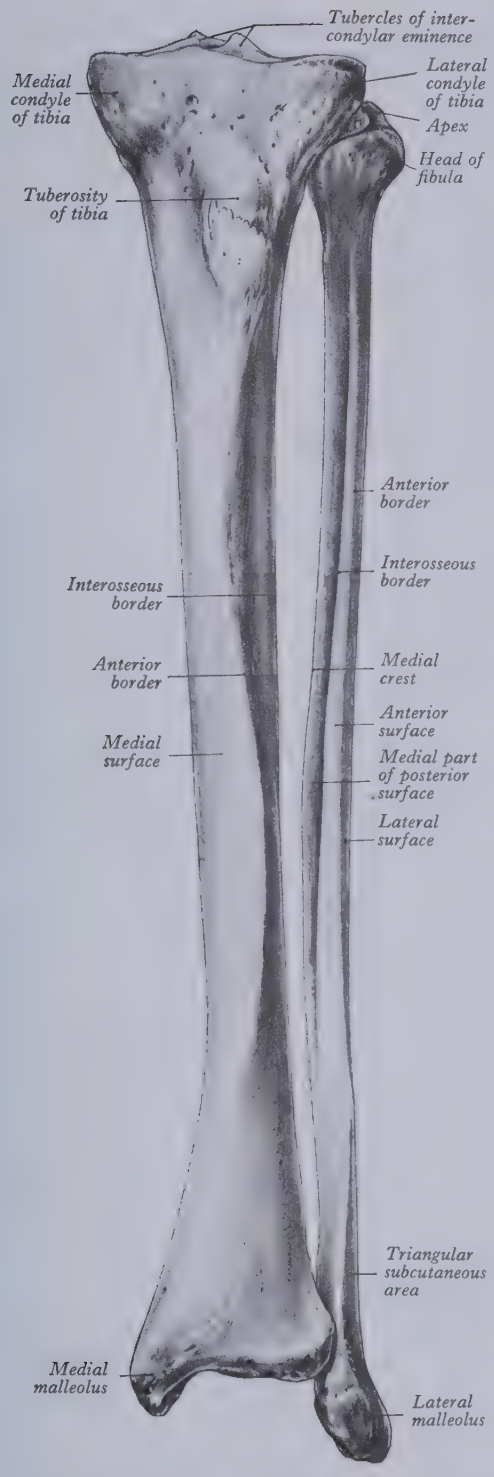
The proximal tibial surface slopes posteriorly and downwards relative to the shaft's long axis; the tilt, maximal at birth, decreases with age; it is more marked in habitual squatters (Kate & Robert 1965). The *medial articular surface* is *oval* (long axis anteroposterior) and perceptibly longer in conformity with differences between the femoral condyles (p. 438). Around its anterior, medial and posterior margins it is related to the medial meniscus, the area of contact being flat. The meniscal imprint, wider behind, narrower anteromedially, is often discernible. The surface is otherwise concave; its raised lateral margin partly invades the medial intercondylar tubercle. The *lateral articular surface* is more *circular*; like the medial it is adapted to its meniscus. Elsewhere the surface, slightly concave to fit the femoral condyle, has a raised medial margin spreading to the lateral intercondylar tubercle. Its articular margins are sharp, except posterolaterally, where the edge is round and smooth; here the tendon of popliteus is in contact with bone.



3.237 The left patella: anterior and posterior aspects, drawn from a fresh, unmacerated specimen, with the articular cartilage preserved.

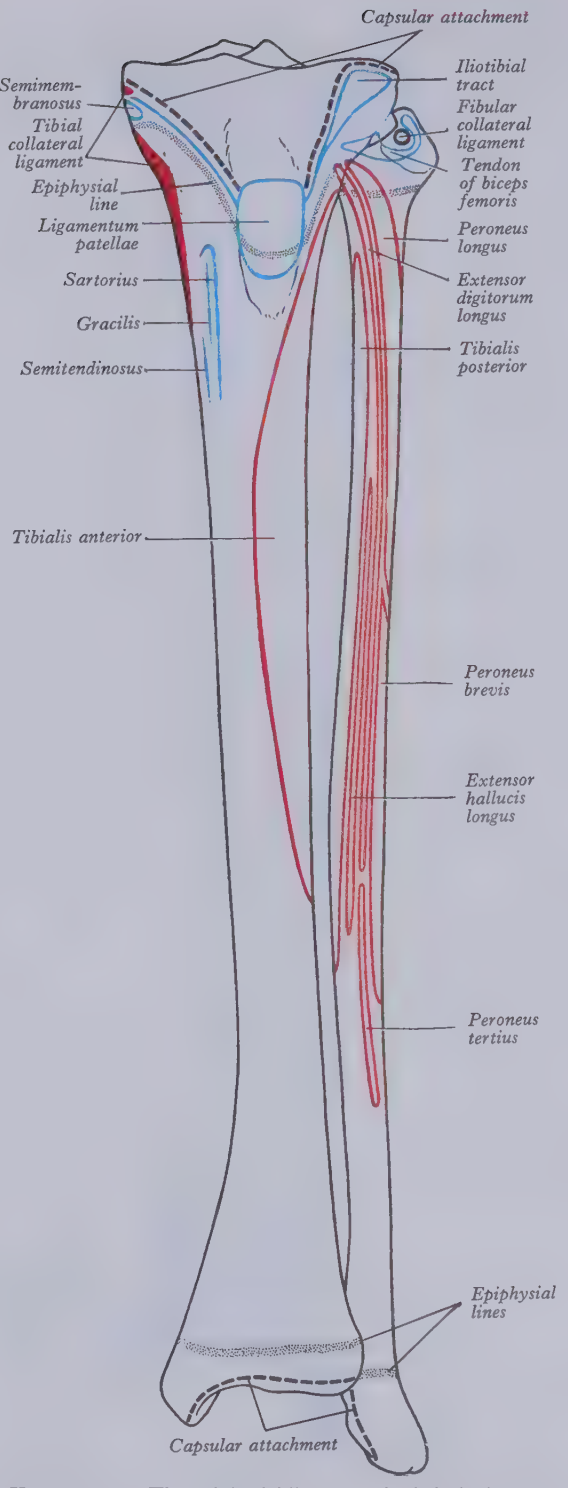
3.238A The proximal articular surface of the right tibia. The imprints of the menisci were very conspicuous in this specimen.

3.238B Outline of A showing the attachments of the menisci and cruciate ligaments.



3.238C Detailed analysis of the surface features of the proximal aspect of the human tibia (left). The condylar areas are shown in full blue, the parts in contact with the menisci being in deep blue, while the remaining condylar regions are in light blue. The attachments of the meniscal cornua are in blue stipple, and those of the cruciate ligaments are in black stipple. The yellow area indicates the extent of contact with the corpus adiposum and the red dots signify vascular foramina. (Adapted with permission from Klaus Jacobsen, Department of Orthopaedic Surgery, The Gentofte Hospital, Copenhagen, *Journal of Anatomy* and Cambridge University Press.)

The anterior intercondylar area (3.238B,C), widest anteriorly, bears on its anteromedial area, anterior to the medial articular surface, a depression in which the anterior cornu of the medial meniscus is attached. Behind this a smooth area receives the anterior cruciate ligament. The anterior cornu of the lateral meniscus is attached anterior to the intercondylar eminence, lateral to the anterior cruciate ligament. The eminence, with medial and lateral tubercles, is the narrow, central part of the area. To its posterior slope the posterior cornu of the lateral meniscus is attached and behind this a **posterior intercondylar area** inclines down and back. A depression behind the base of the medial intercondylar tubercle is for the posterior cornu of the medial meniscus. The rest of the area is smooth and for attachment of the posterior cruciate ligament, spreading back to a ridge for the capsular ligament.



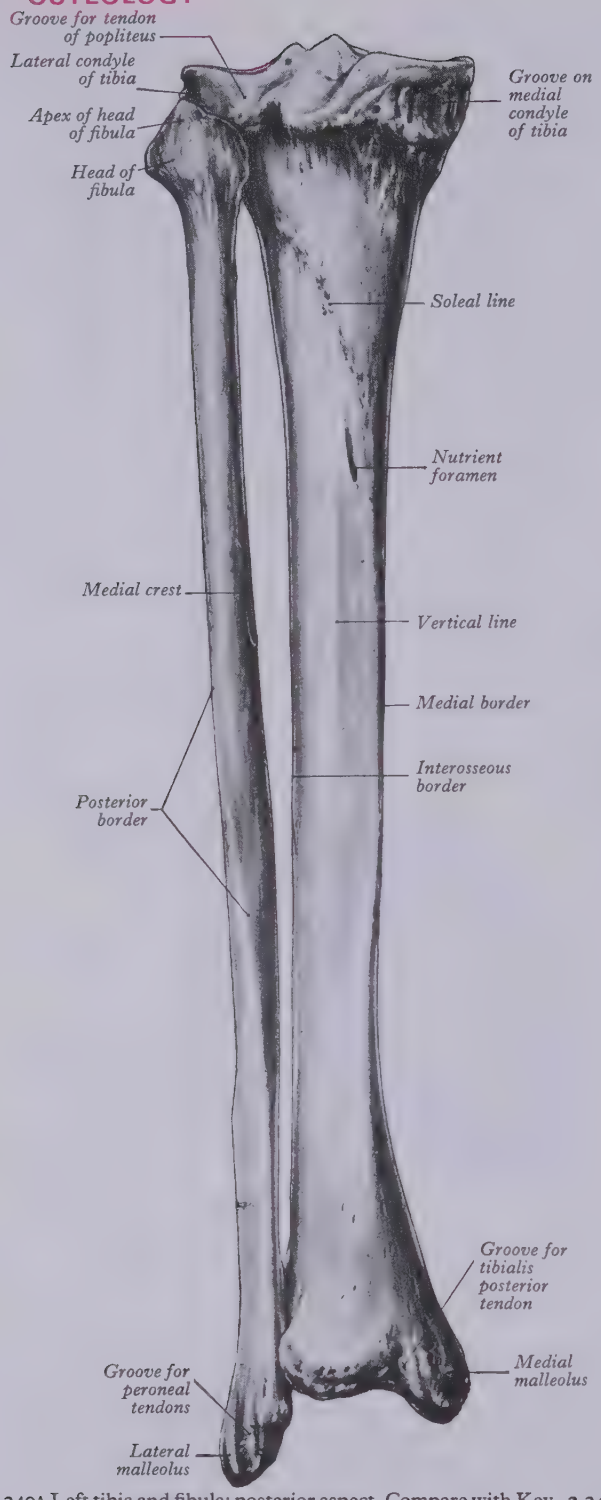
To the proximal edge of the groove on the medial condyle's posterior surface are attached the capsular and posterior part of the tibial collateral ligaments; its distal edge receives the semimembranosus. At the lateral end of the groove a tubercle is the main attachment of the tendon of semimembranosus (Cave & Porteous 1958). To medial and anterior condylar surfaces, marked by vascular foramina, the medial patellar retinaculum is attached.

Measurement of 13 healthy knee joints, with observations on 75 macerated specimens, yielded a highly detailed plan of ligamentous and other attachments (Jacobsen 1974 and 3.238C); much variation was noted; dense fibrous attachments produced facets, separated by more porous areas (p. 444).

The tibia has been investigated stereometrically by Ljungren (1976); analysis confirmed functional adaptation of curvatures

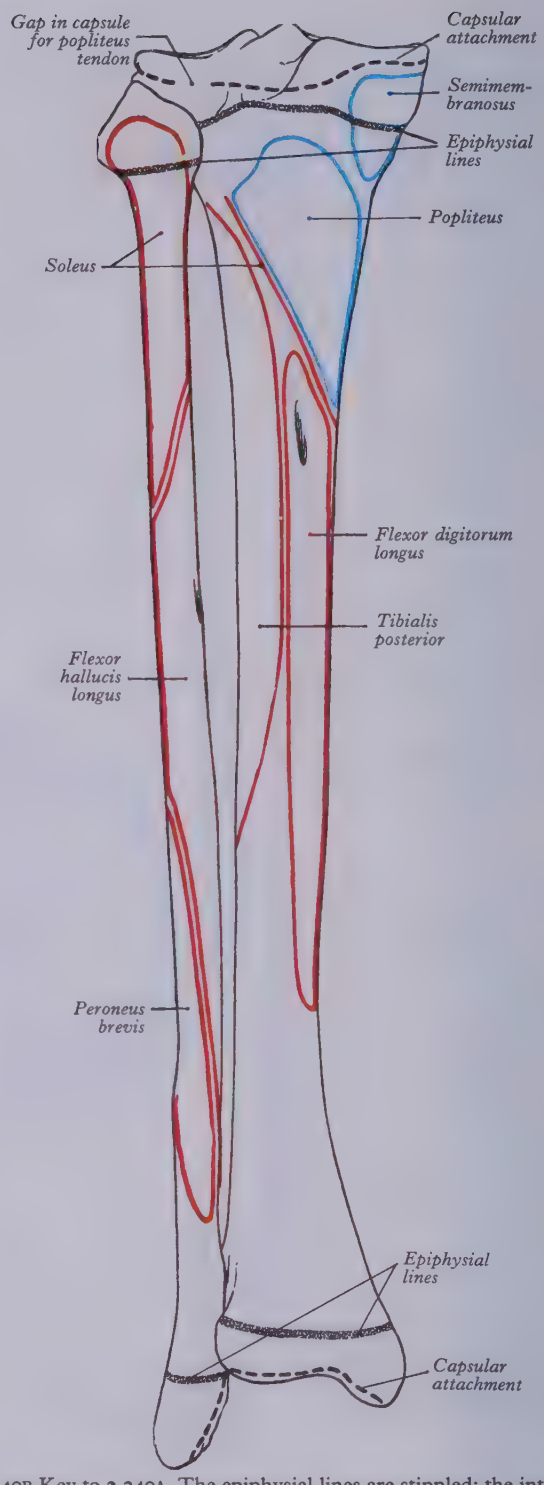
3.239A Left tibia and fibula: anterior aspect. Compare with key, 3.239B.

3.239B Key to 3.239A. The epiphysial lines are stippled; the interrupted lines correspond to the attachments of the capsular ligaments.



and inclinations of tibial condyles and tuberosity, and these were correlated with habits of locomotion in different racial groups.

The fibular facet on the lateral condyle faces distally and posterolaterally. Superomedial to it the condyle is grooved posteriorly by the tendon of popliteus, with a synovial recess between tendon and bone. The condyle's anterolateral aspect is separated from the shaft's lateral surface by a sharp margin for attachment of deep fascia. The iliotibial tract makes a flat but definite marking (triangular and facet-like) on its anterior aspect. Slips from the tendon of biceps femoris are attached anteroproximal to the fibular facet, distal to which proximal fibres of extensor digitorum longus and occasionally peroneus longus are attached.



A line across the **tibial tuberosity** marks the distal limit of the epiphysial line (3.239B and p. 445); ligamentum patellae is attached to the smooth bone proximal to this, its superficial fibres reaching a rough area distal to the line; the attachment may be marked distally by a slight ridge (Lewis 1958a). Distally the tuberosity is subcutaneous; proximal to it bone is related to the deep aspect of the ligamentum patellae, but a *deep infrapatellar bursa* and fibroadipose tissue intervene. In habitual squatters a vertical groove on the anterior surface of the lateral condyle is occupied by the ligament's edge in flexion.

The shaft (3.239A,B,240A,B), triangular in section, has medial, lateral and posterior surfaces, separated by anterior, lateral (interosseous) and medial borders. It is thinnest at the junction of middle and distal thirds, expanding towards both ends.

The *anterior border* descends from the tuberosity to the anterior margin of the medial malleolus and is subcutaneous throughout;

3.240A Left tibia and fibula: posterior aspect. Compare with Key, 3.240B.

3.240B Key to 3.240A. The epiphysial lines are stippled; the interrupted lines correspond to the attachments of the capsular ligaments.

except in its distal fourth, where it is indistinct, it is a sharp crest, slightly sinuous and turning medially in its distal fourth. The *interosseous border* commences distal and anterior to the fibular facet and descends to the anterior border of the fibular notch; to most of it is attached the interosseous membrane, connecting tibia to fibula; above it is indistinct. The *medial border* descends from the anterior end of the groove on the medial condyle to the posterior margin of the medial malleolus. Its proximal and distal fourths are ill-defined, its middle region sharp.

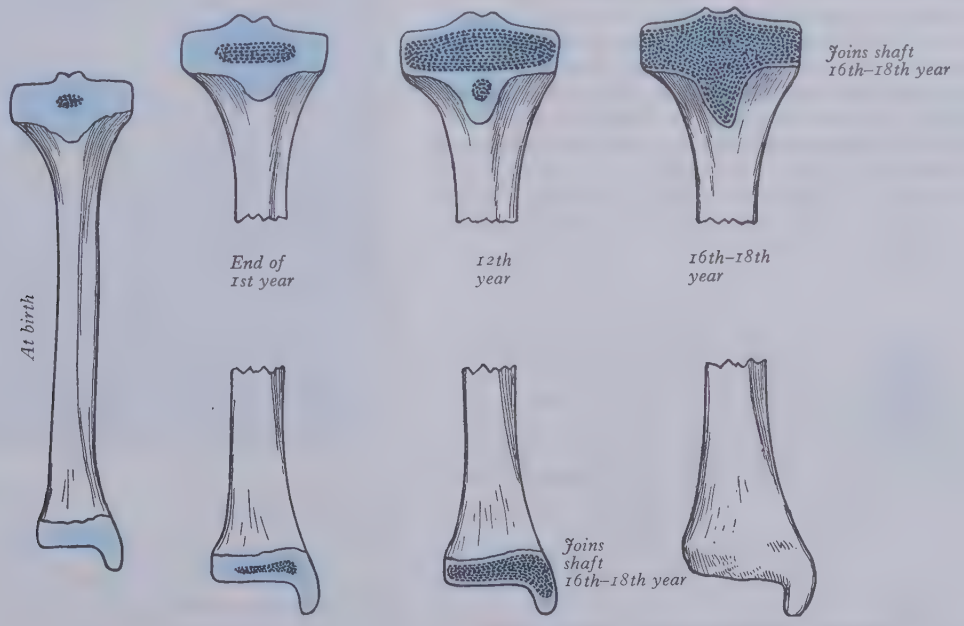
The *medial surface* (really *antero*-medial), between anterior and medial borders, is broad, smooth and almost entirely subcutaneous. The broad, smooth *lateral surface*, between anterior and interosseous borders, faces laterally in its proximal three-fourths and is transversely concave. Its distal quarter swerves anteriorly, due to medial deviation of the anterior and distal interosseous borders. This part of the surface is somewhat convex. The *posterior surface*, between interosseous and medial borders, is widest above, where it is crossed distomedially by an oblique, rough *soleal line* (3.240A), from the centre of which a faint *vertical line* descends but soon fades. A large vascular groove adjoins the line's end, descending distally into bone; it may be lateral or medial to the vertical line. To the *anterior border* is attached crural deep fascia and, proximal to the medial malleolus, the medial end of the superior extensor retinaculum. Proximal to the soleal line the *medial border* is an attachment of popliteal fascia, the posterior fibres of the tibial collateral ligament and slips of semimembranous; distal to it some fibres of soleus and fascia covering deep crural muscles are attached. The distal medial

border merges into the medial lip of a groove for the tendon of tibialis posterior. To the *lateral border* interosseous membrane is attached, except at its extremes. It is proximally indistinct where a large gap in the membrane transmits anterior tibial vessels; distally the border is the anterior boundary of the fibular notch; the anterior tibiofibular ligament is attached to it.

The *medial surface* bears proximally, near the medial border, an area about 5 cm long and 1 cm wide for the anterior part of the tibial collateral ligament and, behind this, semimembranosus; anterior to this are from before, backwards, linear attachments of the tendons of sartorius, gracilis and semitendinosus, which rarely mark the bone (**3**.239B). The remaining surface is subcutaneous but crossed obliquely by the great saphenous vein ascending from *in front* of the medial malleolus.

The *lateral surface* is, in its proximal two-thirds, an attachment for the tibialis anterior. Its distal third, devoid of attachments, is crossed by the tendon of tibialis anterior (lateral to the anterior border), extensor hallucis longus, anterior tibial vessels and nerve, extensor digitorum longus and peroneus tertius, in mediolateral order.

To the *posterior surface* popliteus is attached in a triangular area proximal to the soleal line, except near the fibular facet, and to the *soleal line* the popliteal aponeurosis, soleus and its fascia and deep transverse crural fascia. Proximally the line does not reach the interosseous border and has a tubercle for the medial end of the tendinous soleal arch; lateral to it the posterior tibial vessels and nerve descend on tibialis posterior. Distal to the soleal line, the *vertical line* separates attachments of flexor digitorum longus (medial) and tibialis posterior (**3**.240B). The surface's distal quarter has no attachments, but is crossed medially by the tendon of tibialis posterior travelling to a posterior groove on the medial malleolus. Flexor digitorum longus crosses obliquely behind the tibialis posterior; but posterior tibial vessels and nerve and flexor hallucis longus contact only the lateral part of the distal posterior surface.



The tibia's distal end, slightly expanded, has anterior, medial, posterior, lateral and distal surfaces. It projects inferomedially as the medial malleolus.

Its smooth *anterior surface* bulges beyond the distal surface, separated from it by a narrow groove, continuing the shaft's lateral surface (p. 443). The *medial surface*, smooth and continuous above and below with medial surfaces of shaft and malleolus, is subcutaneous and visible. The *posterior surface* is crossed near its medial end by a nearly vertical, but slightly oblique groove, usually conspicuous, extending to the posterior surface of the malleolus; elsewhere it is smooth and continuous with the shaft's posterior surface. The *lateral surface* is the triangular *fibular notch*, bound by ligaments to the fibula; its anterior and posterior edges project and converge proximally to the interosseous border. The floor of the notch is roughened proximally by a substantial interosseous ligament, but is smooth distally and sometimes covered by articular cartilage. The *distal tibial surface*, articulating with the talus, is wider in front, concave sagittally and transversely slightly convex (i.e. it is *sellar*). Medially it continues into the malleolar articular surface. This articular surface may extend into the groove (vide supra) separating it from the shaft's anterior surface. Such extensions, medial or lateral or both, are *squatting facets*, articulating with reciprocal talar facets (p. 450) in extreme dorsiflexion. These features have been used in racial evaluation (p. 273).

The medial malleolus, short and thick, has a smooth lateral surface with a crescentic facet articulating with the medial talar surface. Its anterior aspect is rough and its posterior continues the groove on the shaft's posterior surface. The distal border is pointed anteriorly, posteriorly depressed.

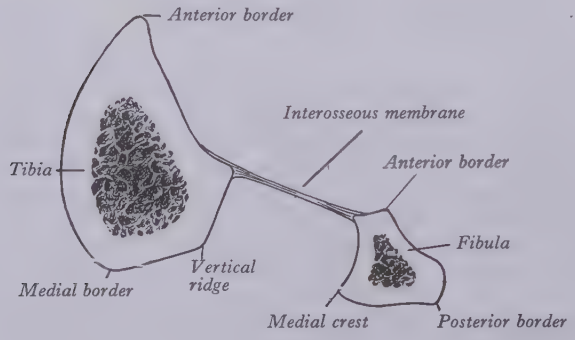
The distal end is related anteriorly to tendons, vessels and nerves lateral to the tibial shaft (vide supra). To an anterior groove near the articular surface, the articular capsule of the ankle joint is attached. The posterior groove is adapted to the tendon of tibialis posterior, which usually separates that of flexor digitorum longus from bone. More laterally, posterior tibial vessels and nerve and flexor hallucis longus are in contact with this surface. To the edges of the *fibular notch* are attached anterior and posterior tibiofibular ligaments. The *medial malleolus* ends proximal to the lateral malleolus, which is also more posterior in plane. To its anterior surface is attached the ankle joint's articular capsule. To the groove for the posterior tibial tendon, on its prominent medial border, the flexor retinaculum is attached. The deltoid ligament, proximal to the distal malleolar border, is attached to its apex and depression.

Ossification of the tibia is by three centres (**3**.239B, 240B,241) in the shaft and both epiphyses. It begins in midshaft about the seventh intrauterine week. The proximal epiphysial centre is usually present at birth; at about 10 years a thin anterior process from it descends to form the smooth part of the tibial tuberosity (**3**.241), but a separate centre for this may appear about the twelfth year, soon fusing with the epiphysis. Distal strata of the epiphysial plate are of dense collagenous tissue, the fibres of which are aligned with the ligamentum patellae. This peculiar structure is attributed to large tensile stresses transmitted via the ligament (Lewis 1958a, Smith 1962b). The distal epiphysial centre appears early in the first year, joining the shaft about the fifteenth in females, seventeenth in males. The proximal epiphysis fuses in the sixteenth year in females, eighteenth in males. The medial malleolus is an extension from the distal

3.241 Stages in the ossification of the tibia (not to scale).

epiphysis, commencing to ossify in the seventh year; it may have a separate centre.

The Fibula



The fibula (3.239–244) is much more slender than the tibia, not being directly involved in transmission of weight. It has a proximal *head*, a long *shaft* and a distal *lateral malleolus*. A thinner part near the head is the *neck*. The shaft varies in form, being variably moulded by attached muscles; these variations may be confusing.

The head, slightly expanded, projects in front, behind and laterally. A round facet, on its proximomedial aspect, articulates with a facet on the inferolateral surface of the lateral tibial condyle; it faces proximally and anteromedially. A blunt *apex (styloid process)* projects proximally from its posterolateral aspect, palpable about 2 cm distal to the knee joint. The common peroneal nerve crosses posterolateral to the neck and can be rolled against bone, causing tingling sensations on the dorsum of foot and toes, especially on the medial side of the hallux.

The distal end or **lateral malleolus** projects distally and posteriorly. Its *lateral aspect* is subcutaneous; its *posterior aspect* has a broad groove with a prominent lateral border. Its *anterior aspect* is rough, round and continuous with the tibial inferior border. The *medial surface* has a triangular articular facet, vertically convex, its apex distal (3.244); it articulates with the lateral talar surface. Behind the facet is a rough *malleolar fossa*.

The shaft (3.239,240) has three borders and surfaces, each associated with a particular group of muscles. The *anterior border* ascends proximally from the apex of an elongated, triangular area continuous with the lateral malleolar surface (vide infra), to the anterior aspect of the fibular head. The *posterior border*, continuous with the medial margin of the posterior groove on the lateral malleolus, is usually distinct distally, but often rounded in its proximal half. The *interosseous border* is medial to the anterior border and usually more posterior (3.242); but in the proximal two-thirds of the bone they approximate, the 'surface' being narrowed to 1 mm or less.

The *lateral surface*, between anterior and posterior borders and associated with peroneal muscles, faces laterally in its proximal three-fourths, the distal quarter twists (spirals) to become continuous with the *posterior groove* of the lateral malleolus. The *anteromedial* (sometimes simply termed *anterior*, or *medial* unqualified) *surface*, between anterior and interosseous borders, usually faces anteromedially but often forwards. Distally wide, it narrows in its proximal half and may be a mere ridge; it is associated with extensor muscles. The *posterior surface*, the largest, between interosseous and posterior borders, is associated with flexor muscles. Its proximal two-thirds is divided by a longitudinal *medial crest*, separated from the interosseous border by a grooved surface, directed medially; the rest of the surface faces back in its proximal half, but its distal half curves on to the medial aspect; distally this area occupies the tibia's fibular notch, roughened by the attachment of the principal interosseous tibiofibular ligament.

3.244 The lower end of the left fibula: medial aspect.

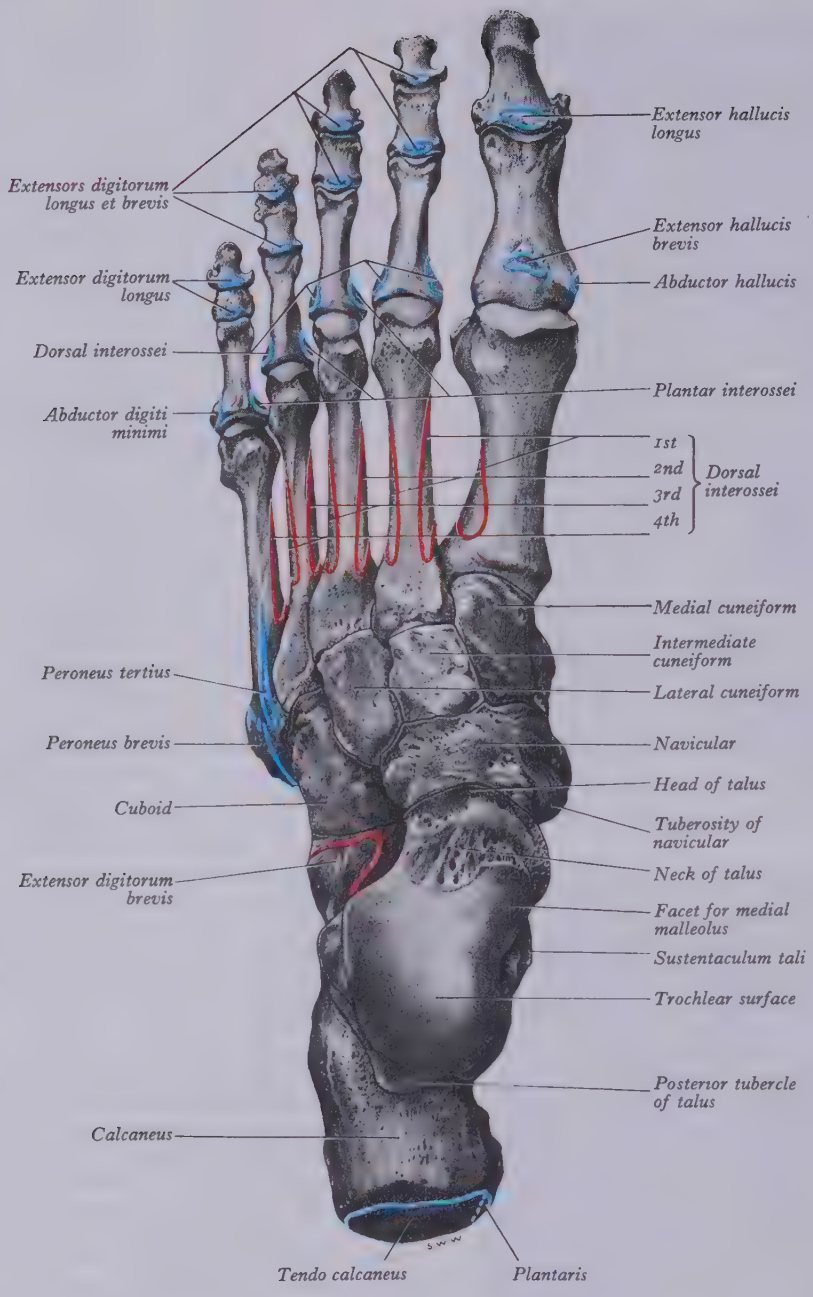
3.245 Stages in the ossification of the fibula.

The triangular area proximal to the lateral surface of the lateral malleolus (3.239A) *is subcutaneous*; the rest of the shaft is obscured by muscles. To the *fibular head* are attached extensor digitorum longus in front, peroneus longus anterolaterally and soleus behind; the fibular collateral ligament is attached in front of its apex and embraced by the main attachments of biceps femoris. To the margins of the articular facet is attached the tibiofibular capsular ligament.

The *anterior border* divides distally into two ridges enclosing the subcutaneous triangular surface (3.239A). The anterior intermuscular septum is attached to its proximal three-fourths, the lateral end of the superior extensor retinaculum distally on the anterior border of the triangular area. Distally on the triangular area's posterior margin is attached the lateral end of the superior peroneal retinaculum. The *interosseous border* ends at the proximal limit of the rough area for the interosseous ligament. The interosseous membrane attached to it does not reach the fibular head, leaving space for anterior tibial vessels. The *posterior border* is proximally indistinct, the posterior intermuscular septum attached to all but its distal end. The *medial crest* is related to the peroneal artery, with a nutrient foramen on or near it close to midshaft. Also attached to it is a layer of deep fascia separating tibialis posterior from flexor hallucis longus and flexor digitorum longus.

The *anteromedial (extensor) surface* has attached to it extensor digitorum longus, extensor hallucis longus and peroneus tertius (p. 646). To the *lateral (peroneal) surface* peroneus longus is attached to its whole width in its proximal third but in its middle third only from its posterior part, behind the peroneus brevis (p. 647). The latter continues its attachment almost to the distal end of the fibula's shaft. The *posterior surface*, divided longitudinally by the medial crest, has complex attachments: between crest and interosseous border it is concave and often crossed by an oblique ridge for an intramuscular tendon of tibialis posterior, which is attached throughout much of this region—usually confined to the proximal three-fourths. Between crest and posterior border in the proximal fourth of the posterior surface the soleus is attached, its tendinous arch being attached to it proximally. Distal to the soleus on this surface the flexor hallucis longus is attached, almost to the bone's distal end. A little proximal to its midpoint it is pierced by a nutrient foramen, directed distally, for a branch of the peroneal artery.

To the anterior surface of the *lateral malleolus* the anterior talofibular ligament is attached and, to the notch anterior to its apex, the calcaneofibular ligament. Tendons of peroneus brevis and longus groove its posterior aspect, the latter superficial and covered by the superior peroneal retinaculum. In the *malleolar fossa* (3.244), pitted by vascular foramina, the posterior tibiofibular ligament is attached posteriorly and, distal to this, the posterior talofibular ligament.



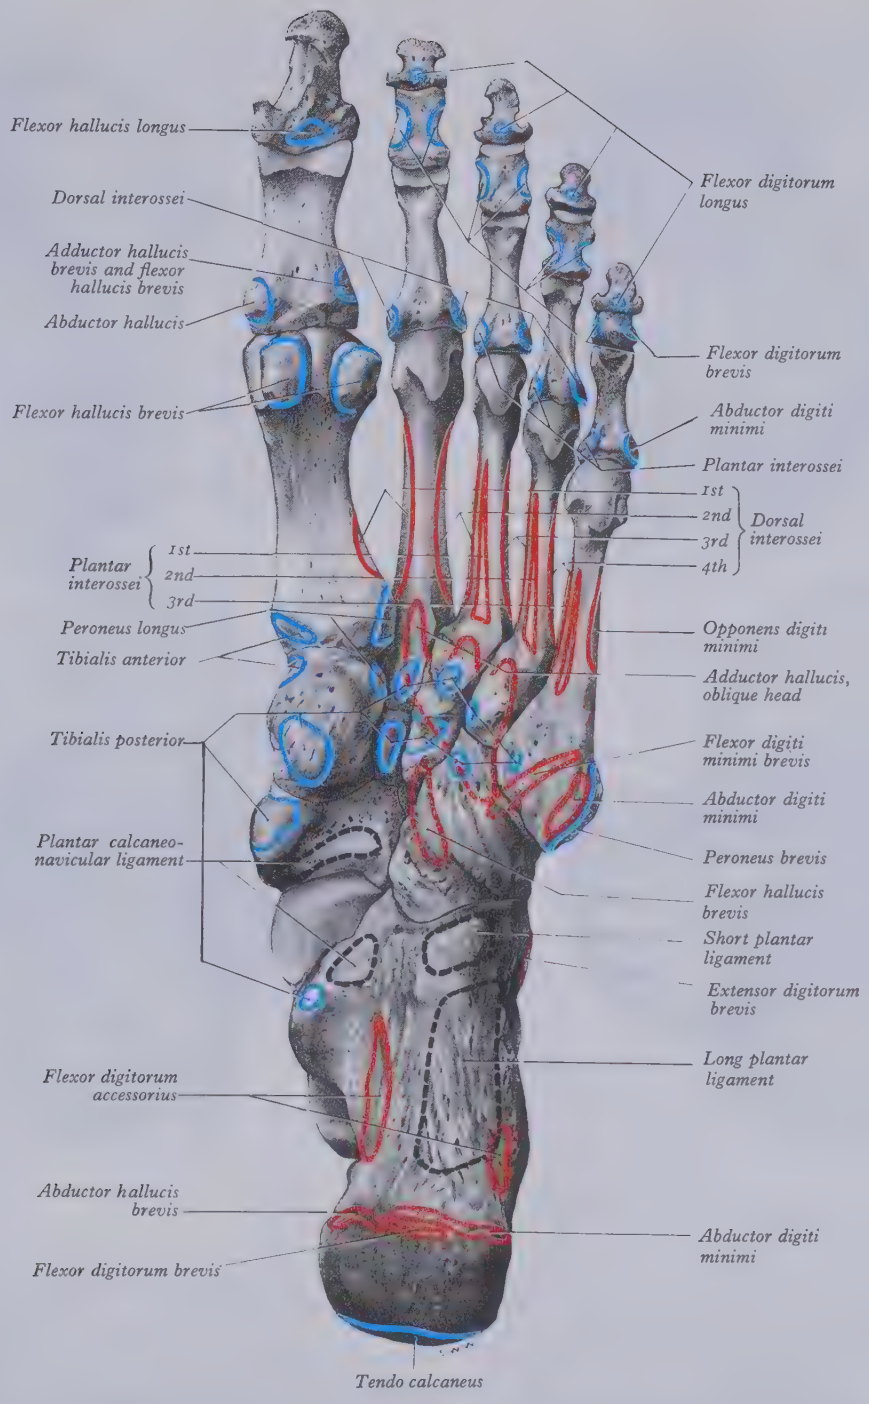
Ossification of the fibula is by three centres (3.243,245) in the shaft and extremities. It begins in the shaft about the eighth intrauterine week, in its distal end in the first year and in its proximal about the third in females and fourth in males. The distal epiphysis unites with the shaft about the fifteenth year in females, seventeenth in males, whereas the proximal does not unite until about the seventeenth year in females, nineteenth in males. In this respect the fibula reverses the ossificatory pattern in other long bones.

THE SKELETON OF THE FOOT

Functionally the pedal skeleton may be divided into tarsus, metatarsus and phalanges or digital bones. In this description the terms *plantar* and *dorsal*, which are self-explanatory, are used, anterior and posterior being inapposite. The terms proximal and distal are also usually employed, with the same significance as in limbs generally. Rotation occurring in early stages of development of limbs (p. 398) explains that, whereas the pollex is the most lateral in the hand, the hallux is the most medial in the foot (p. 400). **Note.** It must be emphasized, as noted elsewhere (p. 12), that these remarks are only valid with reference to the widely adopted descriptive Standard Anatomical Position. Perhaps of assistance to embalmers and prosectors, this has little to recommend it concerning habitual functioning, comparative studies and energetics.

The Tarsus

The seven tarsal bones occupy the proximal half of the foot (3.246,247). The tarsus and carpus are homologous, but tarsal



3.246 The skeleton of the left foot: dorsal aspect.

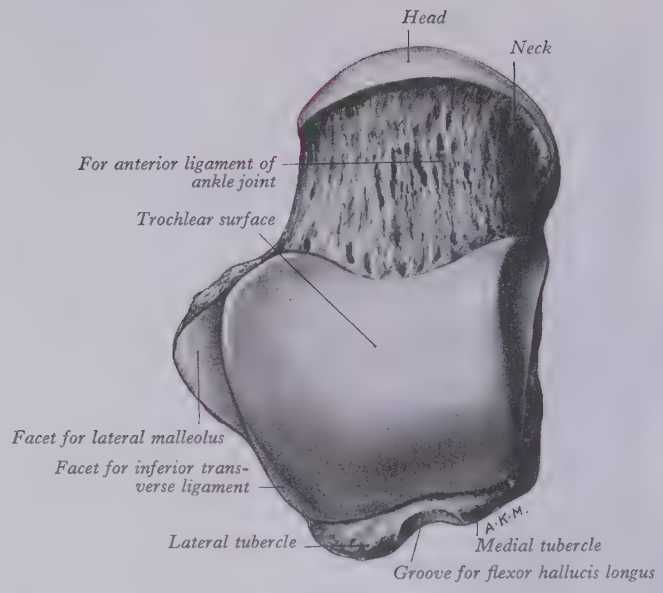
elements are larger to support and distribute weight. As in the carpus, tarsal bones are arranged in proximal and distal rows, but medially is a single intermediate tarsal element. .The proximal row comprises the *talus* and *calcaneus*, the former's long axis inclined anteromedially and down, its distal head being medial to the calcaneus and at a higher level. The distal row contains, mediolaterally, *medial*, *intermediate* and *lateral cuneiforms* and the *cuboid*, which are roughly in parallel and form a transverse arch dorsally convex. Medially, the *navicular bone* is interposed between the talus and cuneiforms. Laterally, the calcaneus articulates with the cuboid.

The foot is at right angles to the leg in standing, tarsus and metatarsus arranged to form intersecting longitudinal and transverse arches. Hence thrust and weight are not transmitted from the tibia to the ground (or vice versa) directly through the tarsus, but are distributed through tarsal and metatarsal bones to the ends of the longitudinal arches (p. 457). In this connection, the cancellous structure of tarsal bones has been reviewed by Sinha (1985). For description each tarsal bone is arbitrarily considered to be cuboidal in form with six surfaces.

Structure of Tarsal Bones

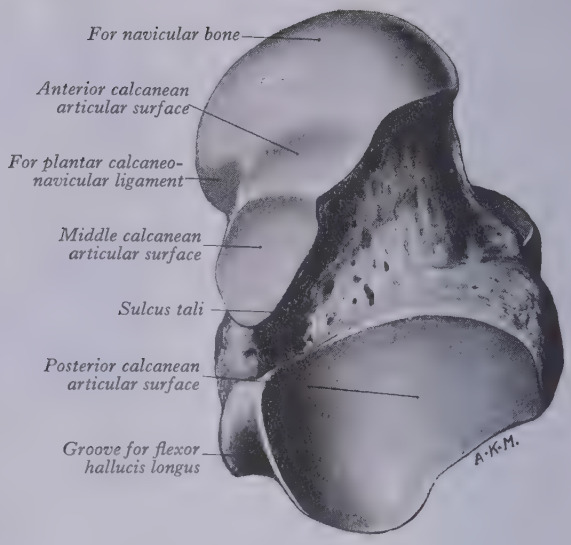
The internal structure of tarsal bones has attracted relatively little attention (Wood Jones 1949, Le Gros Clark 1975). Sinha (1985), in a small series of 10 cadavers, has described the cancellous architecture of all seven bones. His observations emphasize the variation, from the mixed fine and coarse pattern of lamellae in the calcaneus, to the more widely spaced, thicker lamellae of the navicular, and he attempts to equate these appearances with functional stresses acting on these bones. The subject is of considerable kinematic and clinical interest and deserves further study. One such investigation (Bacon et al 1984), using a neutron beam technique on thin sections, shows how the orientation of hydroxyapatite crystals may be used to analyse the cancellous architecture and to associate this pattern with effects of non-osseous structures, such as the plantar aponeurosis.

3.247 The skeleton of the left foot: plantar aspect. The attachments of the tibialis posterior to the metatarsals vary; those to the third and fifth may be absent. The adductor hallucis (oblique head) and the flexor hallucis brevis arise in large part from the ligaments and tendinous extensions in the sole of the foot and not directly from bone; these attachments are shown by interrupted lines.



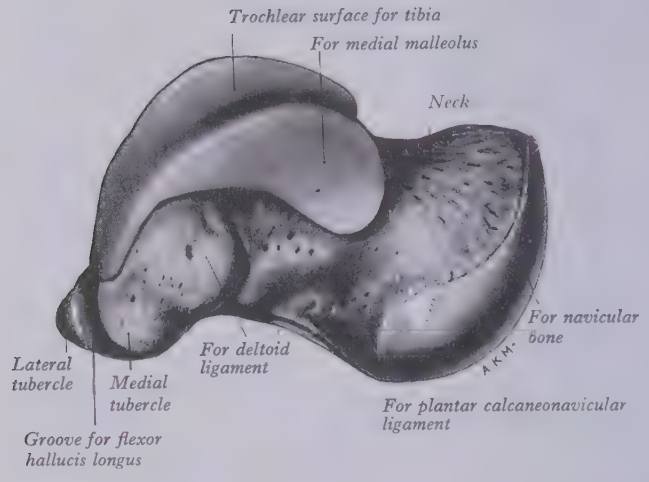
The Individual Tarsal Bones

The Talus

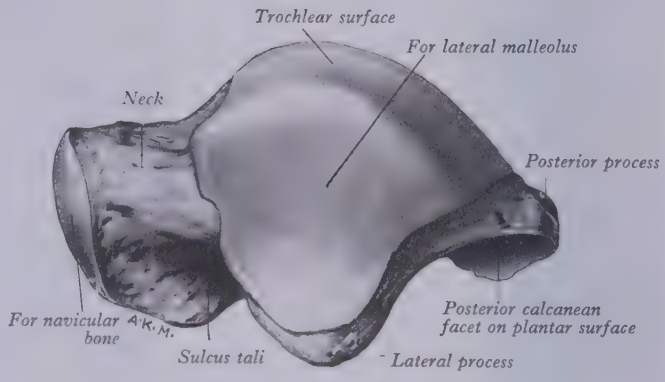


The talus (**3.248A–D**) is the link between the foot and leg, through the ankle joint. Its rounded distal head, proximal trochlear surface for the tibia, facet for the lateral malleolus, and its neck and body are its main features.

The talar head, directed distally and somewhat inferomedially, has a *distal surface*, oval and convex, with its long axis also inclined inferomedially to articulate with the proximal navicular surface. The head's *plantar surface* has three articular areas, separated by smooth ridges; the most posterior and largest is oval, slightly convex and rests on a shelf-like medial calcanean projection, the *sustentaculum tali*. Anterolateral to this and usually continuous with it, a flat articular facet rests on the anteromedial part of the dorsal (proximal) calcanean surface; distally it continues into the navicular surface. Medial to these two calcanean facets a part of the talar head is covered with articular cartilage, continuous with the calcanean navicular areas (**3.248B**) and in contact with the *plantar calcaneonavicular ligament* (p. 537) which is covered here, superiorly, by a plaque of fibrocartilage. When the foot is inverted passively, the dorsolateral aspect of the head is visible and palpable about 3 cm distal to the tibia, but is hidden by extensor tendons when the toes are dorsiflexed.



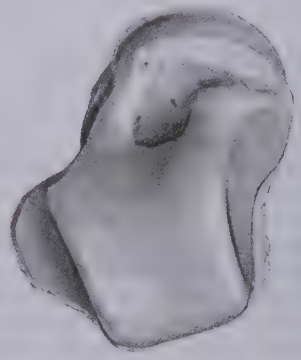
The talar neck, the narrow region between head and body, is medially inclined. Its rough surfaces are for ligaments; the medial plantar surface has a deep *sulcus tali* which, when talus and calcaneus are articulated, roofs the *sinus tarsi*, occupied by interosseous talocalcanean and cervical ligaments.



A

B

C



D

3.248 The left talus: A. dorsal (superior) aspect; B. plantar (inferior) aspect; C. medial aspect; D. lateral aspect.

The talar body is cuboidal, covered dorsally by a *trochlear* surface articulating with the tibia's distal end. It is anteroposteriorly convex, transversely gently concave, widest anteriorly and, therefore, sellar. The triangular *lateral surface* is smooth and vertically concave for articulation with the lateral malleolus. Superiorly it is continuous with the trochlear surface; inferiorly its apex is a *lateral process*. The *medial surface* is proximally (posterosuperiorly) covered by a comma-shaped facet, deeper in front and articulating with the medial malleolus, distal to which the surface is rough with numerous vascular foramina. The small *posterior surface* is the rough projecting *posterior process*, marked by an oblique groove between two tubercles; the *lateral tubercle* is usually larger, the *medial* less prominent and immediately behind the sustentaculum tali (3.246). The *plantar surface* articulates with the middle third of the dorsal calcanean surface by an oval concave facet, its long axis directed distolaterally at an angle of about 45° with the median plane.

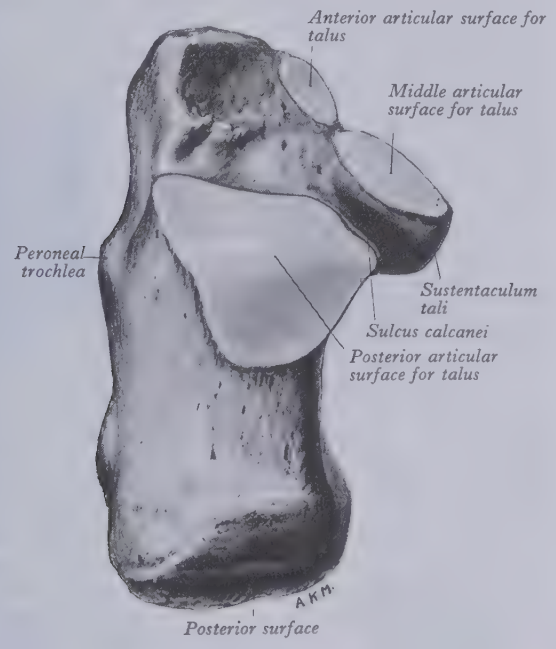
No muscles but many ligaments (4.246,247) are attached to the talus, since it is involved in talocrural, subtalar and talocalcaneonavicular joints.

The long axis of the **neck**, inclined down, distally and medially, makes an angle of about 150° with that of the body; it is smaller (130°–140°) at birth (3.249), accounting in part for the inverted foot in young children. To its dorsal surface the dorsal talonavicular ligament and talocrural articular capsule are attached distally, leaving its proximal part intracapsular. The medial articular facet and part of the trochlear surface may extend on the neck, especially in childhood (3.249). A dorsolateral *squatting facet* commonly occurs on the neck in Indians, but seldom in adult Europeans, articulating with the anterior tibial margin in extreme dorsiflexion (Barnett 1954, Singh 1959); the facet may be

3.249 The left talus of a newborn infant: superior aspect. Compare with 3.248A, and note the angle which the axis of the neck makes with the long axis of the body of the bone.

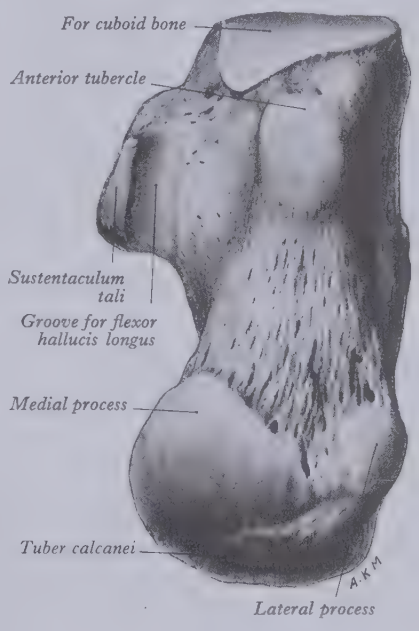
double. Laterally on the neck is attached the anterior talofibular ligament, spreading along the adjacent anterior border of the lateral surface. To the neck's inferior surface the interosseous talocalcanean and cervical ligaments are attached (p. 537).

The medial edge of the **trochlear surface** is straight but its lateral edge inclines medially in its posterior part, often broadened into a small elongated triangular area, in contact with the posterior tibiofibular ligament in dorsiflexion.



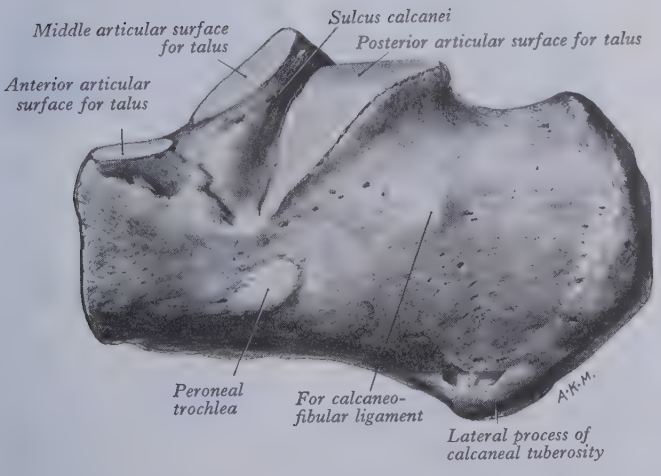
To the *posterior process* is attached the posterior talofibular ligament, which extends up to the groove, or depression, between the process and posterior trochlear border. To its plantar border the posterior talocalcanean ligament is attached. The *groove* between the tubercles of the process contains the tendon of flexor hallucis longus, continuing distally into the groove on the plantar aspect of the sustentaculum tali. To the *medial tubercle* the medial talocalcanean ligament is attached below, whilst above the tubercle are attached the most posterior superficial fibres of the deltoid ligament, its deep fibres are attached still higher to the rough area immediately below the comma-shaped articular facet on the medial surface (**3**.248C).

Sex differences in talar dry weight have been recorded (Singh & Singh 1975); the ranges in adult Indian males and females were 15.1 to 36.8 and 6.0 to 20.5 g, respective means being 23.50 and 15.32 g. Estimation of sex by dimensions has been claimed by Steele (1976).



The Calcaneus

The calcaneus (**3**.250A–D), the largest tarsal bone, projects posterior to the tibia and fibula as a short lever for muscles of the calf attached to its posterior surface. It is irregularly cuboidal, its long axis inclined distally up and laterally. Its smooth, articular anterior end contrasts with its larger, rough posterior aspect. The dorsal surface bears centrally a large articular facet and the plantar is rough; the lateral surface is flat, the medial hollowed.



The superior or **proximal surface** is divisible into three: the posterior third is rough, concavoconvex, the convexity transverse; it supports fibroadipose tissue between the calcanean tendon and ankle joint; the middle third carries the *posterior talar facet*, oval and convex anteroposteriorly; the anterior third is partly articular; distal (anterior) to the posterior articular facet a rough

C

D

3.250 The left calcaneus: A. dorsal aspect; B. plantar aspect; C. lateral aspect; D. medial aspect.

depression narrows into a groove on the medial side, the *sulcus calcanei*, which completes the sinus tarsi with the talus. Distal and medial to this groove an elongated articular area covers the sustentaculum tali, extending distolaterally on the bone's body. This facet is often divided by a non-articular interval at the anterior limit of the sustentaculum tali, forming *middle* and *anterior talar facets*, the incidence of which varies with sex and race. Rarely, all three facets on the upper surface of the calcaneus are fused into one irregular area (Bunning & Barnett 1963, 1965). A detailed analysis of patterns of *anterior* talar articular facets in a series of 401 Indian calcanei revealed four types. Type I (67%) showed one continuous facet on the sustentaculum extending to the distomedial calcanean corner; type II (26%) presented two facets, one sustentacular, one distal calcanean; type III (5%) possessed only a single sustentacular facet; and type IV (2%) showed all anterior and posterior facets confluent.

The anterior surface, the smallest, is an obliquely set concavoconvex articular facet for the cuboid bone.

The posterior surface is divided into three: a smooth proximal (superior) area separated from tendo calcaneus by a bursa and adipose tissue; a middle area, the largest, limited above by a groove, below by a rough ridge, for the calcanean tendon; and a distal (inferior) area inclined down and forwards, vertically striated, which is the subcutaneous weight-bearing surface.

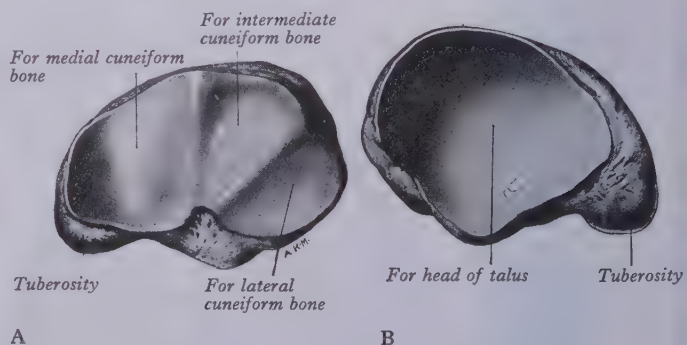
The plantar surface is rough, especially proximally, as the *calcanean tuberosity*, the *lateral* and *medial processes* of which extend distally, separated by a notch. The medial is longer and broader (3.250B). Further distally, an *anterior tubercle* marks the distal limit of the attachment of the long plantar ligament.

The lateral surface is almost flat, proximally deeper and palpable on the lateral aspect of the heel distal to the lateral malleolus. Distally it presents the *peroneal trochlea (tubercle)* (3.250C), exceedingly variable in size and, when well developed, palpable 2 cm distal to the lateral malleolus. It has an oblique groove for the tendon of peroneus longus and a shallower proximal one for the tendon of peroneus brevis. About 1 cm or more behind and above the peroneal trochlea a second elevation may exist for attachment of the calcaneofibular part of the lateral ligament.

The medial surface is vertically concave, its concavity accentuated by the *sustentaculum tali* projecting medially from the distal part of its upper border (3.250D). Superiorly the process bears the middle talar facets and inferiorly a groove continuous with that on the talar posterior surface for the tendon of flexor hallucis longus (3.250B). The medial aspect of the sustentaculum tali can be felt immediately distal to the tip of the medial malleolus; occasionally it is also grooved by the tendon of flexor digitorum longus.

In the *calcanean sulcus* are attached the interosseous talocalcanean and cervical ligaments (p. 537) and the medial root of the inferior extensor retinaculum; the non-articular area distal to the posterior talar facet is the attachment of the extensor digitorum brevis (in part), the principal band of the inferior extensor retinaculum and the stem of the bifurcated ligament.

To the *medial process of the tuberosity*, at its prominent medial margin, abductor hallucis and the superficial part of flexor retinaculum and, distally, the plantar aponeurosis and flexor digitorum brevis are all attached. To the *lateral process* is attached the abductor digiti minimi, extending medially to the medial process. The rough region between the processes proximally and extending to the anterior tubercle distally is the attachment of the long plantar ligament, whilst the tubercle and area distal to it is the attachment of the short plantar ligament. The lateral tendinous head of the flexor digitorum accessorius is attached distal to the lateral process near the lateral margin of the long plantar ligament. To the *posterior surface*, which is wider below, and near the medial side of the tendo calcaneus, the plantaris is attached. The anterior part of the *lateral surface* is crossed by the peroneal tendons, but is largely subcutaneous (p. 651). The calcaneofibular ligament is attached about 1–2 cm proximal to the peroneal trochlea, usually to a low rounded elevation.



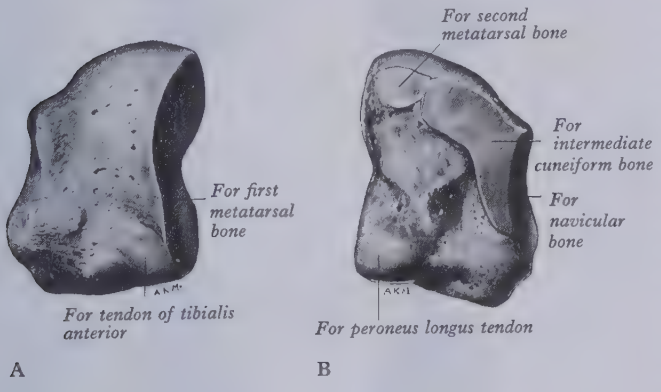
The *sustentaculum tali* is dorsally part of the talocalcaneonavicular joint; its plantar surface is grooved by the tendon of flexor hallucis longus, margins of the groove giving attachment to the deep part of the flexor retinaculum. To the medial margin of the sustentaculum, which is narrow, rough and convex, the plantar calcaneonavicular ligament is attached distally (p. 537), proximally are attached a slip from the tendon of tibialis posterior, and superficial fibres of the deltoid ligament and medial talocalcanean ligament. Distal to the attachment of the deltoid ligament the tendon of flexor digitorum longus is related to the margin of the sustentaculum and may groove it. Distal to the groove for the flexor hallucis longus the large medial head of flexor accessorius is attached.

Singh & Singh (1975) studied variations in calcanean dry weight in both sexes in adult Indians. The male range was 23.3 to 56.8 g (mean = 36.64), and 13.0 to 33.0 g (mean = 24.75) in females. Steele (1976) has claimed sex differentiation on dimensional data. Comparison of right and left calcanei in 52 adults (Webber & Garnett 1976) showed greater density on the side of hand preference; the evidence suggested that the concordance was determined before birth.

The Navicular Bone

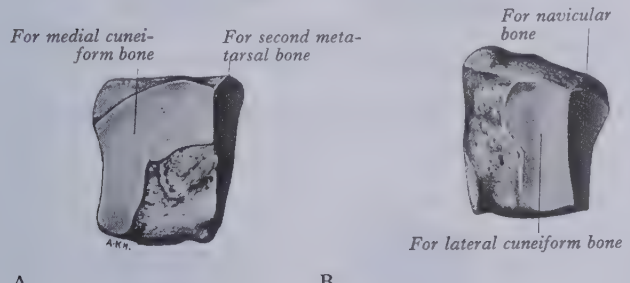
The navicular bone (3.251A,B) articulates between the talar head proximally and cuneiform bones distally. Its *distal surface* is transversely convex and divided into three facets (the medial is largest) for articulation with cuneiform bones. The *proximal surface*, oval and concave, articulates with the talar head. The *dorsal surface* is rough and convex; the *medial*, also rough, continues into a prominent *tuberosity*, palpable about 2.5 cm distal and plantar to the medial malleolus. The *plantar surface*, rough and concave, is separated from the tuberosity medially by a groove. The *lateral surface* is rough, irregular and often bears a facet for articulation with the cuboid.

The facet for the medial cuneiform is roughly triangular, its rounded apex is medial and its 'base' often markedly curved; those for intermediate and lateral cuneiform bones are also triangular with plantar apices. The facet for the lateral cuneiform may approach a wide crescent or a semicircle rather than a triangle (3.251A). To the dorsal navicular surface are attached dorsal talonavicular, cuneonavicular and cubonavicular ligaments. The **tuberosity** is the main attachment of tibialis posterior; a groove lateral to it transmits part of the tendon distally to the cuneiform bones and middle three metatarsal bases. To a slight projection lateral to the groove and adjacent to the proximal surface the plantar calcaneonavicular ligament is attached. To the rough part of the lateral surface is attached the calcaneonavicular part of the bifurcated ligament.



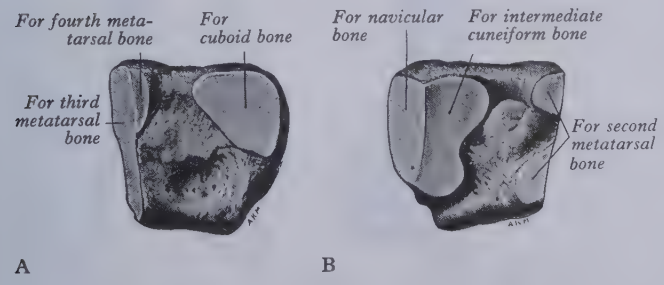
3.251 The left navicular bone: A. distal aspect; B. proximal aspect.

The Cuneiform Bones



The wedge-like cuneiform bones (3.252,253,254) articulate with the navicular proximally and with the bases of the first to third metatarsal bones distally; the medial is the largest, the intermediate smallest. In intermediate and lateral cuneiforms the dorsal surface is the base of the wedge but in the medial the wedge is reversed, a prime factor in shaping the transverse arch. Proximal

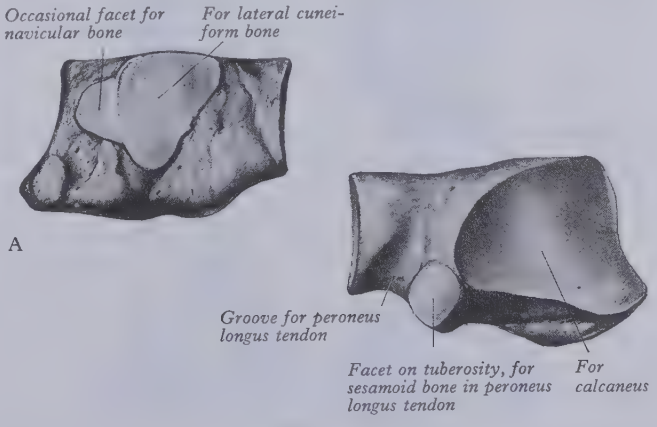
surfaces of all three form a concavity for the navicular, but medial and lateral cuneiforms project distally beyond the intermediate, forming a recess for the second metatarsal base.



The medial cuneiform bone (3.252A,B), articulating with the navicular and first metatarsal base, has a rough, narrow *dorsal surface*. The *plantar surface* receives a slip from the tendon of tibialis posterior. The *distal surface* is a reniform facet for the first metatarsal base, its 'hilum' being lateral. The *proximal surface* bears a piriform facet for the navicular, concave vertically, dorsally narrowed. The *medial surface*, rough and subcutaneous, is vertically convex; its distal–plantar angle carries a large impression for most of the tendon of tibialis anterior (3.252A). The *lateral surface* is partly non-articular; along its proximal and dorsal margins is a smooth right-angled strip for the intermediate cuneiform; its distal dorsal area is separated by a vertical ridge from a small, almost square facet for the dorsal part of the medial surface of the second metatarsal base. Plantar to this the medial cuneiform is attached to the medial side of the second metatarsal base by a strong ligament. Proximally an interosseous intercuneiform ligament connects this surface to the intermediate cuneiform. The surface's distal and plantar area is roughened by attachment of part of the peroneus longus tendon (3.252B).

3.252 The left medial cuneiform bone: A. medial aspect; B. lateral aspect.

3.253 The left intermediate cuneiform bone: A. distal and medial aspect; B. proximal and lateral aspect.



3.254 The left lateral cuneiform bone: A. distal and lateral aspect; B. proximal and medial aspect.

The intermediate cuneiform bone (3.253A,B), articulating with the navicular and distally with the second metatarsal base, has a narrow, *plantar surface* receiving a slip from the tendon of tibialis posterior. The *distal* and *proximal surfaces*, both triangular articular facets, articulate with the second metatarsal base and navicular respectively. The *medial surface* is partly articular; along its proximal and dorsal margins a smooth, angled strip, occasionally double, articulates with the medial cuneiform. The *lateral surface* also is partly articular; along its proximal margin a vertical strip, usually indented, abuts with the lateral cuneiform. Strong interosseous ligaments connect non-articular parts of both surfaces to adjacent cuneiforms.

The lateral cuneiform bone (3.254A,B) is between the intermediate cuneiform and cuboid, articulating also with the navicular and, distally, the third metatarsal base. Like the intermediate, its *dorsal surface*, rough and almost rectangular, is the base of the wedge. Its narrow *plantar* surface receives a slip from the tibialis posterior and sometimes part of the flexor hallucis brevis. The *distal surface* is a triangular articular facet for the third metatarsal base. The *proximal surface* is rough on its plantar aspect, but its dorsal two-thirds articulates with the navicular by a triangular facet. The *medial surface*, partly non-articular, has on its proximal margin a vertical strip, indented for the intermediate cuneiform; on its distal margin a narrower strip (often two small facets) articulates with the lateral side of the second metatarsal base. The *lateral surface*, also partly non-articular, has a triangular or oval proximal facet for the cuboid; a semilunar facet on its dorsal and distal margin articulates with the dorsal part of the medial side of the fourth metatarsal base. Non-articular areas of medial and lateral surfaces receive intercuneiform and cuneocuboid ligaments, important in the transverse arch.

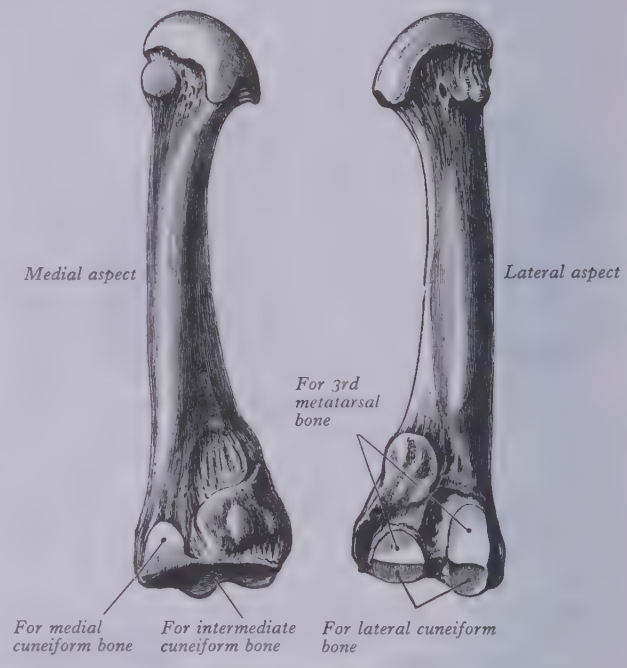
The Cuboid Bone

The cuboid bone (3.255A,B), most lateral in the distal tarsal row, is between the calcaneus proximally and the fourth and fifth metatarsals distally. Its *dorsal surface*, really dorsolateral, is rough for the attachment of ligaments. The *plantar surface* is crossed distally by an oblique *groove* for *the tendon of peroneus longus*, bounded proximally by a ridge ending laterally in the *cuboid's tuberosity*, the lateral aspect of which is faceted for a sesamoid bone or cartilage frequent in the peroneal tendon. Proximal to its ridge the rough plantar surface, due to obliquity of the calcaneocuboid joint, extends proximally and medially, making its medial border much longer than the lateral. The *lateral surface* is rough; from a deep notch on its plantar edge extends the groove for the peroneus longus. The *medial surface*, much more extensive and partly non-articular, bears an oval facet for the lateral cuneiform and proximal to this another (sometimes absent) for the navicular, the two forming a continuous surface separated by a smooth vertical ridge. The *distal surface* is divided vertically into a medial

3.255 The left cuboid bone: A. medial aspect; B. proximal and lateral aspect.

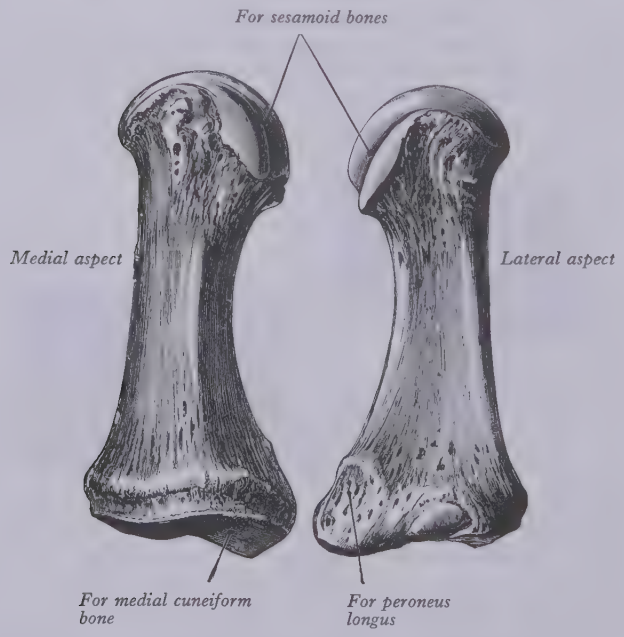
quadrilateral articular area for the fourth metatarsal base and a lateral triangular area, its apex lateral, for the fifth metatarsal base. The *proximal surface*, triangular and concavoconvex, articulates with the distal calcanean surface; its medial–plantar angle projects proximally and inferior to the distal end of the calcaneus.

To the dorsal surface are attached dorsal calcaneocuboid, cubonavicular, cuneocuboid and cubometatarsal ligaments, and, to the proximal edge of the plantar ridge, deep fibres of the long plantar ligament. To the projecting proximomedial part of the plantar surface are attached a slip of the tendon of tibialis posterior and the flexor hallucis brevis. To the rough part of the medial cuboidal surface are attached interosseous, cuneocuboid and cubonavicular ligaments, and proximally the medial calcaneocuboid, which is the lateral limb of the bifurcated ligament.



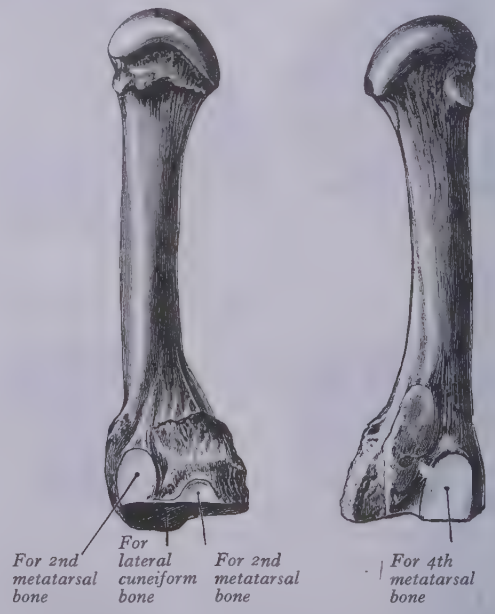
The Metatarsus

The five metatarsal bones, distal in the foot, connect tarsus and phalanges. Like metacarpals, they are miniature long bones, with a shaft, proximal base and distal head. Excepting the first and fifth, the *shafts* are long and slender, longitudinally convex on dorsal, concave on plantar aspects. Prismatic in section, they taper distally. Their *bases* articulate with the distal tarsal row and with each other. The line of each tarsometatarsal joint, except the first, inclines proximally and laterally, metatarsal bases being oblique relative to their shafts. The *heads* articulate with proximal phalanges, each by a convex surface passing farther on to its plantar surface, where it ends on the summits of two eminences. The sides of the heads are flat, with a depression surmounted by a dorsal tubercle for a collateral ligament of the metatarsophalangeal joint.



The Individual Metatarsal Bones

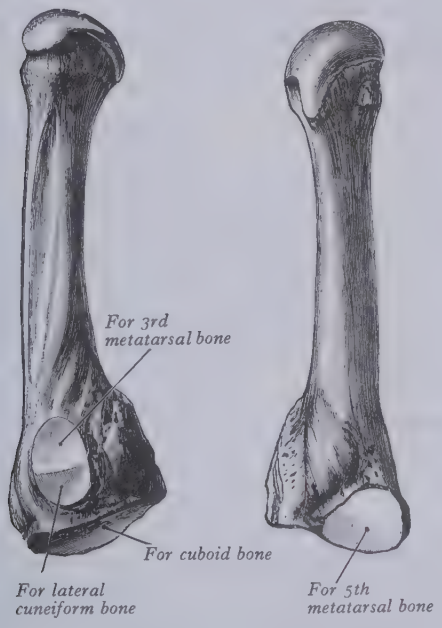
The first metatarsal bone (3.256), shortest and thickest, has a strong *shaft*, of marked prismatic form. The *base* sometimes has a lateral facet or ill-defined smooth area due to contact with the second metatarsal. Its large proximal surface, usually indented on medial and lateral margins, articulates with the medial cuneiform; its circumference is grooved for tarsometatarsal ligaments and, medially, part of the tendon of tibialis anterior is attached; its plantar angle has a rough, oval, lateral prominence for the tendon of peroneus longus. To the shaft's flat lateral surface the medial head of the first dorsal interosseous muscle is attached. The large *head* has a plantar elevation separating two grooved facets, the medial larger, on which sesamoid bones glide. (For the arterial supply of the first metatarsal consult Jaworek 1973.)



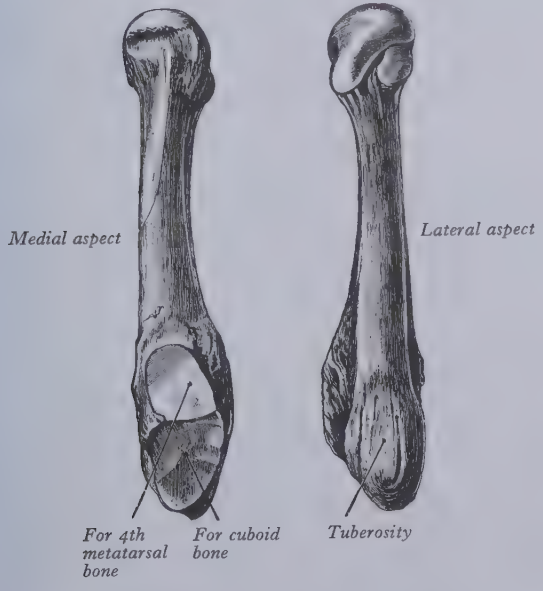
The second metatarsal bone (3.257) is the longest. Its cuneiform *base* bears four articular facets: a proximal one, concave and triangular, for the intermediate cuneiform; a dorsomedial one for the medial cuneiform, variable in size and usually continuous with that for the intermediate cuneiform; two lateral, dorsal and plantar, separated by non-articular bone, each divided by a ridge into distal demifacets articulating with the third metatarsal base and a proximal pair (sometimes continuous) for the lateral cuneiform; these areas vary, particularly the plantar facet, which may be absent (Singh 1960). An oval pressure facet, due to contact with the first metatarsal, may appear on the medial side of the base, plantar to that for the medial cuneiform. To the shaft's medial and lateral surfaces are respectively attached the lateral head of the first dorsal interosseous muscle and medial head of the second.

3.257 The left second metatarsal bone: medial and lateral aspects.

3.256 The left first metatarsal bone: medial and lateral aspects.



3.258 The left third metatarsal bone: medial and lateral aspects.



The third metatarsal bone (3.258) has a flat triangular *base*, articulating proximally with the lateral cuneiform; medially, dorsal and plantar facets articulate with the second metatarsal and, laterally, a single facet with the dorsal angle of the fourth. The medial plantar facet is frequently absent. To the shaft's medial surface the lateral head of the second dorsal interosseous muscle and first plantar are attached, to its lateral surface the medial head of third dorsal interosseous muscle.

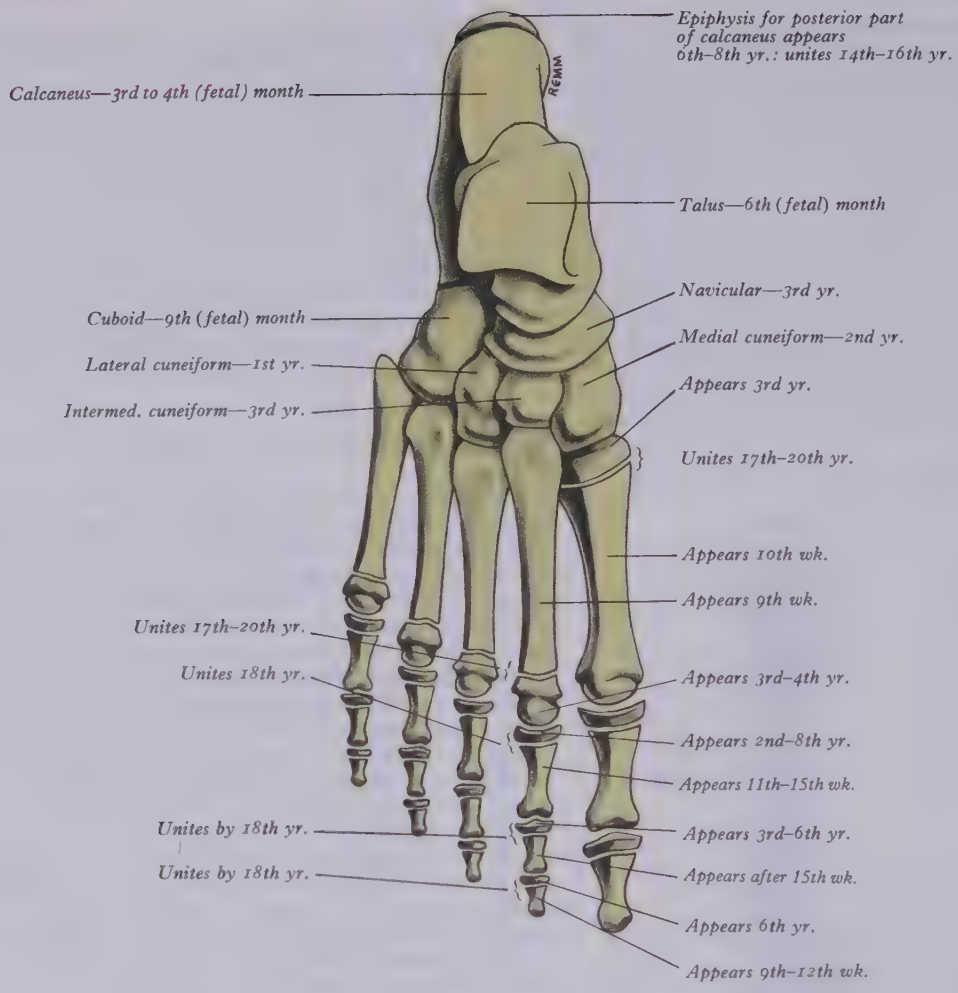
The fourth metatarsal bone (3.259) is smaller than the third. Proximally its *base* has an oblique quadrilateral facet for articulation with the cuboid, laterally a single facet for the fifth metatarsal and medially an oval facet for the third, sometimes divided by a ridge, the proximal part then articulating with the lateral cuneiform (3.259). To the medial surface the lateral head of the third dorsal and second plantar interosseous muscles are attached; to the lateral surface is the medial head of the fourth dorsal interosseous muscle.

The fifth metatarsal bone (3.260) has a *tuberosity (styloid process)* on the lateral side of its base. The base articulates proximally with the cuboid by a triangular, oblique surface, medially with the fourth metatarsal. The tendon of peroneus tertius is attached to the medial part of the dorsal surface and medial border of the shaft, that of the peroneus brevis to the dorsal surface of the tuberosity. A strong band of the plantar aponeurosis, sometimes containing muscle, connects the apex of the tuberosity to the lateral process of the calcanean tuberosity. The plantar surface of the base is grooved by the tendon of the abductor digiti minimi and the flexor digiti minimi brevis is attached here. To the shaft's medial side are attached the lateral head of the fourth dorsal and the third plantar interosseous muscles. The tuberosity can be seen and felt midway along the foot's lateral border; in acute inversion it may be fractured.

3.259 The left fourth metatarsal bone: medial and lateral aspects.

3.260 The left fifth metatarsal bone: medial and lateral aspects.

The Phalanges of the Foot



The phalanges (3.246,247) in general resemble those in the hand; there are two in the hallux, and three in each of the other toes. They are, however, much shorter and their shafts, especially those of the proximal set, are compressed from side to side. In proximal phalanges the compressed *shaft* is convex dorsally, with a plantar concavity. The *base* is concave for articulation with a metatarsal head and the *head* is a trochlea for a middle phalanx. Middle phalanges are small and short, but broader than the proximal. Distal phalanges resemble those in fingers, but are smaller and flatter; each has a broad base for a middle phalanx and an expanded distal end; a rough *tuberosity* on the plantar aspect of the latter is an attachment for the pulp, and a wider area for weight-bearing.

Tendons of the digital long flexor and extensores are attached to plantar and dorsal aspects of bases of the lateral four distal phalanges. In the hallux, flexor hallucis longus and extensor hallucis are likewise attached. The bases of middle phalanges also receive tendons of flexor digitorum brevis and extensores digitorum. The second, third and fourth proximal phalanges each receive a lumbrical on the medial side and an interosseous on each side (Wood Jones 1949). For further details of muscular, capsular and ligamentous arrangements in the toes see 3.246,247 and pp. 541 and 653. The terminal phalanx of the hallux normally shows a small degree of valgus (lateral) deviation, as may the proximal, even in persons who have never worn shoes (Barnett 1962). Comparison of the angulation in 30 students (18–21 years) and 35 aged individuals showed no increase in the latter. The deviation has also been observed in fetal specimens (Wilkinson 1954).

Ossification of the Bones of the Foot

Tarsal bones each have one centre, except the calcaneus, which has a scale-like posterior epiphysis (but vide infra). Centres for calcaneus and talus appear prenatally in the third and sixth month respectively. A detailed study of the calcaneus in 177 human fetuses between 49 and 150 mm (crown-rump length) showed 16% with a lateral perichondral mesenchymatous centre and 11% with an endochondral centre, while only 2% possessed both (Meyer & O'Rahilly 1976.) The cuboid frequently begins to ossify before birth; its centre has usually appeared by six months after birth. The medial cuneiform may have two centres and begins in the second year, the intermediate cuneiform and navicular in the third and lateral cuneiform in the first. The calcanean epiphysis covers most of the posterior and a little of the plantar surface; it begins thus to ossify in the sixth year in females, eighth in males, uniting in the fourteenth or sixteenth respectively. The posterior talar process sometimes has its own centre, and may remain separate or connected to the rest of the bone by cartilage as an *os trigonum*. Other accessory bones occur and may lead to radiological misinterpretation (Trolle 1947 and 3.262).

Metatarsal bones ossify from a primary centre for the shaft and a secondary epiphysis for the base of the first and for the head in the other four. In the second to fourth ossification begins in midshaft in the ninth prenatal week, in the first and fifth about the tenth week. The centre in the first metatarsal *base* appears about the third year, those for second to fifth metatarsal *heads* between the third and fourth years; all unite between seventeenth and

3.261 Plan of the ossification of the bones of the foot.

twentieth years. Like the first *metacarpal* (p. 421), the first metatarsal may also have an epiphysis for its head. The basal tubercle of the fifth metatarsal bone is often an epiphysis.

Phalanges are ossified from a primary centre for shaft and a basal epiphysis. Primary centres for distal phalanges appear between the ninth and twelfth prenatal weeks, and even later in the fifth digit, those for proximal phalanges appear between the eleventh and fifteenth weeks, and later for intermediate phalanges, with wide variation. Basal centres appear between the second and eighth years (usually second or third in the hallux), uniting by the eighteenth year (Venning 1956a,b). Much variation appears in different reports; racial differences probably exist (Kraus 1961). For a summary of the chronology of pedal ossification see **3.261**.

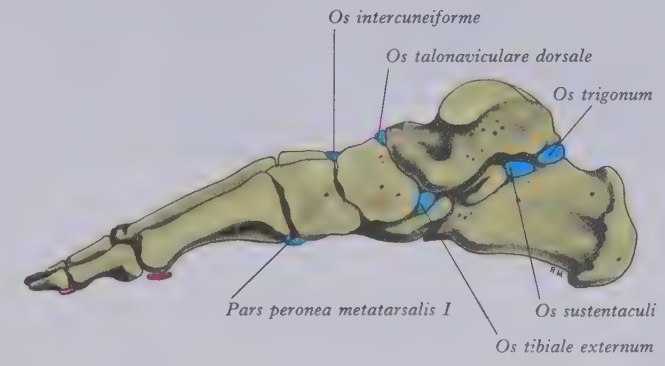
Comparison of Bones of Hand and Foot

The origin of skeletal elements in the hand and foot from terminal segments of primitive pentadactyl limbs has already been considered (p. 400); similarities and differences can now be further examined. Both hand and foot consist of proximal, intermediate and distal components, i.e. carpus/tarsus, metacarpus/metatarsus and phalanges. Carpus and tarsus both contain seven elements (omitting the sesamoid pisiform); although more or less cubical, they vary much in shape and size. Carpal bones are smaller, are concerned in transmission of smaller forces and have retained primitive alignment in rows more than the tarsal bones. Articulation of the tarsus with the foreleg is reduced to one bone (talus); the whole tarsus is divisible into two groups, corresponding to their location in the principal longitudinal arches, with a degree of independent movement absent from the carpus. The calcaneal lever has no equivalent in the *primate* carpus, although similar *carpal* arrangements exist in some quadripedal mammals.

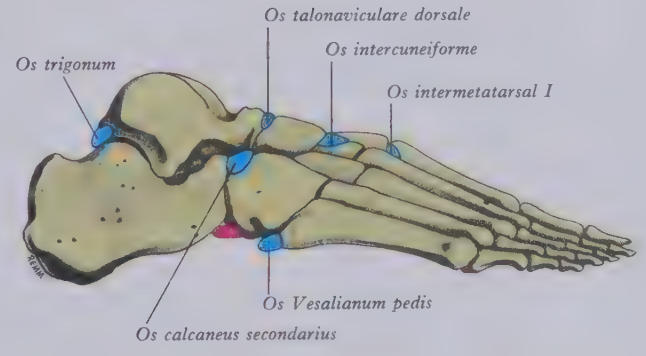
Digital components, metacarpus/metatarsus and phalanges, are more alike. Metacarpals and metatarsals are similar in form, both bound by soft parts into a structural entity. Mobility is very limited at their bases, where they articulate with the carpals or tarsals and with each other. Between both are interosseous muscles, and first and fifth digits also have short intrinsic muscles. On the flexor aspects in hand and foot are large arterial anastomotic arches, superficial and deep to the long flexor tendons crossing them to enter the free parts of the digits. The distal ends of metacarpals and metatarsals are slightly more mobile than the bases; but the third metacarpal and second metatarsal are relatively fixed as axes about which neighbouring elements exercise limited movements concerned with adaptation of the hand's grip to uneven objects and the plantigrade foot to inequalities of surface. Digits can flex and extend through considerable arcs at metacarpo- and metatarsophalangeal joints, with a lesser range of abduction and adduction, all better developed in the hand. Phalanges of the foot are much shorter; and though the phalangeal formula is usually the same, reduction of phalanges by fusion or loss, especially in the fifth digit, is more frequent in the foot.

Functions of the human hand and foot differ greatly and general skeletal similarity is much modified in details. Greater length and mobility of fingers, and especially preservation of a free-ranging opposable thumb, are essential to the grasping habit of a prehensile limb. Divergence of the pollicial metacarpal and its specialized joint with the trapezium contrast with arrangements in the hallux. The pollex is rotated about 90° on its long axis relative to the fingers so that, in the resting position, it is halfway to opposition with them. But the hallux is in the same plane as the other toes, its flexor surface also facing the ground. Moreover, it is tied by transverse metatarsal ligaments to the second metatarsal, thus integrated with its fellows and adapted for propulsion.

This has led to a different digital formula in the foot: in the hand the middle digit projects most, in the foot it is the hallux, taking the major stress transmitted through the lever of the foot in locomotion. Dorsiflexion of the foot to a right angle with the leg, an obvious adaptation to plantigrade habit, is sometimes said to be peculiar to man; but it is the primitive plantigrade adaptation in ancestral mammal-like reptiles. While most mammals become varyingly digitigrade, bringing foot and hand into line with the rest of their limbs, most primates and some carnivores, such as bears, retain plantigrade adaptation in the foot. The outstanding human peculiarity is loss of opposition in the hallux, distinguishing man even from other primates. The foot is, indeed, in general far more specialized for the bipedal habit in man than in any other primate animal. The strong build of the hallux in its metatarsal and phalanges, and the elongation and strength of tarsal bones, together make a powerful lever, on which the whole body can be elevated to add impetus and spring in running and jumping. The arched foot, with a lateral arch to steady it on the ground and a medial for thrust in propulsion, are specializations absent from the hand (pp. 632-635, 4.54 and 4.94). The rotational element in the foot, movements of inversion and eversion and *pedal* pronation and supination (p. 400), are also absent from the hand, which rotates *with the forearm* in supination and pronation. Lewis (1983) has surveyed *in extenso* the evolution of the mammalian foot.



The Sesamoid Bones



Sesamoid bones, like the seeds of sesame, are usually ovoid nodules a few millimetres in diameter, but vary in shape and size, some being large, e.g. the patella (Bizarro 1921). They are not always fully ossified and may be dense fibrous tissue, cartilage and bone in varying proportions, but most are partly ossified. They are usually embedded in tendons closely related to articular surfaces or where tendons angle sharply round bony surfaces. In both sites the sesamoid surface related to another bone is covered by articular cartilage and slides over it, itself often part of an articular surface, as in the pollicial metacarpophalangeal joint. This entails that the tendons involved are partly fused with an articular capsule, as is exemplified by the relation between patella, quadriceps femoris tendon and knee joint (p. 527). In other sites, e.g. the tendon of peroneus longus (p. 647), the sesamoid articular aspect glides over a cartilage-covered osseous surface, here a facet on the cuboid's tuberosity, all enclosed within a so-called bursa, which could well be termed a joint capsule, for the arrangement has all the essentials of a synovial joint. Some consider the sesamoids as *primarily* articular, i.e. embedded in articular capsules, their association with tendons being *secondary* (Patterson 1946). Despite association with articulations, the precise functions of sesamoids are not clear. They may modify pressure, diminish friction and sometimes alter a tendon's direction of pull, e.g. the patella. Where a tendon is acutely deflected close to bone, a sesamoid, if ossified, may aid local circulation, bone being able to resist pressures which could compress the vessels in a tendon; these are, however, sparse and prolonged pressure is unlikely, except perhaps in the foot.

Since sesamoid elements appear during fetal life and in greater numbers than later, they are phylogenetic parts of the skeleton, not merely results of local physical factors; but this possibility cannot be dismissed in every instance. They are much more numerous in extremities of many other mammals. In reptiles, intratendinous ossification near the ends of some limb bones produces nodules like sesamoids, but some fuse later and may be traction epiphyses (Haines 1942a). The proximal epiphysis of the olecranon is an example. Experiments on the patella suggest that phylogenetic and other factors act in the formation of sesamoid bones. Transplantation of limb bud fragments from chick embryos to chorioallantoic membrane has led to the development of a patella, indicating a self-differentiating mechanism (Murray & Huxley 1924). Conversely, removal of the patella in young dogs has been followed by regeneration, provided that normal activity of quadriceps femoris was allowed (Carey et al 1927), suggesting that local mechanical factors are necessary to the formation of sesamoids and perhaps also a parallel between sesamoids and bursae, since the latter also appear regularly before birth in certain sites, but can also develop in others as adventitious structures, apparently in response to local conditions.

The incidence of sesamoid bones has received much attention, but numerical data for individual sites are not always available, and onset and progress of ossification has been little studied.

In the upper limb, sesamoid nodules associated with joints are limited to the palm, two being almost constant in the tendons of adductor pollicis and flexor pollicis brevis, the medial being larger. They articulate with the palmar facets on the joint surface of the first metacarpal head; since they are firmly attached in the articular capsule, and in the tendons involved, they probably conduct some muscular pull to articular ligaments. A sesamoid is

3.262 The sites of sesamoid (red) and accessory bones (blue) in the human foot.

embedded in tendons anterior to the metacarpophalangeal joint of the index digit (35% of hands) and of the fifth (70%), where it is occasionally double. Less frequently, similar sesamoids occur in the third and fourth digits and, in a majority of hands (73%), one exists on the palmar aspect of the pollicial interphalangeal joint (Gray et al 1957). Sesamoid elements in non-articular sites are rare in the upper limb, but one occasionally appears in the biceps tendon near the radial tuberosity.

In the lower limb, the patella is the largest articular sesamoid bone; its relation to the tendon of quadriceps femoris and the capsule of the knee joint exemplifies the arrangements around all sesamoids integrated into synovial articulations. In the foot, sesamoid distribution is like that in the hand. Two, both sometimes double (prompting fallacious diagnosis of fracture), always exist in the tendons of flexor hallucis brevis, plantar to the hallucial metatarsophalangeal joint; they are bound to adjacent ligamentous structures, including the medial part of the plantar aponeurosis. Single sesamoids may occur in the plantar capsule of this joint in all the toes and in interphalangeal joints.

Non-articular sesamoid bones or cartilages are more frequent in the lower limb; that in peroneus longus has been mentioned above. Another, usually appearing later and therefore perhaps adventitious, occurs in the tendon of tibialis anterior where it contacts the distal part of the medial surface of the medial cuneiform bone; the tendon of tibialis posterior may contain a sesamoid gliding on the medial side of the talar head. Sesamoids may also occur in the lateral part of gastrocnemius, behind the lateral femoral condyle, in the tendon of psoas major where it is in contact with the ilium, in the tendon of gluteus maximus as it passes over the greater trochanter and in tendons deflected by the malleoli. In many such sites bursal arrangements occur, and opposing bony surfaces are covered by articular cartilage, as in a synovial articulation. The sesamoid occurring in the gastrocnemius is a *fabella*, articulating with the lateral femoral condyle, and is hence an 'articular' sesamoid.

Sesamoid bones ossify relatively late, except the patella (p. 440), e.g. the hand in early teens. In a group of Caucasians, those sesamoids associated with the thumb began to ossify in males between 12 and 15 years, and in other digits between 15 and 18 years, dates for females being three years earlier (Joseph 1951). No such data appear available for large mixed or other racial groups. Figures for the lower limb are scant and vague.

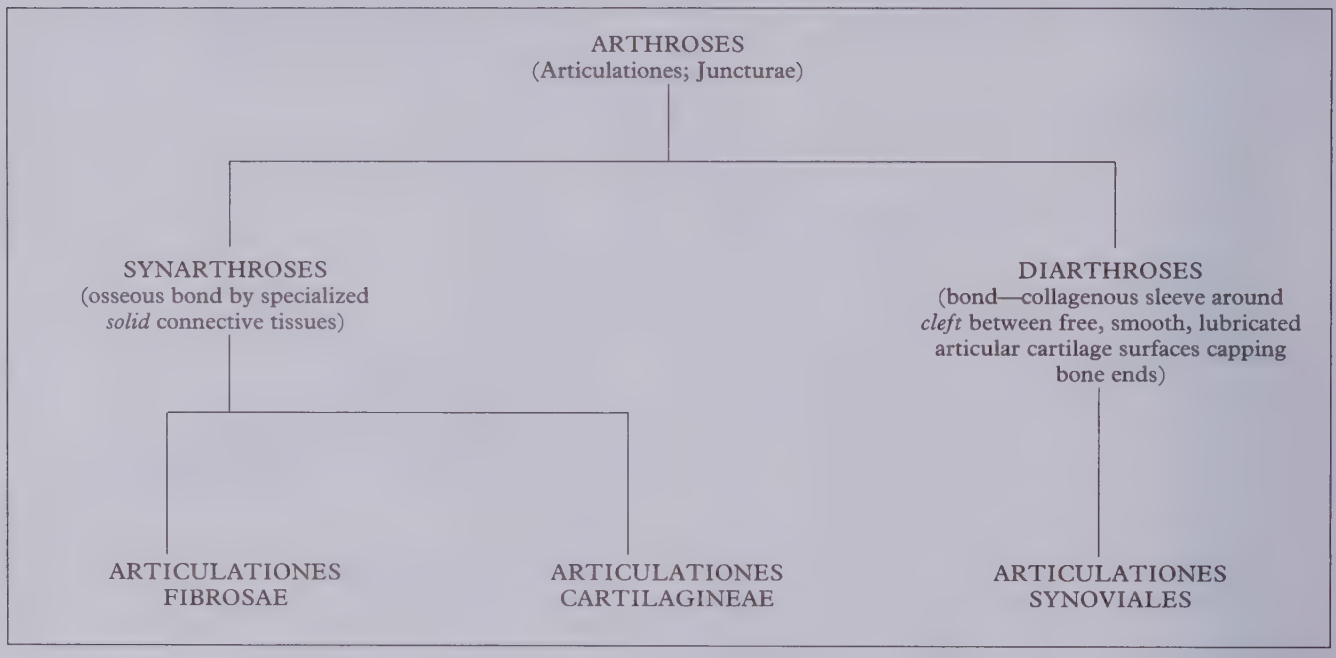
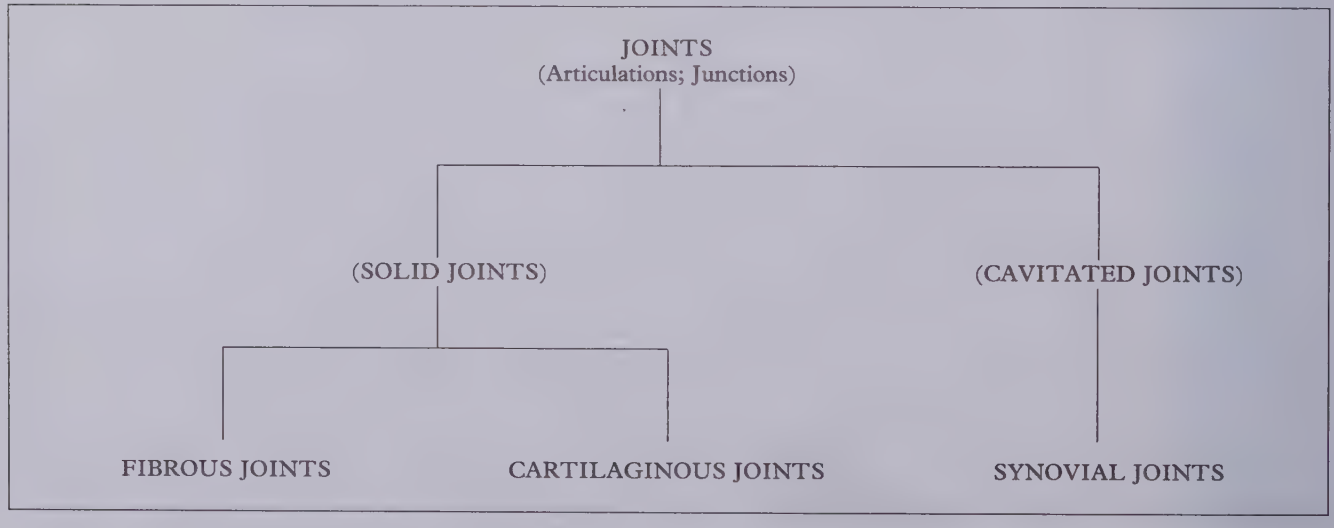
ANATOMY

ARTHROLOGY



4

The Scope of Arthrology



The rigid nature and mode of growth of the skeletal tissue, bone, make it imperative that the skeleton consists of *multiple* osseous elements, each joined to its neighbours by a variety of structural arrangements. All such co-aptations are grouped as **arthroses** (synonyms are: *articulationes*, *juncturae*, anglicized: joints, articulations and junctions). Arthroses are concerned with *differential growth*, with *transmission of forces* (tensile, compressive, shear and torsion) and with *movement* (from consolidation and complete rigidity at one extreme, through grades of restricted movement to, in great variety, relatively free but controlled movement). Which of these attributes predominates varies with site and age, in many instances changing markedly with the latter; scientific study of their functional topography and temporal variation constitutes **Arthrology**. Arthroses are classified in a number of ways, different criteria and degrees of quantitative accuracy being adopted as adequate for different groups of workers. Hence, sources limited to a single classification should be read with due regard to the intended audience, and vary from a simplified introductory grouping, through a somewhat more detailed vocational grouping, to greater mensural information for orthopaedicians and finally the most comprehensive classifications—used by specialist kinesiologists. In the present section *all* these approaches to classification are given, first as a synopsis of principal headings and terms; in later pages and (where indicated) elsewhere, these are defined and described in greater detail. Where the morphology is mixed, or changes radically with time, and in some exceptional topographical situations (e.g. the costal cartilages and the larynx), additional classificatory groups have been included. Although unusual, this confers a more complete logic to the frameworks employed.

INTRODUCTORY CLASSIFICATION OF ARTHROSES

EITHER (CLASSIC NOMENCLATURE)

OR (ANGLICIZED NOMENCLATURE)

ARTHROSES: MAIN VARIETIES

The anlagen of all skeletal units (expanding, initially separate centres of ossification and ultimately consolidated whole bones) are derived from condensations of mesenchyme. In many sites the mesenchyme becomes increasingly fibrous and bone formation occurs directly in this tissue (*intramembranous ossification*, p. 300); elsewhere the mesenchyme differentiates into a hyaline cartilaginous model and, within this, an orderly sequence of transformations leads to *endochondral ossification*. The biological nature, mechanical properties, changes and fate of the specialized connective tissues interposed between adjacent osseous surfaces form the foundation for the broad classification of **arthroses**, firstly into *two* fundamentally contrasting groups. The specialized connective tissues may remain *solid*, often changing character with time, or may develop a narrow but extensive, enclosed, fluid-containing *cavity*. *Solid (non-synovial) joints* are termed **synarthroses** and are commonly grouped according to the principal type of interosseous connective tissue into **fibrous joints** and **cartilaginous joints**. These reflect the two modes of ossification already mentioned.

Synarthroses, of both types, characterize almost all the cranial junctions; their respective derivations, clearly, are the desmocranium and chondrocranium (p. 164); both types are also present in large numbers throughout the post-cranial skeleton which, other than the clavicle, is mainly endochondral in origin.

Cavitated (synovial) joints are formally termed **diathroses** and, with few exceptions (the temporomandibular joint and those involving the clavicle), are between the ends or other circumscribed surfaces of endochondral bones. Here each articular surface is of specialized hyaline cartilage strongly adherent to its bone on one aspect; on the other, it is a free, lubricated, macroscopically smooth, wear-resistant surface which can glide over its fellow with minimal friction. The fine cleft between apposed surfaces contains lubricant and nutritive synovial fluid (*synovia*) and this *synovial cavity* extends to the *synovial membrane* where the fluid is produced and which lines the fibrous capsule and other non-articular surfaces of the joint.

INTRODUCTORY CLASSIFICATION OF ARTHROSES (continued)

I. SYNARTHROSES	bone—solid connective tissue—bone
1. FIBROUS JOINTS (**Articulationes fibrosae**)	
a. Sutures:	bone—collagenous sutural ligament—bone
b. Syndesmoses:	bone—collagenous interosseous ligament, membrane or cord—bone (elastic fibrous tissue is occasionally prominent)
c. Gomphoses:	bone—complex collagenous periodontium—dental cement
2. CARTILAGINOUS JOINTS (**Articulationes cartilagineae**)	
a. Synchondroses: (*Primary cartilaginous joints*)	bone—hyaline growth cartilage—bone
b. Symphyses: (*Secondary cartilaginous joints*)	bone—hyaline growth cartilage—fibrocartilaginous disc—hyaline growth cartilage—bone
SYNOSTOSES:	rigid bony union; after growth has ceased this is the normal fate of synchondroses, ultimately most sutures, and some symphyses
II. DIARTHROSES	bone—cavitated connective tissue—bone
SYNOVIAL JOINTS: (*Articulationes synoviales*)	bone—articular cartilage—synovial fluid in cavity—articular cartilage—bone Bond: surrounding sleeve of collagenous fibrous capsule lined by synovial membrane; extrinsic and intrinsic ligaments. Occasional intracapsular ligaments, tendons, fat pads, fibrocartilaginous discs or menisci

MORE DETAILED NOMENCLATURE (see text for definitions)

(A)

SYNARTHROSES

FIBROUS JOINTS (ARTICULATIONES FIBROSAE)

Sutures (Suturae)
Morphological terms:
serrate
denticulate
squamous
limbous
plane
schindylesis (wedge and groove)
Suturae cranii (33 officially recognized and systematically named)

Gomphoses
('peg and socket';
articulationes dentoalveolares)

Syndemoses
Bonding by collagenous (sometimes elastic) interosseous ligament, cord or membrane sheet. There are 12 officially recognized, named, syndemoses (see text). Criteria for inclusion (or exclusion) remain arbitrary.

CARTILAGINOUS JOINTS (ARTICULATIONES CARTILAGINEAE)

Synchondroses (Primary cartilaginous joints; hyaline growth cartilages)
Varieties and sites:
Synchondroses cranii (between ossific centres in the chondrocranium, within and between named bones. See text for details and names.)
Synchondroses postcranii
epiphysiodiaphyseal
epiphysiocorporeal
intra-epiphysial
multiplex (in compound, e.g. hip, bones)
sternales (between sternebrae)
manubriosternalis (young)
xiphosternalis
sacrales (young)
costal cartilages are atypical (see text)

Symphoses (Secondary cartilaginous joints)
Bone surfaces encased in hyaline growth cartilage are bonded by fibrocartilaginous disc. All are median.
S. *manubriosternalis*
S. *intervertrebrales*
S. *sacrales*
S. *pubis*
S. *menti* (atypical and temporary)

SYNARTHROSES: MIXED

Many large synchondroses have localized bundles of dense collagen. Many sutures possess islands of fibrocartilage (see text).

SYNARTHROSES: PERSISTENCE OR CONSOLIDATION (Synostoses)

Syndesmoses, gomphoses and some symphyses grow with their surrounding tissues, the latter contributing to osseous growth; when growth ceases, however, they *persist* throughout life with only minimal age changes. Some symphyses ossify wholly or in part. Synchondroses and sutures possess both functionally important mechanical properties and are most prominently *growth mechanisms*. When growth ceases the intervening cartilage or fibrous tissue is progressively ossified, bony union occurs and they become **synostoses**. It is usually stated that 'the joint is obliterated' and uncommon to group **synostoses** with **arthroses**. Total function, however, makes it quite logical.

THE SITES OF ARTHROSES

The human skeleton, often simply classed as an endoskeleton, is actually compound; the numerous elements which were endoskeletal from their inception have been blended with exoskeletal derivatives, e.g. the clavicles and bones of the cranial vault, sides, nasofacial region, jaws, palate and tympanic plates. In the middle decades of a full normal human lifespan the mature, 'complete' (but far from quiescent) *named bones* are the constituent structural units of the osseous skeleton. The detailed topography of individual bones including the fleshy/tendinous/aponeurotic attachments of muscles, fasciae, ligaments, articular capsules and other relationships, e.g. neurovascular, visceral, coelomic or bursal, together with a summary of their patterns of ossification are provided in Section 3, *Osteology*. The latter section includes well-defined areas on the surface of a bone which are in *intimate structural/functional juxtaposition* with complementary areas on a neighbouring bone or bones; specialized connective tissues blend strongly with the osseous surfaces, *solid* or *cleft*, and occupy all the intervening territory. Their developmental history, progressive changes (some continuing to senescence) and distinctive functional attributes provide these **arthroses** with an acceptable framework for classification in the present section. Much information, from many viewpoints, is presented concerning the multiple varieties of the sclerous connective tissues, cartilage and bone, also the presently relevant dual modes of ossification, *intramembranous* and *endochondral*, in the opening chapters of *Osteology*. Collagen, prominent in the present context, is considered in terms of varieties, dispositions, mechanical properties and biosynthesis in *The Matrix of Connective Tissue* in Section 1, *Introduction*; here also the less prominent elastic components are reviewed. Brief accounts of the development of skeletal, junctional and related locomotor structures may be found in Section 2, *Embryology*. (Consult tables for nomenclature of varieties of arthroses.)

The foregoing comments have, however, been restricted to surface areas, or borders, of *whole mature* bones. In the present context, throughout late embryonic, fetal and mainly the first two postnatal decades of life, other relevant structural skeletal units are also the separate *centres of ossification*, either endochondral or intramembranous. Each ossific centre and its surrounding specialized tissue are interdependent and co-operate with neighbours in integrated patterns of differential *growth*. As noted (p. 279 et seq) a number of bones, some endochondral (carpals, most tarsals), some intramembranous (nasals, lacrimals, palatines, zygomatics), develop from a single centre of ossification and are classed as a *primary* centre. The remaining (endochondral) postcranial bones also possess, commonly, *one primary centre*, but

MORE DETAILED NOMENCLATURE (see text for definitions)

(B)

DIARTHROSES
(ATICULATIONES SYNOVIALES)
SYNOVIAL JOINTS
(To avoid repetition Joint or Articulation is omitted below)

General Morphology

Simple (one pair of articulating surfaces; male and female)
Compound (more than one pair of surfaces)
Complex (with intracapsular meniscus or disc)

Widely used terms
(Useful approximations)

Surface shape
- *plane*
- *spheroid* (**enarthrosis**; 'ball and socket')
- *ellipsoid*
- *ginglymus* ('hinge')
- *bicondylar*
- *trochoid* ('pivot')
- *sellar* ('saddle-shaped')

Axes of movement
- *uniaxial*
- *biaxial*
- *triaxial*
- *polyaxial*

Types of movement
- *translation*
- *rotation* (*conjunct* or *adjunct*)
- *angulation*
- *flexion/extension*
- *abduction/adduction*
- *circumduction*
- *elevation/depression*
- *protraction/retraction*
- *fixation* (neuromuscular)
- *fixation* (mechanical: close-packing)

During locomotion, postural adjustment and exploratory and manipulative tasks, the above analytical unitary movements are combined in complex patterned arrays at numerous joints.

Fundamental Joint Positions
- *Loose packed*—controlled free *mobility*
- *Close packed*—position of functional *rigidity*

Precise analytical terms
(Less frequently encountered)

Surface topology
- *ovoid*, simple; male and female
- *ovoid*, compound; male and female
- *sellar*; male and female

Almost all synovial articular surfaces are quantitative variants of the above.

Joint mechanics

Movements are related to the concept of the *mechanical axis* of a bone (see text). Movements are all resolvable as rotations around one, two or three orthogonal axes, i.e. possessing 1–3 *degrees of freedom*.

Types of movement

Terms refer to one mobile articular surface moving relative to its fixed partner.

Spin: pure rotation of surface around its mechanical axis.

two varieties—pure and *impure*:
- *Cardinal swing*: tips of mechanical axis trace a chordal path. There is no spin.
- *Arcuate swing*: tips of mechanical axis trace an arcuate path. Joint topology necessitates some associated spin (i.e. conjunct rotation)

All the above terms, and others, are defined and amplified in the following pages.

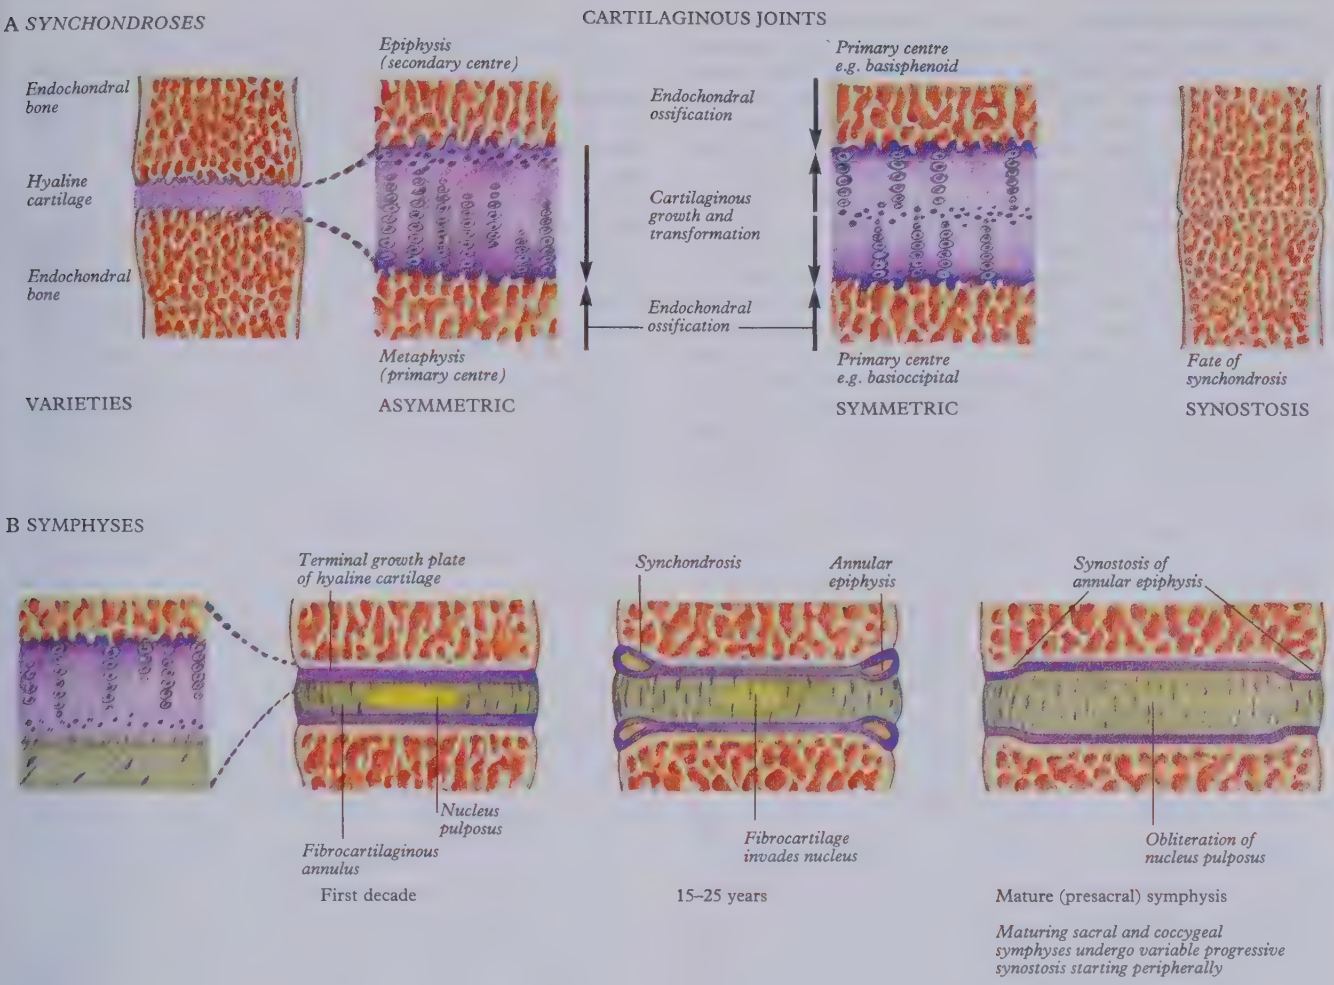
phylogenetically compound bones (e.g. vertebrae, the scapula, innominate or hip bone, sternum and sacrum) possess a number of *separate primary centres*; the majority appear between the seventh week of embryonic life and the fifth month of intrauterine fetal life. Some, however, appear at intervals throughout the first 10–12 postnatal years. *Secondary centres of ossification* (*epiphyses*) appear at times, varying considerably with location, over an even longer period, the earliest at full term and the last after adolescence, about the fifteenth year. Miniature long bones develop a simple, single, terminal epiphysis (see metacarpals, metatarsals, phalanges); other long bones (radius, ulna, fibula, and often tibia) develop similar simple epiphyses at *both* ends; the humerus (both ends) and femur (proximal end), however, have *multiple* secondary loci of ossification. Many epiphyses also characterize the compound post-cranial bones mentioned above. The remaining cranial bones each possess two or more, sometimes many, primary centres of ossification; some are confined to the desmocranium and are almost exclusively intramembranous in nature (frontal and parietals), whereas the centres for the ethmoid are endochondral, being wholly confined to the rostral chondrocranium. The four bones forming the cranial base, and the lateral and posterior walls of its vault—the sphenoid, paired temporals and the occipital—are complex in phylogenetic origin and development; each possesses many centres of ossification, some intramembranous, the remainder endochondral.

Cartilaginous Joints

As indicated in the previous paragraphs and tables, synarthroses, bone junctions bonded by solid connective tissue, are generally divided into two main groups: cartilaginous joints and fibrous-joints. In most instances the distinction is quite obvious and apposite; in a number of sites however some admixture occurs, where a predominantly fibrous articulation contains occasional islands of cartilage or conversely a predominantly cartilaginous articulation contains aligned dense bundles of collagen (vide infra).

Articulationes cartilagineae (cartilaginous joints) are themselves classified into two groups: *synchondroses* (*primary cartilaginous joints*) and *symphyses* (*secondary cartilaginous joints*). When fully formed each group has some distinctive structural and functional features; other features however, although varying quantitatively, they share in common. The terms primary and secondary should, perhaps, be abandoned; they are only apposite in the instances of certain symphyses (vide infra) that, developmentally, are preceded by synchondroses within which further differentiation occurs.

SYNCHONDROSES



These junctions occur where originally separate, but adjacent, centres of ossification appear within a continuous mass of hyaline cartilage. As ossification spreads it invades the *actively growing* zone of cartilage which occupies the interval between contiguous osseous surfaces. Thus a synchondrosis consists of two ossifying fronts closely bonded by a specialized *hyaline growth cartilage*. Structurally, passing towards an ossifying surface the growth cartilage has successive recognizable zones of: relative *quiescence*; proliferative and interstitial *growth*; *transformation* into columns, with cell hypertrophy, matrix calcification and cell death; *ossification* involving chondrolysis, vascularization and osteogenesis. (For details see p. 300.) Where the rate of ossification of both surfaces forming a synchondrosis is approximately equal (e.g. in the cranial base), the growth cartilage has a central quiescent zone equidistant from the surfaces and the above-mentioned zones proceed symmetrically towards *both* surfaces. Where the growth rates are unequal, the growth cartilage structure is correspondingly asymmetrical; extreme examples are synchondroses between the diaphysis and terminal epiphyses of long bones where growth and progressive ossification are mainly (but not exclusively) diaphyseal. In the latter the quiescent stratum lies near the epiphyseal bone and the zonation extends towards the diaphysis. The cartilaginous growth plate grows in girth by the interstitial and subperichondrial methods described elsewhere (p. 309); also activity varies at different radial distances from its centre. In this manner the overall shape of the cartilage and its attendant bones are changed, sometimes profoundly. Thus, the early epiphysis of the femoral head is separated from (bound to) the femoral neck, an extension of the diaphysis, by a relatively simple horizontal growth plate of cartilage. With differential growth the capitular tip of the neck becomes increasingly conical, clothed and tightly bound to a conical growth cartilage and both received by a deep conical recess in the inferolateral part of the otherwise spheroidal ossifying femoral head.

Functionally, synchondroses are primarily *growth mechanisms* and, although contributing slightly to the more flexible skeleton of youth, their growth potential is combined with a considerable ability to successfully resist forces, whether of compression tension, shear or torsion. Thus they permit growth to continue, while there are free but controlled, often powerful, movements executed at neighbouring synovial joints, or more restricted movements at symphyses and some fibrous joints. These features are characteristic of the numerous **post-cranial synchondroses**. Since, with the exception of the clavicle and areas of subperiosteal bone accretion, all post-cranial centres of ossification are endochondral, synchondroses are present in all post-cranial bones derived from two or more centres, i.e. the majority of post-cranial bones. The carpal and most tarsal bones however each develop from a single endochondral centre; their ossifying surfaces advance invading a *complete encasement* of *growing cartilage*. Parts of the latter persist as the specialized articular cartilaginous surfaces of carpal and tarsal synovial joints; elsewhere the bone approaches the perichondrium (now periosteum) and provides attachment for fibrous joint capsules, tendon sheaths, interosseous ligaments, fascial septa and muscles. Clearly, these relatively small bones possess no synchondroses but their essential growth mechanisms have much in common with that of epiphyses. (For details see p. 421.)

Most **post-cranial synchondroses** have not been given specific topographical names, but the general morphological group to which each belongs should be clear after reference to previous paragraphs and Table A of 'More Detailed Nomenclature'. They may be *epiphysio-diaphyseal* (or more precisely epi-*metaphyseal*, or epi-*corporeal*), *intra-epiphyseal* in compound epiphyses, *multiplex* in compound bones with multiple primary centres. Examples of the last having topographical names are: the *triradiate acetabular cartilage* of the developing hip bone, *sternales* between growing sternebrae, *manubriosternalis* (young, before transformation to a symphysis), *xiphosternalis*, *vertebrales* confined to individual vertebrae, *sacrales centrales* (young, soon to be temporary symphyses) and *laterales* (between centra, neural arches and costal processes). Structurally, the pattern of zonation mentioned above and elsewhere (p. 279) requires some amplification. Growth cartilages vary considerably with age, site and species. For reviews of the extensive literature see Knese (1979), Hall (1983) and for recent quantitative studies, Moss-Salentijn et al (1987), and Taylor et al (1987). Most intensively studied are certain synchondroses in small laboratory mammals, mouse, rat and rabbit, and in particular the proximal tibial synchondrosis. In the embryonic stage the cartilaginous 'models' of future endochondral bones consist of generalized hyaline cartilage, its chondrocytes being randomly distributed within copious matrix. With formation and longitudinal advance of the primary endochondral centre of ossification the site of the *presumptive growth plate* of cartilage is indicated by ovoid aggregates (or clones) of chondrocytes. The full zonal pattern is only seen in the *definitive growth plate* between the advancing osseous surface of the metaphysis and that of the epiphysis. Human growth plates are relatively much thicker than those of the laboratory mammals studied, due in large measure to the depth of the 'quiescent' or small cell zone adjacent to the epiphysial bone. This small cell zone is narrow in small mammals but in man it may account for 60–70% of total plate thickness; its significance is controversial. As implied by its earlier name, some regard it as relatively inert; others, however (see reviews and quantitative references), consider it a pool of stem progenitor cells. From the latter, throughout the life of the growth plate (the phase of growth of the bone), successive generations of chondrocyte columns are formed, transformed, partially eroded then form a scaffold for advancing ossification. Thus, when fully active, a growth cartilage contains chondrocyte columns that vary in length, maturity and position. Young columns extend limited distances from the small cell zone (*epiphysial* position); mature forms are *full length* columns; old columns are again short, partly eroded and *metaphysial* in position. (It should be emphasized that these names are purely positional; they were devised for quantitative analyses of growth cartilages in appendicular long bones and as these grow and retreat they all contribute to the advancing surface of *metaphysial* ossification.) The dual views concerning the small cell zone may, reasonably, both be correct; the cells near the epiphysial bone have a low growth potential while the potential to function as a pool of chondrocyte progenitor cells increases markedly as the tips of the chondrocyte columns are approached.

The chondrocytes and matrix of young growth cartilages have the three-dimensional architecture described for hyaline cartilage (p. 288) and the changes in the partitions enclosing chondrocyte columns have been mentioned (p. 305). In the latter the collagen fibrils have been termed 'ladderlike' (Eggli et al 1985). Some large growth cartilages that are habitually subjected to unusually large stresses develop, in addition, dense bundles of collagen, their fibro-osseous disposition reflecting the stress. These *fibrous epiphysial (growth) plates* have been studied by Smith (1962 a,b). In the proximal growth plate of the human tibia the approximately flat condylar parts of the plate are traversed by regularly aligned horizontal bundles (i.e. at right angles to the bone's long axis) and they suffer lateral compression during weight bearing. Where the epiphysis descends anteriorly to form the tibial tuberosity it receives shearing stress due to the oblique pull of the quadriceps femoris and here the cartilage of the growth plate is almost completely replaced by oblique dense collagen. (For other examples of structurally mixed growth cartilages consult references quoted above; and for a general review of the epiphysial vascularization of growth cartilages see Moss-Salentijn 1976.) The fates of post-cranial and cranial synchondroses are considered together below; also mentioned are some unclassified or inappropriately classified junctions involving cartilage.

Cranial synchondroses, as indicated, occur between neighbouring endochondral centres of ossification that develop in the chondrocranium; for its origin, chondrification, and topographical regions, see p. 309; and for a general developmental review Bosma (1976). Some regions of the chondrocranium remain unossified: the lateral, alar and septal nasal cartilages and remnants occupying and near the foramen lacerum. In contrast the largely endochondral auditory ossicles interconnect by specialized synovial joints, while the malleus and stapes are connected to the temporal bone by equally specialized fibrous

4.1 Varieties of cartilaginous joints (articulationes cartilagineae). A. Synchondroses in sectional view. The principal tissues involved, more detailed architecture and main growth patterns of symmetrical and asymmetrical synchondroses. In some locations lesser degrees of asymmetry occur; synostosis is the normal fate of almost all synchondroses when *endochondral* growth has ceased. B. Intervertebral symphyses (presacral) in sectional view, displaying changes with age. Note that partial or complete synostosis is the normal fate of sacral and coccygeal symphyses. For discussion and for manubriosternal and pubic symphyses see text and individual joints. C. Less common interchondral and osseochondral junctions; see text for other locations.

arrangements, the fibrous stratum of the tympanic membrane (p. 380) and the annular ligament respectively. The endochondral centres of ossification are for the inferior nasal concha (single), the ethmoid (three), the sphenoid (multiple pre- and post-sphenoidal centres for the body, conchae, lesser wings and roots of greater wings, see p. 376), the temporal bones (multiple centres for each petromastoid part and styloid process, see p. 380), the occipital bone (multiple centres for basilar, condylar and squamous parts up to the highest nuchal lines, see p. 373). Clearly, the sites of basicranial synchondroses are numerous, some within the individual bones, others between them. All contribute in some measure to basicranial growth but those that persist for limited periods, and coalesce early, are unnamed; official names are reserved for those making substantial contributions. Avoiding repetition of the prefix synchondrosis in each case, these are: *spheno-ethmoidalis, spheno-occipitalis, sphenopetrosa, petro-occipitalis, intraoccipitalis anterior* and *intraoccipitalis posterior*. Although they are not officially named, presumably because of their relatively early fusion, it seems appropriate to include the main intrinsic synchondroses of the sphenoid. Suggested names are: *intrasphenoidalis transversus* between pre- and post-sphenoidal parts of the body and *intrasphenoidalis lateralis*, bilaterally separating the body from the conjoined greater wings and pterygoid processes (see p. 376). As mentioned, the cranial synchondroses are approximately symmetrical in structure, their zones of growth and differentiation passing from the centre towards both ossifying surfaces.

The fate of synchondroses. When those aspects of growth of parts of a bone, or between bones, joined by a synchondrosis near completion, classic cartilaginous growth, transformation and endochondral ossification ceases. For a period the cartilaginous plate is relatively quiescent, but becomes irregularly thinned; complex histological changes now supervene and involve the cartilage from both osseous surfaces. (For histological details and references see p. 307.) Finally, the synchondrosis is wholly replaced by complete bony union between the originally separate osseous surfaces, i.e. it has formed a **synostosis**. The latter has lost its cartilaginous growth potential and mechanical properties, but has assumed the maximal rigidity of bone. (For mechanical properties see p. 276 et seq.) This continues and enhances the effectiveness of post-cranial bones in carrying a variety of powerful stresses, either in almost static postures or during movement patterns involving synovial and (to more limited degrees) median symphysial or fibrous joints. Rigidity of the neurocranium, both during and after completion of growth, is functionally imperative, affording geometric and protective support and encasement of the brain, special sense organs and their vasculature and associated fluids (blood and cerebrospinal fluid).

Terminology: Some Brief Comments

The fate of synchondroses raises a number of points, some directly, others indirectly, which require amplification; they also provide examples of the kind of limitations inherent in many biological classifications. Thus, it is commonly stated that 'synchondroses are temporary junctions, and with cessation of growth, the joint is obliterated as bony union occurs'. Apparently useful and self-explanatory, all parts of this statement need comment. *Temporary*: while strictly correct in relation to all true synchondroses (vide infra), it must be emphasized that their periods of activity and times of synostosis vary greatly in different sites. Some fuse early, in fetal or perinatal life, others throughout the first decade, many in the latter half of the second decade, while the spheno-occipital basicranial synchondrosis may continue well into the third decade (p. 376, see also under ossification of individual bones). Many are therefore fully active through many years of intense patterns of locomotion and their essential properties are a unique *combination* of growth potential and strength of interosseous bonding. *Cessation of growth*: this clearly does not refer to overall growth, e.g. of the whole body, skeleton, body segment or even a whole bone. Patterns of osseous fusion are complex and, as mentioned above, extend over lengthy periods; even some long bones that develop simple terminal epiphyses at both ends (e.g. fibula, ulna) have asynchronous fusion times. The growth referred to specifically is solely the equilibrium between endochondral ossification, cartilaginous growth plate proliferation and transformation of the growth plate in question. When fusion *has* occurred, however, subperiosteal and subendosteal bone accretion and resorption and trabecular remodelling may *continue*; finally, at the microscopic level, osteon removal and replacement at varying rates continues throughout life. *The joint is obliterated*: this clearly implies acceptance of synarthroses as a major classificatory group, with synchondroses (also, symphyses, sutures, syndesmoses, gomphoses) as well-defined subgroups. Osseous fusion is not included in the official Nomenclature or by the majority of authors. Some authorities, however, find it quite logical to include **synostoses** as extreme forms of synarthroses. This becomes increasingly so when growth potential and rigidity are regarded as equally relevant arthrological ingredients as active movement.

Unusual Junctions Involving Cartilage

Hitherto in this section, and in general use, arthroses have been defined as co-aptations of *osseous* surfaces, and their classification stemmed from the variety of specialized intervening connective tissue and its solid or cleft state. A number of junctions, however, have many arthrodial features but are not accommodated by the general classification of arthroses; these occur where substantial masses of cartilage remain unossified in normal development. (Some masses develop irregular patches of calcification in later decades.) Thus the junctions may be between bone and cartilage, or between two adjacent cartilages. The bone involved may be endochondral or intramembranous; or finally a cartilage may join with a fibrous suture or a synchondrosis. The junctions are similar to either fibrous synarthroses or to synovial joints. Particular reference can be made to the nasal, laryngeal and costal cartilages, also those of the auditory tube and auricle (pinna). Fibrous junctions occur between the borders of contiguous nasal cartilages; the septal cartilage is, in part, continuous with the lateral nasal cartilage but elsewhere fibrous bonds extend to the internasal suture, perpendicular plate of the ethmoid, the vomer, the nasal crest (and intermaxillary suture) and anterior nasal spine of the maxillae and the septal process of the lateral nasal cartilage. At these junctions perichondria fuse or perichondrium and periosteum (and in some sites sutural ligament) blend.

A fibrous junction joins the perichondrium of the elastic auricular fibrocartilage and the periosteum of the roughened outer rim of the external acoustic meatus. A similar fibrous union suspends the perichondrium of the superior recurved border of the cartilage of the auditory tube and the inferior perichondrium of the sphenopetrosal synchondrosis (periosteum after synostosis, the upper attachment spreading on to the petrous quadrate area). The larynx and hyoid bone furnish further examples of specialized and uncommon varieties of connection and junction. Most extensively the laryngeal cartilages are connected to each other, and the thyroid and epiglottic cartilages to the hyoid bone, by three-dimensional complexes of fibro-elastic membranes and their ligamentous thickenings. These *interchondral* and *osseo-chondral* structures are detailed on pp. 462, 468; although not officially listed as synarthroses (subgroup *syndesmoses*) it seems quite logical to regard them thus. Additionally, the cricoid cartilage bears four discrete articular surfaces, one bilateral pair on the sloping superior border of its lamina, another lateral pair at each junction of lamina and arch. These articulate respectively with the articular surface on the base of each arytenoid cartilage and those on the medial aspects of the tips of the inferior cornua of the thyroid cartilage. The crico-arytenoid and cricothyroid articulations to which these surfaces contribute (p. 1252) are *interchondral* synovial joints.

The costal cartilages are often, usefully, considered as unossified cartilaginous extensions of the ribs; first to seventh reaching the sternum, eighth to tenth only reaching the cartilage above, eleventh and twelfth being short blunt cones with free intermuscular tips. The cartilages are, however, traditionally described as separate topographical entities (p. 335) and,

depending on its level, each engages in from one to five different types of junction (p. 498). The costochondral junctions are unusual synarthroses where the convex tip of the cartilage is received by a complementary recess in the tip of the rib; perichondrium and periosteum are continuous, as are the collagenous elements of bone and cartilage. The sternochondral joints (often called sternocostal joints) vary; the second to seventh are often synovial, with *fibrocartilaginous* articular surfaces on both chondral and sternal aspects. (For the disposition of the intra-articular, capsular and other ligaments see p. 498.) Quite frequently synovial cavities are absent in some or all these joints; in these cases a thin dense lamina of tightly adherent fibrocartilage is interposed between cartilage and bone—an unclassified variety of synarthrosis. This type of junction is usually present at the manubrial end of the first costal cartilage. (It may be noted that it is commonplace for the *whole* first costal cartilage and attached rib and sternum, or the manubriochondral junction alone, to be classified quite incorrectly as a synchondrosis.) The fifth to ninth costal cartilages carry a variable number of simple interchondral synovial joints and also irregular syndesmoses in the form of short interchondral ligaments between borders or apical (particularly cartilages eight to ten), anchoring their tips to the superjacent border.

SYMPHYSES

A symphysis is another variety of cartilaginous synarthrosis; distinctive attributes although prominent are few; they share many features with other arthroses and only differ quantitatively. Topographically, all symphyses are median and, with one exception, they are confined to the axial skeleton. The latter include the following named symphyses: the *manubriosternalis* between manubrium and sternal body; *intervertebralis* between successive vertebral bodies (regionally grouped—cervical, thoracic, lumbar, sacral and coccygeal); also axial is the *symphysis menti* between the bilateral halves of the fetal mandible and continuing only into the first postnatal year when synostosis supervenes. Histologically the mental junction is quite unlike other symphyses (see p. 367), but the use of its name is so widespread that retention seems inevitable. Finally bilateral appendicular bones, the medial surfaces of the bodies of the pubes, are conjoined at the *symphysis pubis*.

Ignoring regional specializations (mentioned below) the general architecture of a symphysis consists of two well-defined surface areas of articulating endochondral bones; the osseous surfaces are from a few millimetres to over a centimetre apart and bonding them are strong, tightly adherent, solid connective tissues. Each bony surface is firmly attached to a thin lamina of hyaline cartilage and, in turn, these blend with the surfaces of a thick, strong, but deformable pad (or disc) of fibrocartilage. Collagenous ligaments extend from the periostea across the symphysis and blend with the hyaline and fibrocartilaginous perichondria; they do not form a complete capsule (as is the case in synovial joints), but they are similar in containing plexuses of afferent nerve terminals, which also penetrate the periphery of the fibrocartilage. The combined strength of the hyaline and fibrocartilage with the ligaments exceeds even that of the bones to which they connect; thus they can easily withstand the habitual range of stresses (compression, tension, shear and torsion) encountered without disruption. Tears are usually the result of sudden, unexpected massive stresses occurring when the body is in an inappropriate posture. The architecture of the fibrocartilaginous tissues is such that it combines the *strength* mentioned with limited degrees of elastic deformability, thus allowing the restricted but appreciable ranges of *movement* that characterize symphyses. Fibrocartilaginous disc compression narrows the interosseous interval, while tension lengthens it; thus when these occur simultaneously in opposite sectors of the disc, the latter becomes cuneiform (wedge-shaped) and its attached bones are relatively inclined (angulated). Torsional stress increases or decreases the spiralization of collagenous discal microarchitecture and permits slight relative rotation. Although the ranges of movements possible at a symphysis are not great and primarily determined by its intrinsic anatomy, this is, however, further limited by the additional articulations and ligaments that involve the bones but are extrasymphyseal; e.g. the numerous syndesmoses and synovial zyapophysial joints between adjacent vertebrae, articulations of the clavicles and costal cartilages with the sternum, and the sacro-iliac joints, interosseous sacro-iliac, sacrotuberous and sacrospinous ligaments. All these features profoundly affect movement patterns at their related symphyses.

Further comments on symphyseal structure, functional attributes and nomenclature. Thick fibrocartilaginous pads or discs that most characterize symphyses are not simple deformable masses of feltwork, but present precise zonal variations in microstructure, particularly in their arrangement of collagenous and elastic fibres adapted to their habitual stresses. Best investigated and most complex are the intervertebral discs. (See p. 489 for their main subregions, fibre architecture, cellularity, physicochemical properties and profound age changes.)

Solid specialized connective tissues, by definition, characterize synarthroses and, while this obtains in thoracolumbar and sacrococcygeal series of intervertebral symphyses, significant proportions of the remainder develop a single central or a bilateral pair of narrow fluid-filled clefts in (or near) their fibrocartilaginous pads. Over 30% of manubriosternal symphyses develop a central horizontally elongate cleft (p. 498) and over 50% of interpubic discs develop a median elongated cleft in the oblique long axis of the disc. (For variations in size and position see p. 517.) The second to sixth (sometimes seventh) cervical intervertebral discs develop laterally placed small fluid-filled cavities in the fibrous tissue between the inferolateral bevelled edge of the vertebral body above and the superolateral lip of the vertebral body below. Some regard these cavities as sited in the peripheral parts of the discs and non-synovial in character; others regard them as small synovial joints near, but external to, the discs (p. 490). The synovial or non-synovial nature of all the above clefts remains controversial; they perhaps reflect a stage in the evolution of synovial joints. Caution should also prevail concerning the dogmatic assertion that *no* movements of translation occur between their free moist surfaces until adequate objective evidence has accummulated. Distinct possibilities seem to be translations at the cervical cavities during spinal movements and translation with distraction at the interpubic cleft, particularly during the later stages of pregnancy.

The common statement that synchondroses are temporary and concerned with growth, whereas symphyses are permanent and concerned with movement, is an oversimplification, only partly correct and with much omitted. *Both* are concerned with *strength* and the ability to withstand and transmit considerable stresses and with *growth*; and, in contrasting ways, both contribute either directly or indirectly to the total *movement patterns* of the parts involved. The strength and mechanical properties of cartilaginous joints need little further comment, but it may be reemphasized that the rigidity of synchondroses increases the efficiency of positive movements at related syndesmoses, symphyses and particularly synovial joints. It may also be reiterated that the movements at symphyses are not a simple extrapolation of the mechanical properties of a fibrocartilaginous pad or disc assessed in experimental isolation. For example, movement of a vertebra relative to its neighbour is a three-dimensional summation of the properties of *all* its intervertebral arthroses (syndesmoses and synovial joints, in addition to the complex symphysis) acting in concert, but each with its particular array of stresses. (During their growth phases the mechanical properties of the *intravertebral synchondroses* are also significant.)

The prominent role of synchondroses in skeletal *growth* is widely recognized, investigated and discussed, whereas growth of and involving symphyses is often ignored or receives but scant mention. *Symphysial growth* may, for convenience, be considered from two aspects (although interrelated); these are intrinsic growth of the fibrocartilaginous disc and growth of the hyaline cartilaginous plates into which (e.g. vertebral) endochondral ossification progresses and later 'annular' epiphyses form (vide infra). At the manubriosternal symphysis its limiting plates of proliferative hyaline cartilage are progressively invaded by the ossifying fronts of the manubrium and first sternebra; normally

no epiphyses are formed. At the pubic symphysis, however, the growth plates of hyaline cartilage that are involved with endochondral ossification on the symphyseal aspects of the bodies of the pubes after puberty commonly develop scale-like epiphyses, usually anterosuperiorly. The occurrence of intervertebral and pubic epiphyses adds some complexity to the traditional description of symphyses. At these sites, as indicated, the epiphyses appear at, or soon after, puberty and continue slow growth for about a decade before synostosis with the main bone. During this period the epiphysis is completely encased by proliferative hyaline cartilage, its interosseous lamina being a narrow (epiphysiocorporeal) synchondrosis and its symphyseal lamina a simple extension of the terminal plate of hyaline growth cartilage. The latter was, of course, originally derived from the early embryonic cartilaginous vertebral model (p. 159). These growth plates are the proliferative source of cartilage into which all endochondral ossification of the vertebral *bodies* occurs cranially and caudally (and constituting about 80% of the length of the mature vertebral column, see p. 315). The remaining 20% is provided by growth of the fibrocartilaginous discs; their regional variations in thickness and their cuneiform sagittal profile (vertically thicker ventrally) in the cervical and lumbar secondary spinal curvatures are described on p. 315. Where the fibrocartilage blends with the lamina of hyaline cartilage some bundles of collagen pass from the former and, without interruption, interlace within the matrix of the latter. The hyaline laminae show the zonal variation in structure previously described and common to all growth cartilages.

Terminology. It may be noted that clinically and radiologically the term intervertebral symphysis is seldom used; instead '*the intervertebral disc*', or simply '*the disc*', and radiologically '*the disc space*' are often used to indicate *all* tissues between the vertebral bodies. Formally, however, the fibrocartilaginous intervertebral disc, with its age-dependent nucleus pulposus (p. 490), is regarded as part of a symphysis, completed by paired laminae of terminal growth cartilages and their associated ossifying or mature osseous surfaces.

Fates of symphyses. The widely quoted generalization that 'synchondroses are temporary while symphyses are permanent' is only partly correct; there are prominent exceptions. Normally permanent, but exhibiting age changes, are the cervical, thoracic, lumbar and lumbosacral intervertebral symphyses, the pubic symphysis and about 90% of manubriosternal symphyses. The age changes in intervertebral discs are detailed on p. 490; the development of narrow fluid-filled clefts are mentioned above and under individual joints; also allusions to changes in the pubic symphysis in the later stages of pregnancy are made above and on p. 518. In contrast, the joints between successive sacral bodies, between sacrum and coccyx and between coccygeal segments, after preliminary stages, form well-developed symphyses; however, their normal fate is partial or complete *synostosis*; the process is slow and lengthy (pp. 329, 332). After 30 years of age about 10% of manubriosternal symphyses develop partial or complete synostosis; again the phenomenon may be slow and lengthy (p. 393).

Articulationes Fibrosae

Fibrous joints in most instances consist of predominantly collagenous junctions between bones but in a minority of situations fibro-elastic tissue predominates. Three main groups of fibrous articulation are generally recognized, namely, sutures, gomphoses and syndesmoses (4.2).

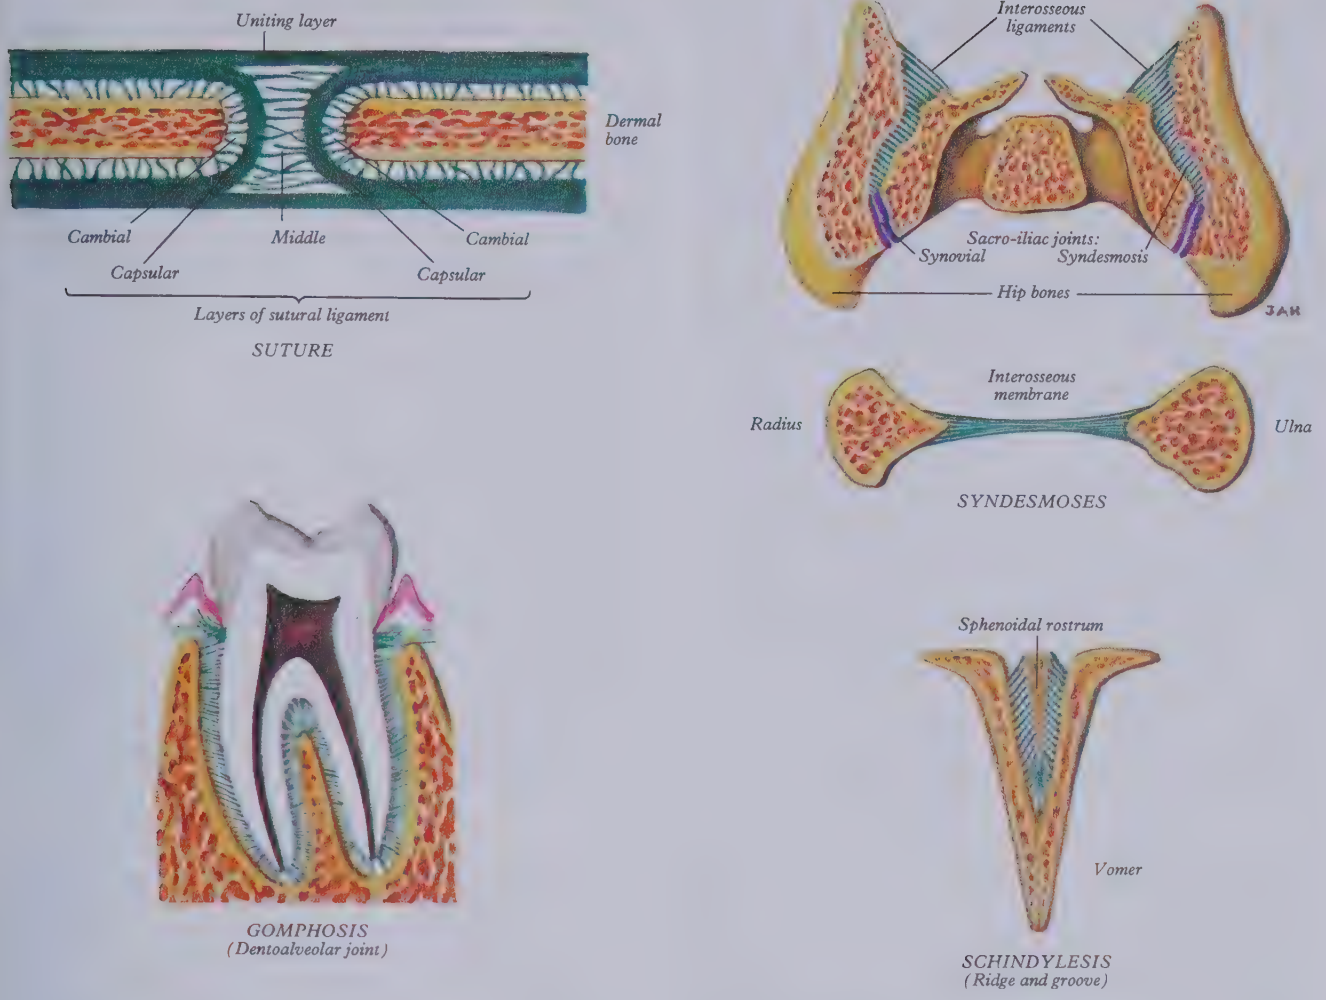
SUTURES

Sutures, limited to the skull, occur wherever margins or broader surfaces of bones are separated only by connective tissue, the *sutural ligament* or membrane, which is a surviving unossified part of mesenchymatous sheets in which dermal bones develop (p. 340). Sutural ligaments display regions of differentiation concerned in growth and binding of apposed bone surfaces (Pritchard et al 1956). Each bone is covered on its sutural aspect by a layer of osteogenic cells (the 'cambial' layer), itself overlaid by a capsular lamella of fibrous tissue (4.2), both collectively corresponding to periosteum and continuous with this at the margins of the sutural surfaces, both inside and outside the skull. Between these two layers of sutural periosteum is a central stratum of loose fibrous connective tissue, varying in width according to age and the interval between the particular bones involved. This central stratum contains thin-walled blood vessels, the veins communicating with diploic vessels, intracranial venous sinuses and external veins in the scalp. The fibrous periosteum adherent to the bones crosses the interval between them, as two uniting layers (external and internal) which enclose the sutural ligament and add to its strength. Experimental evidence suggests that during active growth the orientation of collagen fibres in sutural membranes is adaptable to several factors, in particular to the direction of growth of minute bone spicules (Kośkinen et al 1976).

In view of the occurrence of fibrous tissue in synchondroses (p. 463), it is interesting to find that, during growth, secondary cartilage formation often occurs in sutural ligaments, suggesting a relation between fibrous and cartilaginous joints.

When cranial growth, including in its earlier stages growth at sutures, ends, osteogenic cells generally bring about complete ossification of sutural ligaments; but this is a slow process (p. 393), ultimately leading to obliteration and rigid synostosis. Sutural fusion, however, does not even begin until the late twenties, proceeding slowly thereafter; yet it is clearly necessary that sutures should cease to be slightly flexible joints as soon as possible after birth. Sutural ligaments may effect an almost immovable bond between large areas of bone, especially where these show reciprocally adapted irregularities, even if fine as in the intermaxillary junction; but such immobility cannot be effected at narrow edges of bones in the cranial vault. At these, however, their margins develop spikes and recesses which interlock so well that the bones are difficult to separate even when denuded of all fibrous connective tissue. Where the edges are saw-like, the junction is a *serrate suture*. A *denticulate suture* has small toothlike projections, often widening towards their ends to provide even more effective interlocking. When such sutures are tied by sutural ligament and periosteum, almost complete immobility results. The sagittal suture is serrated and much of the lambdoid denticulate. Where bones overlap, as at the temporoparietal suture, this is a *squamous suture*; the adjacent bone surfaces are reciprocally bevelled and, if mutually ridged or serrated, the junction is sometimes termed a *limbous suture*. Simple apposition of contiguous surfaces, usually rough and reciprocally irregular, is inappropriately named a *plane suture*, instances being sutures between the palatine bones, between the maxillae and at the palatomaxillary sutures. Although surface demarcations between such bones show none of the interlocking evident at serrate or denticulate sutures, irregular surfaces of contact, tied by wide expanses of sutural ligament, provide much resistance to shearing or torsion; like other sutures they are, for all practical purposes, immovable. In summary therefore sutures, although in some locations providing slight perinatal flexibility, are essential structural mechanisms for sutural bone growth, combined with the necessary rigidity and geometry in the upper neurocranium and in the nasofacial and palatine skeleton.

A schindylesis is a specialized suture where a ridged bone fits into a groove on a neighbouring element, e.g. the cleft between the alae of the vomer that receives the rostrum of the sphenoid.



GOMPHOSES

A gomphosis or **peg-and-socket joint** (*articulatio dentoalveolaris*) is a specialized fibrous articulation restricted to the fixation of teeth in alveolar sockets in the mandible and maxillae. The collagen of the periodontium connects dental cement with alveolar bone (see pp. 1309, 1310, for details).

SYNDESMOSES

A syndesmosis is a fibrous articulation in which bony surfaces are bound together by an interosseous ligament, by a slender fibrous cord or an aponeurotic membrane, usually affording slight but occasionally more extensive movement between them. For

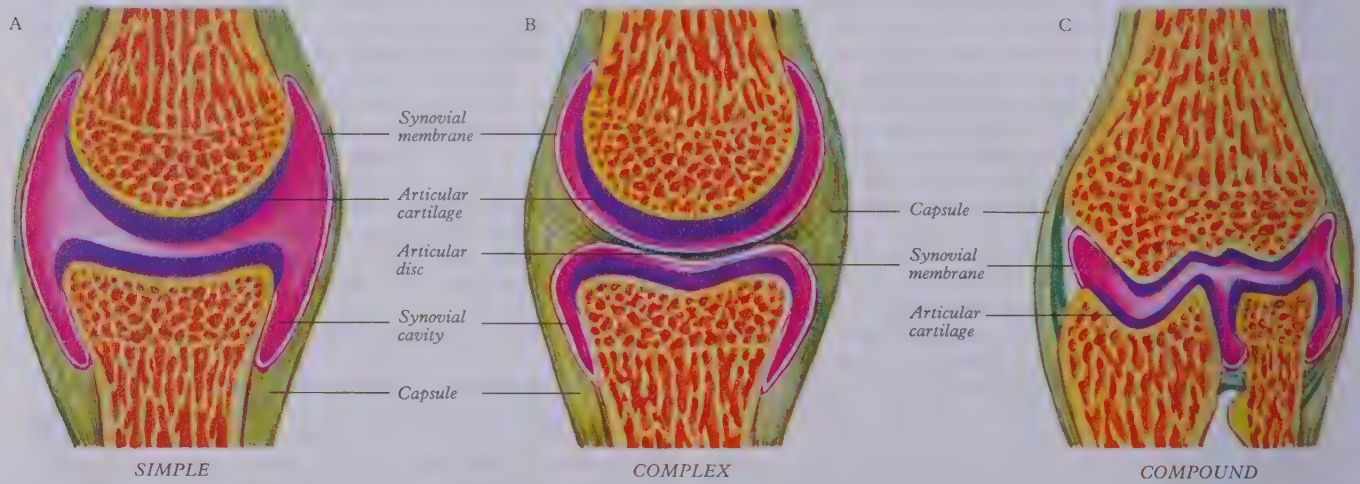
FIBROUS JOINTS

4.2 Some examples of the principal varieties of fibrous joints (articulationes fibrosae). A diagram of each variety in section is clearly indicated. Note some do not regard schindyleses as sufficiently distinct from sutures to merit a separate group. Syndesmoses are difficult to define because of the large numbers and great variety of fibrous interosseous structures. The officially (internationally) recognized list has changed a number of times over recent decades (the list increasing with welcome additions). It should, perhaps, be indicated that the massive interosseous sacro-iliac ligament illustrated is not, as yet, in the official list.

long considered rare in mammals, the term was until quite recently restricted to the inferior tibiofibular joint *alone* (but vide infra). Clearly this was unsatisfactory; nevertheless interosseous fibrous connections occur in such profusion and great variety of form that, despite repeated attempts, no consensus concerning a precise definition of *syndesmosis* has emerged. The following remarks may serve to illustrate some inconsistencies and difficulties and perhaps provide a background for the curious assortment of structures officially recognized as syndesmoses given below.

Though not usually so described, the dorsal part of the sacro-iliac junction, through its massive interosseous sacro-iliac ligaments, *is*, rather than 'closely resembles' a syndesmosis (4.2). The sacro-iliac joints proper, primarily synovial, also are often invaded by fibrous tissue late in life and may become entirely fibrous articulations, differing little from syndesmoses (p. 466). The inferior tibiofibular joint, for long accepted as a typical *syndesmosis*, alternatively could well be considered no more than an interosseous ligament, adjacent to the ankle joint or to a synovial extension of it when this exists, as it occasionally does in man and regularly in other primates. If this is accepted, the term syndesmosis could be extended to many other interosseous ligaments, as in the carpus and tarsus, and also to include interosseous membranes of the forearm and foreleg, especially since these are already described as 'intermediate' joints in the radio-ulnar and tibiofibular series (but vide infra). Since ligaments are almost all 'interosseous', it becomes difficult to restrict use of the term 'syndesmosis' at all, unless it be insisted that only very short *extrinsic* ligaments close to a synovial joint are so designated. (Plainly intrinsic and intracapsular ligaments of synovial joints must be excluded.) These appear to be the kind of criteria which limited use of the term to a single human joint, a restricted and irrational usage rendering all the more unsatisfactory the occasional substitution of the term 'syndesmology' for arthrology. The former is a word of unfamiliar derivation and hence obscure in meaning, whereas the stem **arthron**, a joint, is widely familiar in medical and biological application, e.g. arthritis, arthroplasty, and the name of the largest animal phylum, the *Arthropoda*. Official re-adoption of the internationally accepted term **arthrology** is most welcome.

In *Nomina Anatomica* (1977) the term **syndesmosis** was extended to include the following ligaments: pterygospinous, stylohyoid, interspinous, supraspinous, intertransverse, ligamenta flava and ligamentum nuchae. The *syndesmosis radio-ulnaris* includes the antebrachial interosseous membrane and oblique cord, the *syndesmosis tibiofibularis*, the crural interosseous membrane and ligament and the anterior and posterior tibiofibular ligaments. This particular choice of ligaments is, however, quite arbitrary; many others could as reasonably have been included as syndesmoses. In the opinion of the present writers the list should be greatly expanded within a strictly defined framework.



Synovial Joints

Synovial articulations (4.3,4) operate differently from *non-synovial* fibrous and cartilaginous joints. Although the bones involved are linked by a fibrous capsule usually having intrinsic ligamentous thickenings, and often by accessory ligaments internal or external to it, the osseous surfaces concerned are *not* in continuity. They are covered by articular cartilage, a stratum of specialized hyaline cartilage (occasionally fibrocartilage) of varying thickness and precise topology, and contact is strictly between these cartilaginous surfaces, which have a very low coefficient of friction (Charnley 1959). Sliding contact is facilitated by viscous *synovial fluid* (synovia), like a lubricant in some respects but also concerned in the maintenance of living cells in the articular cartilages. Its properties are considered later (p. 475). The coefficient of friction in synovial joints has been picturesquely described as equal to 'ice on ice'.

A fibrous capsule encloses such joints completely, with some exceptions, e.g. the hip joint (p. 520), where it is interrupted by synovial protrusions; such exceptions are described with individual joints. The capsule is lined by *synovial membrane*, which also covers all intra-articular surfaces except those in compression contact during activity; these include non-articulating osseous surfaces, tendons and ligaments partly or wholly within the fibrous capsule, as at the shoulder and knee. Where a tendon is attached inside a joint and issues from it, a synovial prolongation usually accompanies it beyond the capsule. Some extracapsular tendons are separated from it by a synovial bursa (p. 502) continuous with the joint's interior. Such protrusions are potential avenues for spread of infection into joints.

A third type of intra-articular structure, *not* covered by synovial membrane, is an *articular disc* or *meniscus*. This occurs between articular surfaces where congruity is low and consists of fibrocartilage, its fibrous element usually predominant. A disc may extend across a synovial joint, dividing it structurally and functionally into *two* synovial cavities. Peripherally discs are connected to fibrous capsules, usually by vascularized connective tissue; but the union is sometimes closer and stronger, as in the knee and jaw joints. Discal peripheries are invaded by vessels and afferent and motor (sympathetic) nerves. Their main part contains few cells, but surfaces may have an incomplete stratum of flat cells, continuous at attached perimeters with adjacent synovial membrane; however the two groups of cells are not alike (p. 474). The term *meniscus* should be reserved for incomplete discs, like those in the knee joint and occasionally the acromioclavicular joint. Complete *discs* occur in the sternoclavicular and inferior radio-ulnar joints; that in the temporomandibular joint may be complete or incomplete. Discs often have small perforations; where menisci are usual, complete discs may occur or may be slightly perforated. The function of intra-articular fibrocartilages is uncertain, experiments being difficult to devise or effect. Views advanced are deductions from structural or phylogenetic data, with the help of mechanical analogies. The plethora of suggestions is hence not surprising; it includes shock absorption, improvement of fit between surfaces, facilitation of combined movements, checking of translation at joints such as the knee, deployment of weight over larger surfaces, protection of articular margins, facilitation of rolling movements and spread of lubricant. The temporomandibular disc has attracted particular attention because of its exceptional, perhaps unique, design and biomechanical properties. Osborn (1985) has surveyed these properties and examined some factors relating to the *stabilization* of the disc and its possible role as a *destabilizer* of the mandibular condyle, permitting trauma-free complex movements (see p. 487).

In the study of evolution of articular discs attention has been focused on equating them with skeletal vestiges, such as the quadrate bone (jaw joint) or the os intermedium carpi (inferior radio-ulnar joint), not upon comparative function. Such contentions are usually based on tenuous evidence but nodules of bone, or lunules, do occur in some primate discs but rarely in mankind (Lewis et al 1970). A more interesting comparative functional observation is that joints containing discs usually display translatory movements, combined of course with others (vide infra, p. 477). For example, in the temporomandibular joint, translation of the condyle forwards and backwards accompanies angulation or hinging. However, the disc, though usually thin, also occurs in carnivores where such translation is negligible. It is apposite to note (Moffat 1957) that, during evolution of mammalian from primitive reptilian jaw joints, the tendon of the lateral pterygoid muscle may have been partially incorporated into the temporomandibular disc; but it is absent in earlier mammals, monotremes and marsupials. Such conflicting observations illustrate how indecisive attempts to elucidate function from morphology often prove. It is more plausible that the pliant and sometimes elastic qualities of discs and menisci provide adaptable surfaces in joints where they occur, facilitating simultaneous movements of different kinds in the compartments of a joint thus divided (p. 486), perhaps also ensuring uninterrupted lubrication (MacConaill 1932). Where translation occurs, complete congruity is impossible except in a (hypothetical) entirely plane articulation, the nearest approximation to this being some sesamoid joints. All articular surfaces exhibit some curvature and translation is always compounded with some other movement (p. 477). But translation does occur and intra-articular cartilages may aid in controlling shift from one position to another, as in rolling at the knee joint (p. 530). The tapering profile of menisci enables them to fit between incongruent surfaces, obviating large

4.3 Synovial joints, some main structural features and one elementary type of classification: A. simple; B. complex; C. compound joints (see text). For clarity, the articular surfaces are artificially separated. A and B are purely diagrammatic and not related to particular joints. C, however, is a simplified representation of some features of an elbow joint but the complicated contours due to the olecranon, coronoid and radial fossae and profiles of articular fat pads present in a true section have been omitted.

collections of synovial fluid between them and preserving a filmy distribution over articular surfaces. Advantages of this in damping turbulence and drag accord with the lubrication theory. This argument provides an attractive hypothesis but its experimental demonstration is at present difficult to envisage.

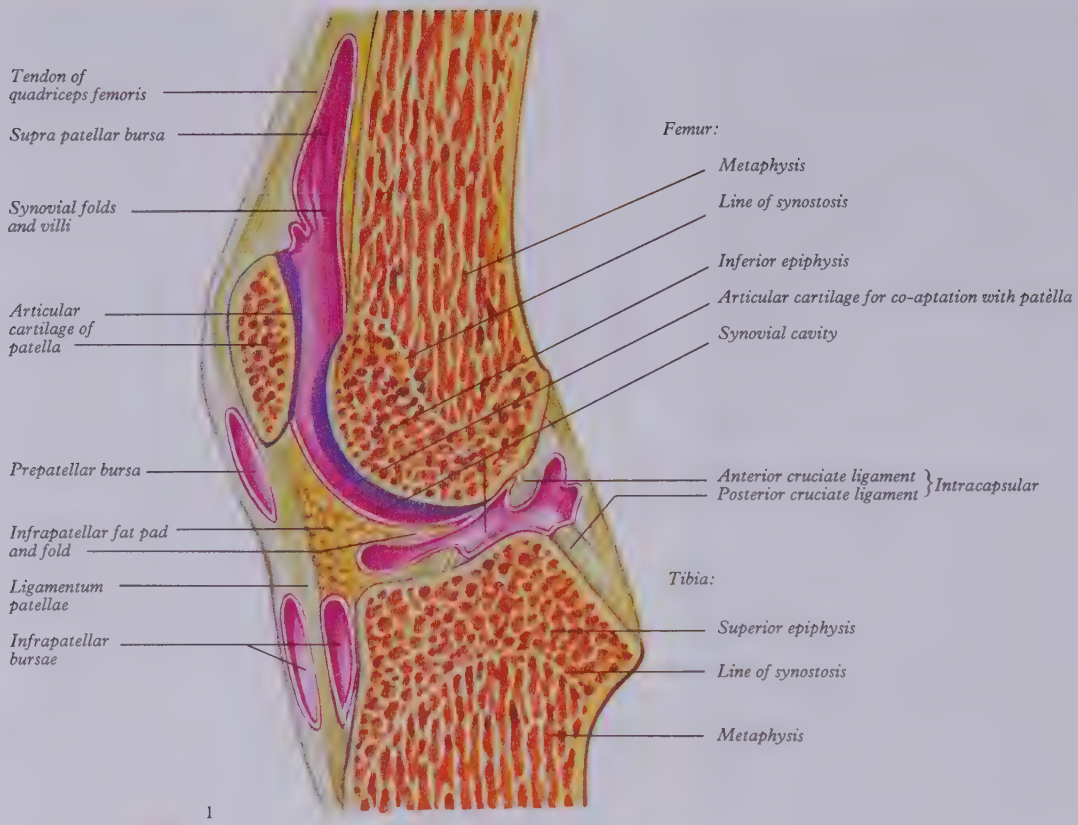
A complete articular disc creates in effect two joints in series, comparable with concatenations of multiple joints, whose individual small ranges of movement nevertheless summate. This arrangement occurs in the carpus and tarsus but is carried further in multiplication of interphalangeal joints in flippers of extinct aquatic reptiles and extant aquatic mammals such as some whales. By such analogy one may liken the talus of some mammals to a meniscus, in terms of function; it is equally tempting to equate some menisci with degenerate skeletal elements. The various views propounded are not reciprocally exclusive; discs may have evolved by more than one route, just as they may assist in more than one way the smooth performance of synovial joints.

Functions of two other quite common types of intra-articular structure, *labra* and *fat pads*, are also uncertain. A labrum is a fibrocartilaginous annular *lip*, usually triangular in cross-section like a meniscus and attached to an articular margin, e.g. the glenoid and acetabular labra, which deepen their respective sockets and add to areas of contact. They may act as lubricant spreaders and, like menisci, may reduce synovial space to capillary dimensions, thus limiting drag. However, unlike menisci, labra are not compressed between articular surfaces. Small *fibrous labra* (*connective tissue rims*) have been described along the ventral or dorsal margins of the zygapophysial joints at lumbar levels and also meniscus-shaped *fibro-adipose meniscoids* at the superior or inferior poles of the same joints. (For brief comments and reference see p. 490.) Fat pads are closely associated with synovial membrane, with which they are therefore described (p. 474).

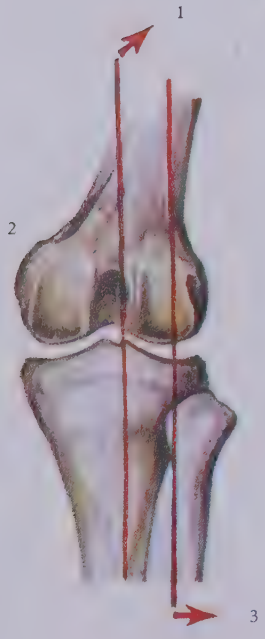
EVOLUTION OF SYNOVIAL JOINTS

Much speculation, observation and experiment have been directed to the mechanics of synovial joints by anatomists, orthopaedic specialists, physicists and engineers. The basic problem is to account convincingly, in terms of movement, loading and lubrication, for the efficiency by which joints preserve smoothness of action without jamming under most variable conditions, except when diseased. It has proved impossible even to postulate, much less to construct, a single mechanical joint meeting all requirements of living arrangments. Lubrication theory has not yet explained the outstanding effectiveness of synovial joints, although progress has been made (p. 475).

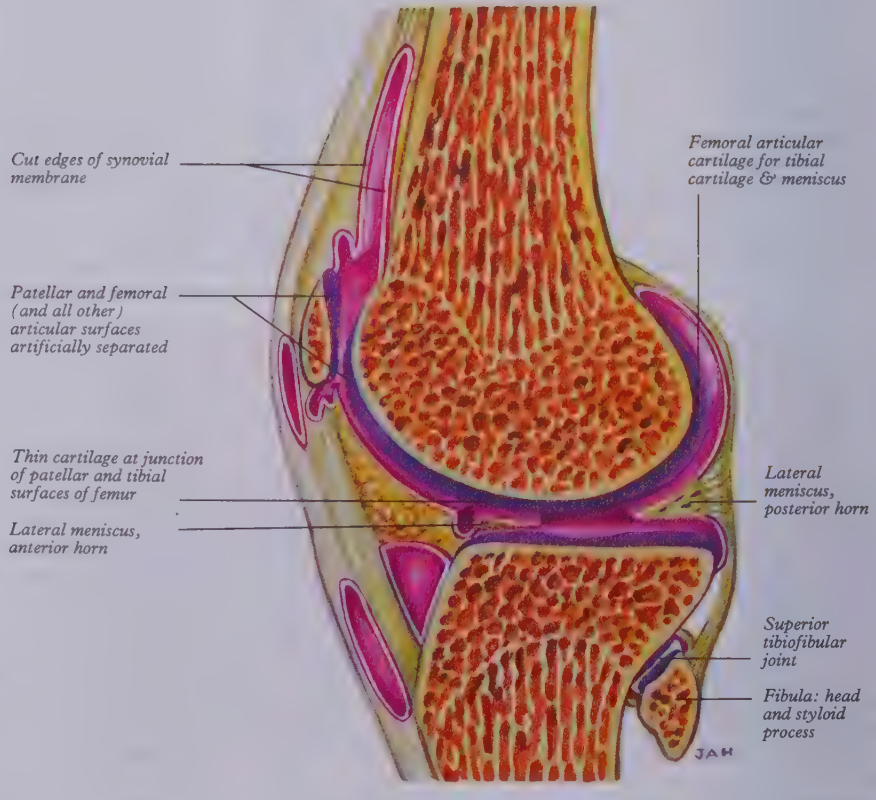
What are the advantages of sliding articulations? That these are considerable is shown by the increasing dominance of synovial joints in vertebrate phylogeny. Evolution of joints has attracted little attention; few joints or vertebrate groups have been systematically studied. Synovial articulation occurs as far down the scale as lungfish (Dipnoi), especially in joints of jaws (Haines 1942b). Hence, the synovial joint is not particularly novel, in general features at least. Nevertheless, most movable bony junctions in piscine ancestors of land vertebrates were simpler, as in surviving species. These simpler joints may illustrate stages in the development of synovial joints. Fibrous and cartilaginous joints may be assumed to be the simplest and probably primary form, the next step being appearance of multiple fluid-filled cavities in the deformable tissue. A further advance is held to be union of these into a single joint cavity, surrounded by a substantial cuff of tissue uniting the skeletal components involved. This pattern resembles cavitated symphyses (p. 468). Finally complete dissolution of continuity between bones would markedly increase amplitude of movement. With subsequent development of a synovial stratum and a fibrous capsule, the fluid-containing cavity is confined and the fluid reduced to a mere film between surfaces approximated in smooth, sliding contact.



Examples of all such stages occur in living vertebrates; interestingly synovial joints in more primitive land animals, although they replace other arrangements in limb articulations, are in some respects inferior to piscine mandibular joints, which may have been the first vertebrate articulations refined to synovial status.



The stages hypothecated above accord with major events in prenatal development of human synovial joints. Perhaps most significant is breakdown of interzonal mesenchyme (p. 175) to form a presumptive synovial cavity. Potentiality of mesoderm for cleavage (forming considerable cavities or clefts between surfaces in contact and hence mobilized) is clearly significant to the evolution of synovial joints. In addition to established mesodermal discontinuities, including the whole range of coelomic and synovial arrangements, fully differentiated connective tissue retains this potentiality, revealed in the occurrence of such acquired structures as adventitious bursae and pseudarthroses. It is reasonable to suppose that, once a region of pliant connective tissue is established between rigid skeletal elements, the ultimate appearance of a synovial cavity is an evolutional and mechanically significant probability.

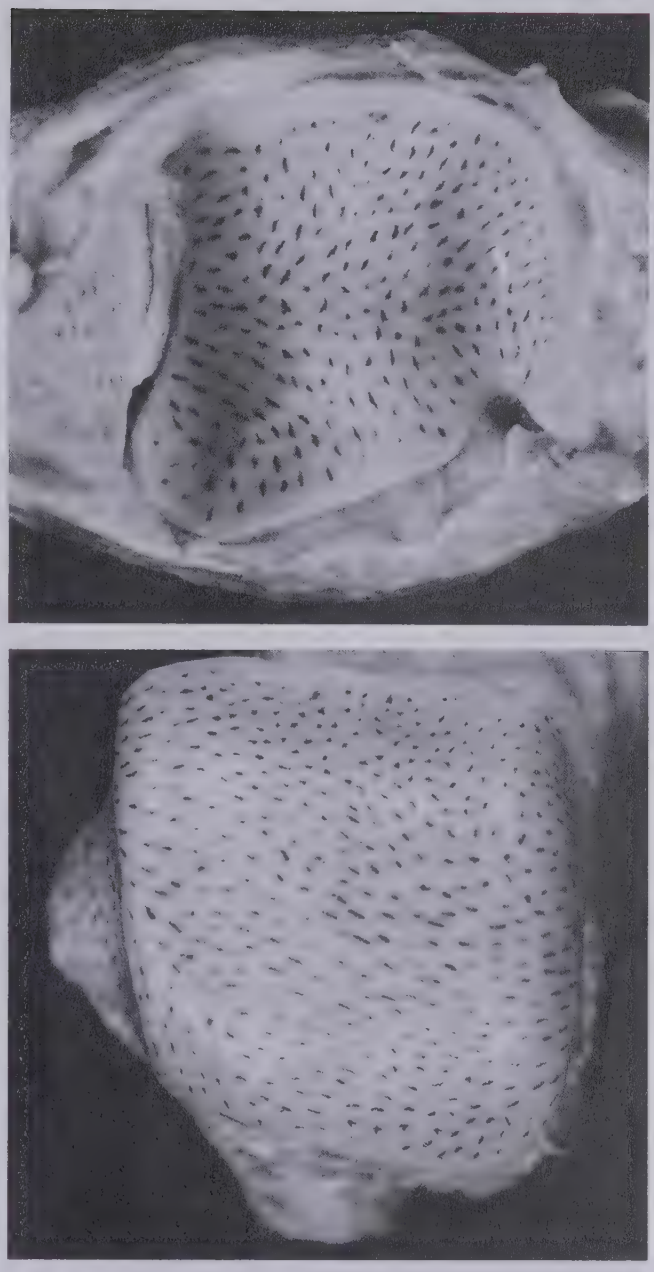


It is considered likely that synovial joints have developed not only as discontinuities in skeletal bars but also by approximation of separate elements. Mammalian tibiofibular joints may have thus evolved, the bones being out of contact in reptiles; but these synovial arrangements are probably extensions of the knee and ankle joints and not new formations. A better example, perhaps, is the occasional synovial joint between clavicle and coracoid process (p. 500, Lewis 1959), which may consist merely of a bursa or, more frequently than either arrangement, a fibrocartilaginous junction, an excellent example of lability of joints in occurrence and structure. A synovial joint such as the sacro-iliac may retrogress to a simpler form and may, like others such as interphalangeal, carpal and tarsal articulations, disappear entirely either by synostosis in individuals or as an evolutionary phenomenon. The avian tibiotarsus and tarsometatarsus illustrate reunion of once separate bones; the opposite tendency, towards multiplication of elements by new joint formation, is apparent in phalangeal patterns in the paddle-like extremities of some aquatic mammals and extinct reptiles.

Evolution of synovial joints at mammalian level shows two tendencies. Firstly, their number increases by replacement of non-synovial joints, particularly in limbs, eventually reaching their smallest terminal articulations. Secondly, synovial joints increasingly specialize, especially by limitation of movement to that habitually required. A typical non-synovial joint, such as a symphysis, is essentially multi-axial, however limited in range; its movements are basically angulation, torsion or rotation ('swing' and 'spin', see p. 480) and 'translation'; all others are combinations of these. From the restricted data available, the earliest synovial joints are likely to have had the same repertoire, with improvement in range and smoothness. The ancestral vertebrate limb probably had joints approximating to a 'ball-and-socket' form; palaeontological data and synovial joints in extant primitive amphibians and reptiles support this supposition. This view also entails that proximal joints have remained less specialized than the more distal; they certainly are closer to multi-axial activity. A multi-axial joint requires more complex muscular control than a bi-axial, in which more reliance can be placed on ligaments, an advantage even greater in uni-axial joints. This advantage obtains both in dynamic and static situations: for when a multi- or bi-axial articulation is in substantially uni-axial movement, muscle must be used to prevent unwanted movement in other axes. Similarly, when a joint is to be maintained static in a particular posture, or as an adjunct to some other phase of movement, this is effected more economically if joint surfaces and disposition of adjoining ligaments limit movement in some directions. Unless this interferes with overall activity, the trend is towards uni-axial function and this appears to be the evolutionary tendency in limbs. This is tantamount to saying that joints are adapted to motions required in the behaviour of a particular animal form. To take the argument further, a joint may even disappear if its activity ceases; examples have occurred in many mammals; in the human skeleton the process appears as synostosis of sternal and sacral segments, conferring rigidity on joints having a limited degree of mobility in some other mammals.

Refinement of a joint, in limitation of direction and range of movement to whatever is habitually required, favours skilled control and the most advantageous distribution of available muscle power. Bulky muscles around a joint may impede it and it is an

4.4A, 1–3. Principal structural features displayed in two parasagittal sections of the left knee joint, which is synovial and both compound and complex. 2. Line diagram of the posterior aspect showing the planes of section in 1 and 3. The synovial cavity and bursae are, for clarity, shown as slightly distended; the articular surfaces of the patella, femur and tibia and the meniscal surfaces are thus artificially separated. These illustrations should be studied both with the accompanying introductory text and also with the detailed account of the knee joint (p. 526 et seq).



advance if restraining activities can be transferred from muscles to ligaments and articular geometry. Joints may be arrested in temporary but prolonged static positions, as required of human hip and knee in standing. If joints can be maintained in a nearly close-packed position (p. 483) by gravity, muscular effort can be reduced, e.g. the usual human mechanism of standing (p. 657). This commonly cited example of joint control prompts a concept of *stability* at joints, a now somewhat overworked term with *static* implications. Joints are, however, primarily *dynamic*; during movements qualities stabilizing them in one position are equally important in controlling transit from one attitude to another. In the medical context it is natural to view these factors as preserving articular *integrity*—a clinical approach deviating more towards factors preventing dislocation than towards functional interpretation of structure. Synovial joints of higher vertebrates are precisely engineered to accomplish habitual movements with greatest efficiency commensurate with the resources available; but, before analysis of individual joints, the intimate structure of the tissues of synovial joints must be considered.

STRUCTURE OF SYNOVIAL JOINTS

Articular surfaces are mostly formed by a special variety of *hyaline cartilage* reflecting their preformation as parts of cartilaginous models in embryonic life (Barnett et al 1961, Ghadially & Roy 1969); but, as exceptions to this, surfaces of the sternoclavicular and acromioclavicular joints and both temporomandibular surfaces are of dense fibrous tissue, with isolated groups of chondrocytes and little surrounding matrix, again reflecting their formation by *mesenchymatous* ossification. However, to regard cartilage of most articular surfaces as unmodified hyaline cartilage and merely the unossified surface sectors of growing cartilaginous models obscures its special features. In long bones articular cartilage is a specialized tissue long before the subjacent bone has ossified (Davies & Edwards 1948); the organization of mature articular cartilage is distinctly radial, with variation in cellular type and arrangement, fibrous architecture and calcification at varying levels from its surface (p. 288). (Split-line phenomena in articular cartilage and their possible relations to architectural and mechanical properties are discussed on p. 290. Examples of split-line patterns in a talocrural joint are shown in 4.4B.)

Articular cartilage has a wear-resistant, low-frictional, lubricated surface, slightly compressible and elastic and thus ideally constructed for easy movement over a similar surface but also able to absorb large forces of compression and shear generated by gravity and muscular power, qualities specially important at one extreme of a joint's most habitual movement, the so-called 'close-packed position' (p. 483).

The thickness of articular cartilage is said to range from 1–2 mm, but this is more typical of small bones in aged individuals; in youth it may reach 5–7 mm in larger joints; such young cartilages are typically white, smooth, glistening and compressible. Ageing cartilages are thinner, less cellular, firmer and more brittle, with a less regular surface and a yellowish opacity. In contrast to the 'glassy' moistness of fresh, wet articular cartilage and to the measurements held to support this early impression of smoothness, more refined techniques have emphasized the relative 'roughness' of its free surface. Dowson et al (1969) and Longfield et al (1969) observed a 'centre-line average' of undulations varying from 30×10^{-6} to 200×10^{-6} inch, much inferior to mechanical bearings (5×10^{-6} to 15×10^{-6} inch); but when covered by synovial fluid the surface has a very low coefficient of friction (<0.002). Under load the 'troughs' between the 'crests' have been considered to trap pools of synovial fluid. Others (McCutchen 1959) have proposed a porous nature (with a pore size of 6 nm) like a sponge, saturated at rest with synovial fluid; increasing load and compression is presumed to 'weep' fluid from this porous surface. Scanning electron microscopy has renewed interest in these surfaces. When *detached* blocks of articular cartilage were first viewed many described patterns of undulation as constant features (e.g. McCall 1968, Gardner & Woodward 1969, Walker et al 1969, Redler & Zimny 1970, Redler 1974). But this view has been criticized; undulation was not apparent in cartilage *still attached* to bone and was therefore regarded as artefactual, atypical or pathological (Clarke 1973a, Ghadially et al 1976, Ghadially 1983). The only constant features revealed in 'normal', mature articular cartilage were numerous oval, fusiform or round *shallow pits*, considered to overlie groups of chondrocytes (Clarke 1973a,b, Ghadially et al 1974,1975,1976). In juvenile cartilage pits are replaced by small 'humps' of similar size. Doubt was thus cast on the 'enrichment theory' of joint lubrication (p. 476 and Ghadially et al 1977). Nevertheless, despite impressive micrographs of attached cartilage, the tissue was of course subjected to all the rigors of preparation for scanning electron microscopy. To what extent 'pits and humps' are due to this remains uncertain.

4.4B Articular surfaces of the left talocrural joint demonstrating the patterns of split-lines in the articular cartilages produced by multiple insertions of a round-bodied needle, previously immersed in Indian ink. *Above*, tibiofibular mortice; note interosseous and inferior transverse tibiofibular ligaments. *Below*, superior (tibial) and lateral (fibular) surfaces of the talus. For possible significances of split-line configuration, see p. 278. Photography by Kevin Fitzpatrick, Guy's Hospital Medical School, London.

Such difficulties have been circumvented by studying fresh necropsy specimens of weight-bearing areas of lateral femoral condyles by reflected light interference microscopy (Longmore 1976, Longmore & Gardner 1978). Observed curvatures, undulations and irregularities were classified into groups of decreasing dimension: (1) *primary anatomical contours*, e.g. ovoid or sellar surfaces; (2) *secondary undulations* of 100–500 μm crest to crest; (3) *tertiary hollows* 20–50 μm in diameter and 0.5–2 μm deep. (4) *quaternary ridges* 1–4 μm in diameter and 130–275 μm deep. Longmore & Gardner (1978) emphasized the tertiary hollows, whose size, shape and distribution were shown to be age-dependent (a phase of *maturation* from 0–21 years being followed by *ageing* from 22 to 50 years). In the youngest surfaces tertiary hollows were largely circular and tightly packed; with increasing age they were separated, becoming circular or oval, sometimes in clusters or 'figure of eight' pairs and the areas between them, although 'granular and fuzzy', were relatively smooth. From 21 years onwards quaternary ridges, appearing sporadically between 10 and 20 years, occurred more often in focal patches in some 'inter-hollow areas'. Tertiary hollows appeared to correspond to underlying chondrocytic lacunae, quaternary ridges perhaps representing incipient cartilage fibrillation associated with ageing, though Bloebaum & Wilson (1980) concluded that they were simply shrinkage 'wrinkles' attributable to drying of the surface when exposed to air.

Articular cartilages are moulded to bone, but variations in thickness often accentuate subjacent osseous surface shape. Typically, convex surfaces are thickest centrally, thinning peripherally; concave surfaces are the reverse of this. Precise configuration, degree of congruence in various positions and dispositions of surrounding capsule and ligaments are all related to the types and ranges of movement permitted at a joint (vide infra). (For a simplified classification based on articular geometry see pp. 477 and 479).

Articular cartilage has no nerves or blood vessels (except occasional vascular loops reaching and even penetrating the calcified zone (p. 290). Nutrition is considered to depend on (1) a peripheral vascular plexus in synovial membrane (*circulus vasculosus articuli*), (2) synovial fluid and (3) blood vessels in adjacent marrow spaces; the relative importance of these is disputed.

The free surface of articular cartilage, devoid of perichondrium, was described by MacConaill (1951) as consisting of a special layer, the *lamina splendens* (p. 288), appearing as a bright line when oblique sections are examined by negative phase contrast microscopy. This is now known to be a diffraction effect which occurs at any edge between regions of different refractive index (e.g. the cut edges of a cartilage section) and provides no evidence of an anatomically distinct surface layer (Aspden & Hukins 1979); it is now considered that the term lamina splendens is inappropriate and should be abandoned. The zone of articular cartilage adjacent to the joint cavity is mainly a layer of collagen fibres arranged in various planes with small, oval chondrocytes lying in the matrix deep to it. An interrupted electron-dense surface coat of a particulate or filamentous appearance, generally 0.03 – 0.1 μm thick, covers it, with a layer of proteoglycan particles and associated filaments occasionally intervening (Ghadially et al 1982). Synovial fluid and matrical lipidic debris, the product of chondrocytic necrosis, may contribute to the surface coat which is ephemeral in nature, the stable, permanent articular surface being that bounded by the most superficial collagen fibres (Ghadially 1983).

With advancing age, undulations of articular surfaces deepen and develop minute, ragged projections perhaps due to wear and tear. Erosion occurs in pathologically 'dry' joints and where synovial viscosity is altered; but in healthy joints changes are extremely slow. Replacement of eroded surface by proliferation of deeper layers is uncertain; mitoses are absent from adult articular cartilage and amitotic cell division has not been substantiated.

Ultrastructural observations (Broom & Marra 1984, 1986) reveal a highly complex, three-dimensional reticulum of interconnected fibrils in articular cartilage, with obvious functional implications.

The fibrous capsule has parallel but interlacing bundles of white collagen fibres, forming a cuff with its ends attached continuously round the articular ends of the bones concerned, usually in small bones near the peripheries of articular surfaces, but this varies considerably in long bones; in these part or all of the attachment may be a significant distance from the surface. It is perforated by vessels and nerves and may have apertures through which synovial membrane protrudes as bursae. The capsule usually has local thickenings of parallel fibre bundles; such *capsular (intrinsic) ligaments* are named by their attachments. Some capsules are reinforced or replaced by tendons of nearby muscles or expansions from them. *Accessory ligaments* are separate from capsules and may be *extracapsular* or *intracapsular* in position.

All ligaments, although yielding little to tension, are pliant and do not resist normal actions, being designed to check excessive or abnormal movements. All ligaments are taut at the normal limit of a particular movement (p. 485); they are, however, *slightly elastic* and protected from excessive tension by reflex contraction of appropriate muscles (Smith 1954).

Synovial membrane (Barnett et al 1961) derived from embryonic mesenchyme lines non-articular areas in synovial joints, bursae and tendon sheaths, all regions where movement occurs between apposed surfaces, which are lubricated by a fluid superficially like egg-albumin (hence named *synovia*) secreted and absorbed by the membrane. In joints it lines fibrous capsules and covers exposed osseous surfaces, intracapsular ligaments and tendons. It is absent from intra-articular discs or menisci and ceases at the margins of articular cartilages, the peripheral few millimetres of which are a structural *transitional zone* between synovial membrane and articular cartilage.

Pink, smooth and shining, the internal synovial surface has a few small *synovial villi* (Ghadially 1983) which increase in size and number with age (Curtis 1964). Elsewhere folds and fringes may project into the joint cavity, some constant enough to be named, e.g. alar folds and ligamentum mucosum of the knee. Accumulations of adipose tissue occur in the synovial membrane in many joints; these *articular fat pads* were once misnamed 'mucilaginous glands'. Such pads, folds and fringes are flexible, elastic and displaceable cushions occupying potential spaces and irregularities in joints which are not wholly filled by synovial fluid; they accommodate to the changing shape and volume of these irregularities during movement. They increase synovial area and may promote distribution of lubricant over articular surfaces (cf. intra-articular discs and menisci). Synovial villi are normally few but more numerous where the membrane rests on areolar tissue near articular margins and on surfaces of folds and fringes. They increase with age and become prominent in some pathological states.

Synovial membrane varies in local structure. Basically it has a cellular *intima* on a fibrovascular *subintimal lamina* (*subsynovial tissue*) often loose and areolar, but sometimes of organized lamellae of collagen and elastin fibres lying parallel to the membrane's surface, between which are fibroblasts, macrophages, mast cells and fat cells (Davies 1950, Shaw & Martin 1962). The elastic component may prevent redundant fold formation during joint movement, folds which might be compressed between articular surfaces. Subintimal adipose cells form compact lobules surrounded by fibro-elastic interlobular septa, which are very vascular and impart firmness, deformability and elastic recoil. Where synovial membrane covers intracapsular ligaments or tendons the subintima is scarcely a separate zone, being merged with the adjacent capsule, ligament or tendon.

The synovial intima (*lamina propria synovialis*), or synovial lining layer, consists of pleomorphic *synoviocytes* embedded in a granular, amorphous, fibre-free intercellular matrix. There is considerable regional variation in synoviocyte morphology and numbers, which appears to be dependent on the underlying subintimal tissue (Barnett et al 1962). The synoviocytes of normal human joints form an interlacing, discontinuous layer, one to three cells and 20–40 μm deep, between the subintima and the joint cavity (Castor 1962). They are not separated from the subintima by a basement membrane and are distinguished from the subintimal cells only by their association to form a superficial layer (Henderson & Pettipher 1985). In many locations, but particularly over areolar subintimal tissue, areas free from synoviocytes are commonly found, while conversely over fibrous

subintimal tissue the synoviocytes may be flattened and closely packed, forming endothelioid sheets. Neighbouring cells are often separated by distinct gaps but where they approach more closely their processes may interdigitate. The latter situation is common in compact areas of rat's synovial intima, where cells may be linked by tight junctions and desmosomes (Roy & Ghadially 1967), although these junctions have not been identified in human synovial tissue (Henderson & Pettipher 1985).

Human synoviocytes are generally elliptical, with numerous cytoplasmic processes (Castor 1962) but can vary considerably in form (Key 1932). They consist of at least two morphologically distinct populations, termed *type A* and *type B* (Barland et al 1962, Wynne-Roberts & Anderson 1978, Ghadially 1983).

Type A synoviocytes are macrophage-like cells characterized by surface ruffles or lamellipodia (often described as filopodia, since they resemble these when sectioned), plasma membrane invaginations and associated micropinocytotic vesicles, a prominent Golgi apparatus but little granular endoplasmic reticulum. There is immunohistochemical evidence for the presence of surface receptors characteristic of macrophages on what are believed to be type A synoviocytes (Theofilopoulos et al 1980).

In contrast, *type B* synoviocytes, which predominate in the intima of most species (Ghadially 1983) and resemble fibroblasts, have abundant granular endoplasmic reticulum but contain fewer vacuoles and vesicles and have a less ruffled and branched plasma membrane than type A synoviocytes.

Cells intermediate in appearance between types A and B have been described and variously named as *intermediate, type C* or *type AB* (Ghadially 1983). Using ultrathin serial sections of rat synovial membrane, Graabaek (1984) has demonstrated conclusively that there are two distinct synoviocyte types, equivalent to A and B, and that cells which in a single section seemed intermediate in appearance could be shown by examination of other sections to be invariably of a type equivalent to B (termed type S by Graabaek). It has been suggested that the intermediate type of synoviocyte might be a precursor type A and B (Kinsella et al 1970) but the findings of Graabaek cast doubt on this.

The possiblity that precursors of type A synoviocytes may originate in bone marrow and be part of the mononuclear phagocyte system was proposed by Fell (1978) and demonstrated by Edwards (1982), using genetic markers for tracing cell lines related to mononuclear macrophages in radiation chimeras. The derivation of type B synoviocytes is still uncertain. Edwards & Willoughby (1982) have shown that in normal synovial membranes type B cells are derived neither from the bone marrow nor from type A cells. They could be of local origin from within the intima and be replaced by cell division or, as suggested by Ghadially (1983), derive from a stem cell population in the local subintima. Synoviocytes are not, however, an actively dividing cell population in normal synovial membranes (Key 1932, Coulton et al 1980), although their division rate increases dramatically in response to acute trauma and acute haemarthrosis (Ghadially 1983). It is interesting to speculate that in such conditions it is the type B cells which divide in situ while the type A cell population is increased by migration of bone-marrow derived precursors.

The *functions* of the cells of the synovial intima include the removal of debris from the joint cavity (mainly by type A cells) and the synthesis of some of the components of the synovial fluid (by both types of cells).

1. *Removal of debris*. Once a synoviocyte has ingested particulate matter it becomes capable of migrating into the subintima (Vernon-Roberts et al 1976), and it is probable that migrating synoviocytes carry ingested material to the lymphatic channels of the subintima which remove it from the joint. Fluid containing protein may be taken into the synoviocytes by micropinocytosis; there is evidence of the removal of injected peroxidase by type A cells but not by type B in this manner (Linck & Porte 1981).

2. *Synthesis*. It is generally assumed that some of the hyaluronic acid of synovial fluid is synthesized by the synoviocytes, although it could be manufactured by subintimal fibroblasts. While there is evidence that, like most mammalian cells, synoviocytes synthesize some forms of glycosaminoglycans, the evidence that these include hyaluronic acid is inconclusive (Henderson & Pettipher 1985). The presence of hyaluronic acid within the vesicles of synoviocytes could be due to micropinocytotic uptake from synovial fluid instead of, or as well as, synthesis by the cells. The ultrastructure of the intimal synovial cells suggests strongly, however, that they are involved in some form of synthesis and secretion, although the nature of the secretory products is so far only speculative. One or both of the synoviocyte types could be involved in the secretion of the proteoglycan-like material, lubricin, which acts as an articular cartilage lubricant; it has been shown to be produced by cells isolated from the synovial membrane and is not produced by fibroblasts from other sources (Swann 1982). Synoviocytes could also secrete some of the constituents of the extracellular matrix which surrounds them, e.g. collagen, proteoglycans and fibronectin (Henderson & Pettipher 1985). It has been proposed by Glynn (1977) that type A synoviocytes synthesize and release lytic enzymes during the phagocytosis of joint debris, damage to joint tissues being limited by the secretion of enzyme inhibitors by type B cells.

3. *Other functions*. Some intimal synoviocytes can present antigens to lymphocytes and can therefore rapidly stimulate an immune response to foreign material appearing in the joint cavity (Klareskog et al 1982). They may also have some control over the functioning of chondrocytes; it is known that mononuclear cells secrete factors which stimulate chondrocytes to degrade their matrix (Jasin & Dingle 1981) and it is possible that type A cells have a similar function. They may also control blood flow in the synovial membrane by the release of prostanoids such as the vasoconstrictor thromboxane A_2 and the vasodilator prostacyclin (Blotman et al 1983, Salmon et al 1983).

Synovial fluid occupies synovial joints, bursae and tendon sheaths. In synovial joints it is clear or pale yellow, viscous, slightly alkaline at rest (diminishing in activity) and has a small mixed population of cells and metachromatic amorphous particles. Viscosity, volume and colour vary in different joints and species; it is difficult to correlate these variations with particular joints or with size, weight or exertion. In human joints volume is low; usually less than 0.5 ml can be aspirated even from a large joint such as the knee.

The physical properties of synovial fluid include viscous, elastic and plastic components. Disagreements and inconsistencies in earlier investigations were often due to inadequate technique and ignorance of its non-Newtonian properties; i.e. with low rates of shear, the fluid is highly viscous but viscosity decreases with increased rates of shear, suggesting that in slow movement weight-bearing capacity would be maximal and in fast movement impedance due to fluid drag would be reduced. It was subsequently shown that the *product* of viscosity and shear rate is almost constant and hence also the weight-bearing capacity. Viscosity is very sensitive to changes in dilution and falls with increasing temperature and pH. Elasticity is similarly affected by changes in dilution, pH and temperature but it increases with higher rates of shear, unlike viscosity in similar conditions. For earlier reviews consult McCutchen (1959), Barnett et al (1961), Dintenfass (1963), Negami (1964), MacConaill (1966), Dowson et al (1969), Longfield et al (1969), Freeman (1973).

The composition of synovial fluid suggests a dialysate of blood plasma, containing protein (about 0.9 mg/100 ml) mainly derived from blood (Swann 1978), and added mucin, mostly hyaluronate, a sulphate-free glycosaminoglycan containing equimolar concentrations of glucuronic acid and N-acetyl-glucosamine; much evidence shows its visco-elastic and thixotropic (plastic) properties as largely due to hyaluronate content. Synovial mucin has been variously considered an attrition product of articular cartilage matrix, a secretion of subintimal mast cells, or a product of type A synovial cells. Light microscopy, histochemistry and tissue culture have proved inadequate but colloidal-iron techniques combined with electron-microscopy show a positive reaction for glycosaminoglycan in plasma membrane, filopodia, cytoplasmic vesicles and Golgi apparatus of type A synovial cells. This, with comparable results in other cells synthesizing glycosaminoglycans, is considered to confirm type A cells as sites of synovial hyaluronate synthesis (Ghadially & Roy 1969).

Synovial fluid protein is partly free and partly bound to glycosaminoglycans, including hyaluronate. Much appears to be

of haematogenous origin, the relative concentration of the individual proteins probably depending on their molecular weights and on the permeability of the synovial vessels (Swann 1978). The protein associated with hyaluronate may be either loosely or firmly bound. About 10–30% of the loosely bound protein is derived from blood plasma (Fraser et al 1977), as is most of that firmly bound (termed hyaluronate-protein). The remainder of the latter, some 2%, differs from plasma protein and is probably produced by synovial intimal cells (How et al 1969). Approximately 0.5% of synovial fluid protein can be separated as a lubricating glycoprotein fraction (LGP–1); this lubricates articular cartilage like whole synovial fluid. Although hyaluronic acid is an efficient lubricator of soft connective tissues, including synovial membrane, tests have shown that it is ineffective on articular cartilage, where LGP–1 appears to be uniquely involved. (See Swann 1978 and Swann et al 1981 for further information.)

The origin of non-haematogenous proteins of synovial fluid is uncertain but ultrastructure of the type B cells of the synovial intima is typical of that of cells manufacturing and secreting protein, suggesting that they may be sources of at least some of them.

The small tally of cells (about 60 per ml in resting human joints) includes monocytes, lymphocytes, macrophages, synovial intimal cells and polymorphonuclear leucocytes (Bauer et al 1940). Higher counts, characteristic of youth and of other species, may be due to more active movements before sampling. The amorphous, metachromatic particles and fragments of cells and fibrous tissue in synovial fluid are considered due to wear and tear.

Functions of synovial fluid include provision of a liquid environment, small in range of pH, for joint surfaces, nutrition of articular cartilages, discs and menisci, lubrication and reduction of erosion. Its nutritive role, compared with direct diffusion from vascular plexuses, is uncertain; despite general agreement on its lubricant value details of its actions are still disputed.

Models proposed for lubrication in joints have largely paralleled current advances in engineering physics. First proposed was 'fluid film' or 'hydrodynamic' lubrication, familiar in engineering, bearing surfaces being separated by a substantial layer of lubricant, its effectiveness depending on the rheological properties of the fluid in bulk. Later theoretical refinement included consequences of fluid elasticity, the 'elastohydrodynamic model'; but criticism of suitability of the articular environment for simple fluid-film lubrication arose and 'boundary lubrication' was proposed, in which properties of the solid surfaces are combined with those of extremely thin layers of lubricant molecules. 'Weeping lubrication' followed, in which the porous, fluid-filled deformable nature of the articular surface was emphasized; it was proposed that surfaces under load were lubricated by a film of fluid expressed from the 'pores'. Then 'boosted lubrication' came forward suggesting that compression of articular cartilages traps fluid pools in irregularities of their surfaces; increasing compression is supposed to force a small-moleculed, mobile fraction of synovial fluid *into* the cartilage contact area, fluid left in the 'valleys' becoming increasingly enriched in hyaluronate and hence more viscous and thus a more effective and protective lubricant. But major ridges and valleys are probably artefacts (p. 473) and 'pits' and 'humps' in vivo are not proven. Considering the wide variation in joint geometry, structure and activity, it seems likely that multiple mechanisms may operate under different conditions. Despite much research, theories of joint lubrication remain speculative (Freeman 1973).

Synovial membrane not only *produces* fluid but also *removes* materials from articular cavities. Small molecules of crystalloids and soluble dyes can cross it directly into subintimal capillaries and venules, the former fenestrated according to Kos (1970). Particles pass into subintimal lymphatic capillaries for transport to regional lymph nodes. Intra-articular introductions of tracers, such as thorotrast, colloidal carbon and ferritin, followed by electron microscopy, has revealed the marked phagocytic powers of type A synovial cells, which rapidly enclose particles in phagocytic vesicles. The source of subintimal macrophages is uncertain; some may enter joints from blood but many are probably type A cells of intimal origin which enter subintimal tissues (Ghadially & Roy 1969).

CLASSIFICATION AMD MOVEMENTS OF SYNOVIAL JOINTS

Several criteria have been used in classifying synovial joints and their movements; but these differ in universality, scientific accuracy and utility. They include complexity and number of articulating surfaces, number and position of principal axes of movement, general geometry of surfaces and major movements, and association of more precise geometry with analysis of movements as bases for *human kinesiology*. This can be considered only briefly here (p. 477); detailed treatises are available (Steindler 1955, Barnett et al 1961, MacConaill & Basmajian 1977).

Complexity of form. Most synovial joints have *two* surfaces (*male* and *female*) and are *simple* articulations. In some one surface is wholly convex (male) and greater in area than its opposing concave (female) surface; in a few, both are concavoconvex, the larger being considered male. A joint with more than two surfaces is *compound*, e.g. the elbow. (The humerus presents two male surfaces, capitulum and trochlea, which 'mate' with the radial and ulnar female surfaces. The convex, male, circumference of the radial head also 'mates' with the female radial notch of the ulna.) In all compound joints articulating territories remain distinct; male surfaces never pass on to female surfaces of an adjoining pair. Thirdly, when it contains an intracapsular disc or meniscus a joint is *complex*.

Degrees of freedom. Analysis of positional changes of one of a pair of articulating bones is often best effected by considering rotations around three mutually perpendicular axes, whose directions may, for convenience, vary with the joint concerned. Often they correspond to the main bodily planes, i.e. vertical, transverse and ventrodorsal axes; but alternatives may be more appropriate, e.g. many prefer to consider the movements of humerus on scapula around a vertical axis, an oblique transverse axis in the plane of the scapula and a third at right angles to both (4.5).

When movement is practically limited to rotation at one axis, a joint is termed *uni-axial*; it has *one degree of freedom*. If *independent* movements can occur around two axes, it is *bi-axial*, with *two degrees of freedom*. Since there are three axes for independent rotation, joints may have up to *three degrees of freedom*. This apparently simple classification requires amplification.

Firstly a bone can rotate at a ball-and-socket joint on three main axes *and* any others in intermediate positions. Such a *multi-axial* joint, however, still has only three degrees of freedom; all intermediate rotations can be resolved into components involving *three* orthogonal axes.

Secondly if movement referred to one plane is examined in its *full range*, a single relevant axis cannot be fixed in space but is a succession, changing continuously as movement progresses; because articular surfaces are not simple, their radius of curvature changes across any profile (p. 480) to a variable extent in different forms of joint (vide infra). But a *mean position* of such a moving axis is often '*the axis*' of usual description. For many purposes such approximate axes are useful particularly when gross movements only are considered.

Thirdly simple movements apparently limited to one plane are often in fact compound. For example, what appears simple angulation is often accompanied by rotation of one bone about its long axis, a direct consequence of the complex articular curves (p. 479). When, as is usual, such rotation is not independent, i.e. never isolated, it is not considered an additional degree of freedom (e.g. movements of ulna, p. 509).

Fourthly many movements involve *translation*: one surface slides bodily across its partner with minimal rotation or angulation (cf. 'plane' joints, infra). Translation, however, often accompanies large angulations (e.g. shoulder joint). Note that translation is not included in the above classification.

General Classification of Synovial Joints

General shape of synovial joints has been widely used to classify them, usually into seven varieties. While this has some practical value, it affords no exclusive basis for separation because they are merely variations, sometimes extreme, of two basic forms (p. 478).

Plane joints are appositions of almost flat surfaces (e.g. intermetatarsal and some intercarpal joints); slight curvature is usual although often disregarded, movements being considered pure translations or slides between bones. Nevertheless, in precise dynamics even slight curvatures cannot be ignored (vide infra).

Ginglymi (hinge joints) resemble hinges and are shaped to restrict movement to one plane, i.e. they are uni-axial. They have strong collateral ligaments, interphalangeal and humero-ulnar joints being examples. But surfaces of such biological hinges differ from regular mechanical cylinders: their profiles are not arcs but varyingly spiral and the main to-and-fro swing must include some (conjunct) rotation (vide infra).

Trochoid (pivot) joints, also uni-axial, have an osseous pivot in an osteoligamentous ring, allowing rotation only around the pivot's axis. Pivots may rotate in rings, as the radial head rotates within the annular ligament and ulnar radial notch; or rings may rotate, as the atlas (with its transverse ligament and carrying the head) rotates around the dens of the axis.

Bicondylar joints are largely uni-axial, with a main movement in one plane but also with limited rotation about a second axis orthogonal to the first. The rotation is of two varieties: *conjunct*, an integral and inevitable accompaniment of the main movement; *adjunct* which can occur independently and may or may not accompany the principal movement. They have two convex *condyles* (knuckles) articulating with concave surfaces (sometimes also inappropriately named condyles). Condyles may be almost parallel (e.g. knee) with a common fibrous capsule or well apart in separate capsules (e.g. temporomandibular joints) which necessarily co-operate in all movements as a *condylar pair*.

Ellipsoid joints are bi-axial, with an oval, convex (male) surface apposed to an elliptical (female) concavity, as in radiocarpal and metacarpophalangeal joints. *Primary* movements are about two orthogonal axes (e.g. flexion–extension, abduction–adduction), which may be combined as circumduction (vide infra); rotation around the third axis is largely prevented by general articular shape.

Sellar (saddle) joints, also bi-axial, have concavoconvex surfaces; each is most convex in a particular direction but at *right angles* to this they are maximally *concave* (p. 478). Convexity of the larger is apposed to concavity of the smaller surface and vice versa. Primary movements occur in two orthogonal planes but articular shape causes axial rotation of the moving bone. Such *conjunct rotation*, as mentioned above, is never independent and is not simply a by-product of 'imperfect' mechanics but is functionally significant in habitual positioning and limitation of movement (pp. 483, 485). The most familiar sellar joint is the pollicial carpometacarpal; others include the talocrural (ankle) and calcaneocuboid joints.

Spheroidal joints ('ball-and-socket') are formed by reception of a globoid 'head' into an opposing cup, e.g. hip and shoulder joints. These are multi-axial, with three degrees of freedom. Their surfaces, although resembling parts of spheres, are not strictly spherical but slightly ovoid. (*Articulatio ovoidalis* is an accepted alternative.) Consequently, in most positions congruence is not perfect, occurring only in *one* position, at the end of the commonest movement (vide infra).

Articular Movements and Mechanisms

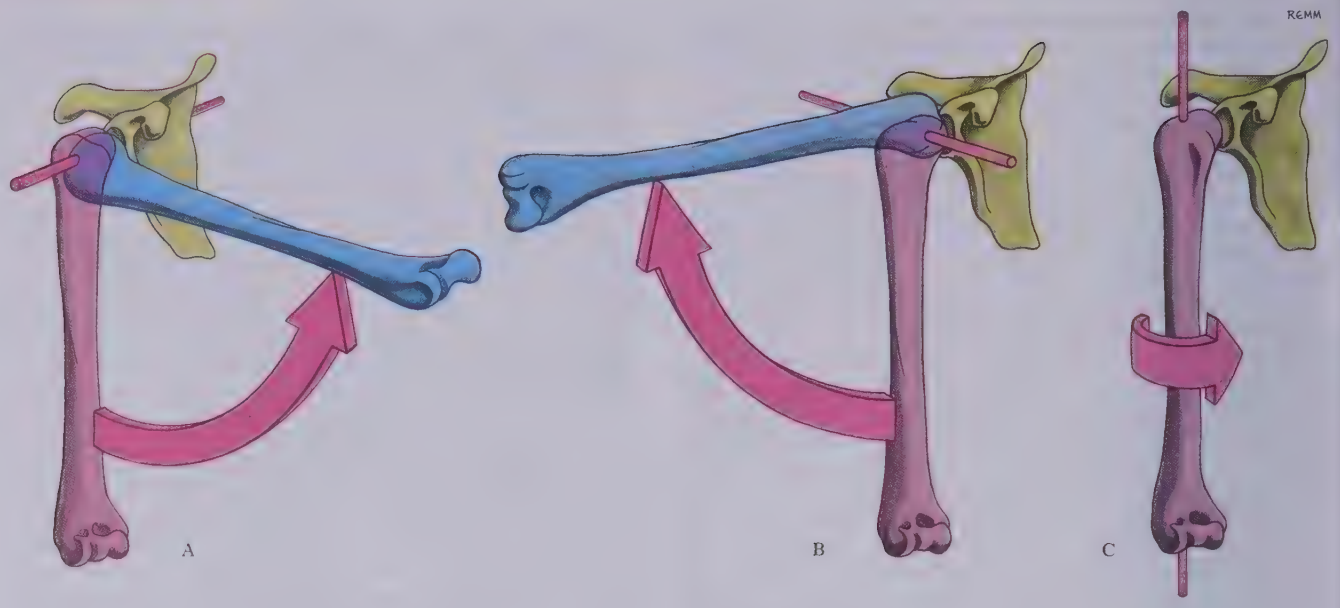
Articular movement will first be considered in terms and concepts usual in standard textbooks, followed by a review of the more advanced concepts and theories of modern kinesiology. Articular movements are usually considered to be gliding and angulation, circumduction and rotation. Almost always these four are combined in infinite variety. Where movement is slight, reciprocal surfaces are near in size; where it is wide, the bone habitually more mobile has the larger articular surface.

Translation, the simplest motion, is sliding without appreciable angulation or rotation. Often combined with other movements, in some carpal and tarsal articulations it is often considered the only motion permitted; but even here cineradiography reveals considerable rotation and angulation of small carpal and tarsal bones during their movements.

Angulation implies change in angle between (topographical) axes of articulating bones. Two types are common, especially in limbs, around orthogonal axes: (1) *flexion* or bending and *extension* or straightening and (2) *abduction* and *adduction*.

Flexion, a widely used term, is difficult to define. It often means approximation of two *ventral* surfaces around a *transverse* axis. But the thumb is almost at right angles to the fingers; its 'dorsal' surface is thus lateral and flexion and extension at its joints is around anteroposterior axes. At the shoulder flexion is more reasonably referred to an oblique axis through the centre of the humeral head in the plane of the scapular body, the arm moving anteromedially forwards and hence nearer to the trunk's ventral aspect. Again, flexion at the hip, which has a transverse axis, brings the thigh's morphologically *dorsal* (but topographically ventral) surface to the trunk's *ventral* aspect reflecting rotation of the hind limb bud in early embryonic life (p. 174). Description at the talocrural (ankle) joint is again complicated by the foot's posture at a right angle to the leg. Elevation diminishes this angle and is sometimes termed flexion; but it is approximation of two dorsal surfaces and might equally be called extension. Flexion has also been defined as fetal posture, implying that elevation of the foot is flexion, a view supported by withdrawal reflexes in which elevation is always associated with flexion at knee and hip, the converse holding in crossed extensor reflexes. Definitions based on morphological and physiological grounds are thus contradictory. To avoid confusion in this instance *dorsiflexion* and *plantar flexion* are used for talocrural movements.

Throughout this section and elsewhere, therefore, it is evident that care must be exercised, when using positional terms, to indicate whether they stem from phylogenetic, ontogenetic or physiological data and how these relate to descriptions of mankind in 'the anatomical position'.



Abduction and adduction occur around anteroposterior axes except at the pollicial carpometacarpal and shoulder joints, for reasons stated. The terms generally imply lateral or medial angulation, except in digits, where arbitrary planes chosen are midlines of the middle manual digit and second pedal digit, because these are least mobile in this respect. Abduction of the thumb is around a transverse axis and away from the palm. Similarly, abduction of humerus on scapula occurs in the scapular plane around an oblique axis at right angles to it (4.5).

Circumduction occurs when the distal end of a long bone circumscribes the base of a cone, its apex at the joint, e.g. shoulder and hip joints. It combines successive flexion, abduction, extension and adduction.

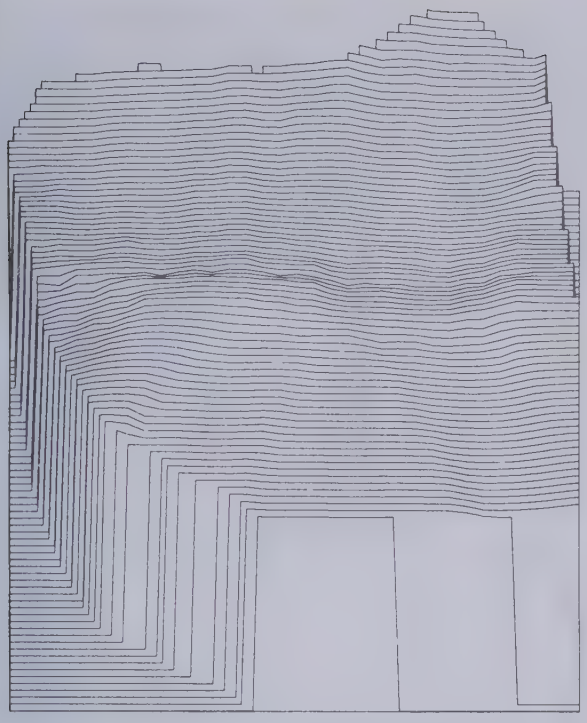
Rotation is another term used widely but often imprecisely. Its *restricted sense* denotes movement around some notional 'longitudinal' axis, which may even be in a separate bone, e.g. the dens of the second cervical ('axis') vertebra on which the atlas rotates. An axis may be approximately the centre of the shaft of a long bone, as in medial and lateral humeral rotation (4.5). Again, it may be at an angle to the bone's topographical axis, as in movement of radius on ulna in pronation and supination, where it joins the centre of the radial head to the base of the ulnar styloid process; and in medial and lateral femoral rotation, where the axis joins the centre of the femoral head to the lateral femoral condyle (p. 523). In these examples rotations can be independent, as *adjunct rotations*, providing an additional degree of freedom. They must be distinguished from *conjunct rotations* which always accompany some other main movement due to articular geometry (p. 481). However, in some articulations *conjunct* may be combined with some *adjunct* rotation and the latter may either increase or nullify the former at different times. Furthermore, with the exception of slight simple translation, *all* movements are in fact rotations. For example (p. 503) medial and lateral humeral rotations occur around the bone's long axis (vertical, in the anatomical position); swinging, 'angular' movements (flexion–extension and abduction–adduction) are rotations around the other two axes.

Kinesiology

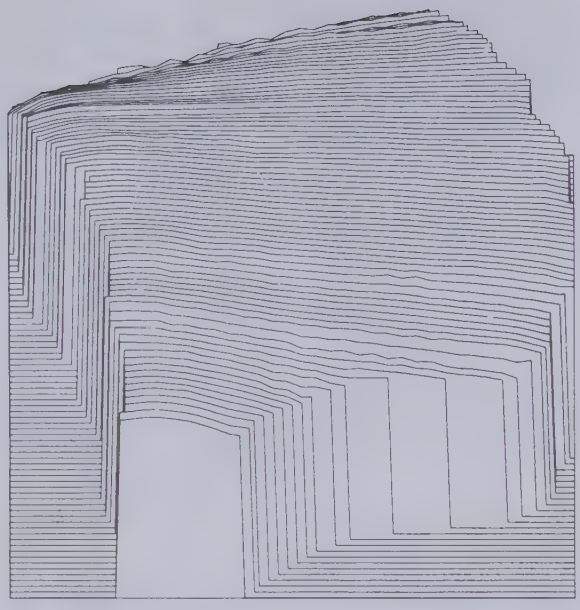
The preceding account summarizes views and terminologies evolved over many years by simple observation of articular

4.5 The shoulder joint is polyaxial and possesses three degrees of freedom. The three mutually perpendicular axes around which the principal movements of flexion–extension (A), abduction–adduction (B) and medial and lateral rotation (C) occur are shown. Note that in the case of the shoulder the axes are referred to the plane of the scapula and not to the coronal and sagittal planes of the erect body as a whole. An infinite variety of additional movements may, of course, occur at such a joint, e.g. those involving intermediate planes, or there may be movement combinations or sequences. However, these can always be resolved mathemetically into components related to the three axes which are illustrated.

anatomy and obvious geometrical changes. For many purposes this is adequate. More recently closer attention has amassed more objective observations, experimental results and theory to form an emerging science of *kinesiology*, a branch of biomechanics requiring new terminology, revision of older concepts and unfamiliar mathematical treatments. These developments are considered briefly here; useful expositions are given by MacConaill (1946, 1950, 1953, 1964, 1966a, 1977), Steindler (1955), Barnett et al (1961), Kapandji (1970). Two fields of study are relevant here: (*a*) *osteokinematics* dealing primarily with overall bone movements with little reference to joints, and (*b*) *arthrokinematics*, concerned with articular mechanics. Certain generalizations about shapes of articular surfaces must first be considered and then replacement of an irregular bone by a single *mechanical axis*—concepts which necessarily precede study of surfaces and movements of particular joints.



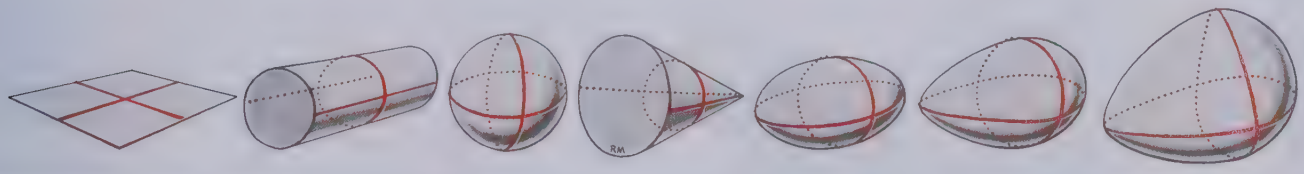
The Shape of Articular Surfaces



Although the usual classification of synovial joints into seven types is based on shape, this does *not* entail a like number of fundamentally different surface shapes. Articular surfaces are never truly flat, nor exactly parts of spheres, cylinders, cones or ellipsoids (4.6). They are more nearly parts of surfaces of *ovoids* (4.6B) or compounded of more than one such surface. When these are either convex or concave, they may be termed male or female *ovoid articular surfaces*. The other well-recognized type is *sellar*, convex in one plane and concave at approximately right angles to this; even here curvatures are convex or concave *ovoid* profiles. Articular profiles vary from nearly flat to nearly spheroidal; but evidence increasingly indicates all to be *ovoid* or *sellar* (4.7). However, quantitative topology of conarticular surfaces has, for most joints (especially human), not yet been detailed. Palfrey & Ziemer (4.6A) have attempted such analyses on fresh talocrural joints (amputation specimens) and a more extensive analysis of tarsal joints has been contributed by Langelaan (1983). In the former study physical damage and desiccation were minimized (but not eliminated) and multiple casts in dental wax were made of talar and tibial trochlear surfaces; coronal and sagittal slices (3 mm or less) were prepared. Multiple points, marked along curved cartilage profiles, were assigned spatial co-ordinates determined by projection and tracing upon grid paper. Similar data were assessed for subchondral osseous surfaces. Subsequent analysis yielded two-dimensional contour maps and three-dimensional reconstructions. Much more exact data of shape, congruence, variation in thickness of cartilage, conarticular surface areas and differences between profiles of cartilage and subchondral bone were obtained.

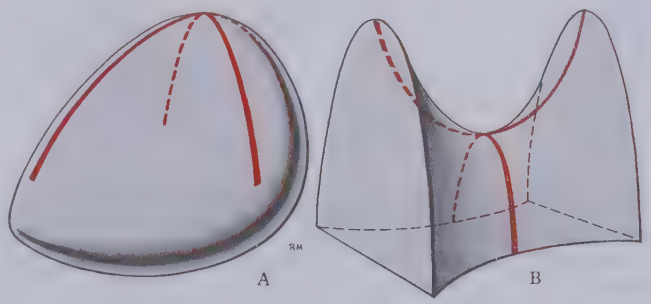
Certain terms applied to ovoid surfaces and their properties are relevant both to movements of articular surfaces and of whole bones. Two points on an ovoid may be joined by a curved line which is the shortest distance between them, this being a *chord* distinct from any longer line joining them which is an *arc* (4.8) (MacConaill & Basmajian 1977). Any point moving on an ovoid surface traces a chordal or an arcuate line (or a succession of these), as will be considered further below. This usage of *chord* and *arc* is unfamiliar (they are usually applied to *circles* on plane surfaces). To clarify the concept imagine two points on a plane but deformable surface; these may be joined by the shortest route, a straight line, a *chord* (*geodesic*); *any* longer route may be called an *arc* (*non-geodesic*). Even if the surface is now formed into a sphere, cylinder, ovoid, sellar surface etc., relation between chord (geodesic) and arc (non-geodesic) is of course preserved.

A figure enclosed by three chords is a *triangle* (4.8), the sum of its angles exceeding 180° on an ovoid surface but being less than this on a sellar surface and precisely 180° when it is flat. Deviation from 180° depends on degree of curvature, an important fact in arthrokinematics (vide infra). Any three-sided figure in which at least one side is an arc is a *trigone*.

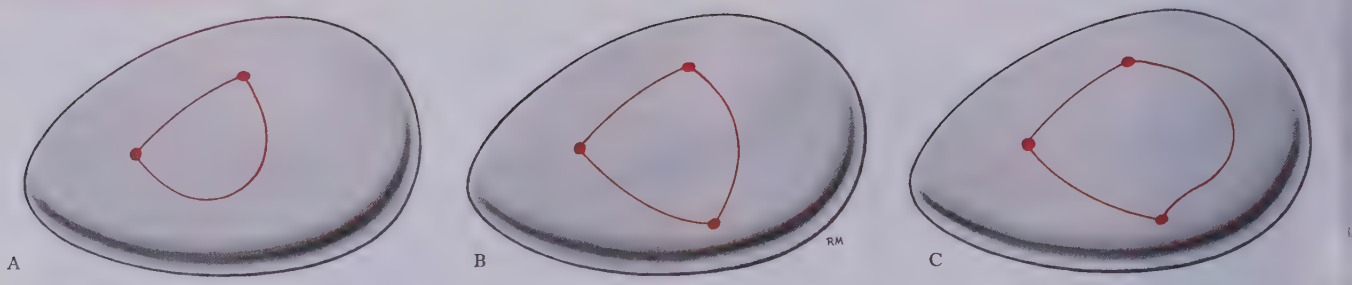


Sectional profiles of ovoid surfaces (4.9A) reveal two properties: firstly radius of curvature varies continuously, a profile being considered a series of short segments of circles of different radius and a line joining their centres being the *evolute* of the profile. Rotation of a bone by sliding on such a profile is referrable not to one axis but to successive points on the evolute. Secondly if on a convex ovoid surface a smaller segment of a similarly curved concave surface slides (4.9B), the two will fit perfectly only in one position (cf. close-packed position, described below); in all other positions surfaces are not congruent, the area of contact being much reduced and cuneiform intervals separating them elsewhere. (Theoretically, in a 'perfect', incompressible ovoid, contact would be linear; it is an *area* because of superficial undulations (p. 473) and compressibility of cartilage.)

4.6A *Left*, a computer reconstruction of a sagittally sectioned cast of the trochlear surface of a fresh human tibia (left side, female, aged 63) viewed posteriorly. The medial malleolar surface is not included. It is a modified female sellar surface and reciprocally curved to its mating surface on the talus. Anteroposteriorly the surface is concave; lateromedially (left to right) there is a central convexity flanked by anterior and posterior concavities.

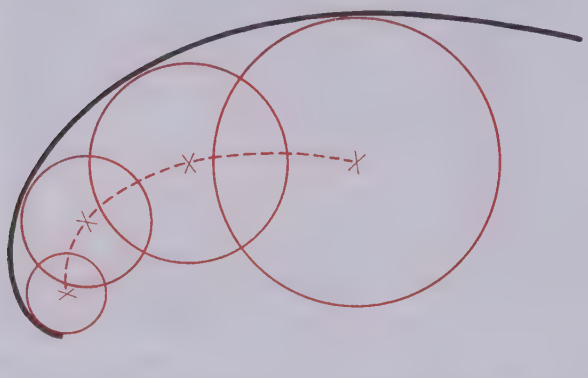


Right, a computer reconstruction of a coronally sectioned cast of the trochlear surface of a fresh human talus (left side, male, aged 62) viewed anteriorly. The triangular facet for the 'inferior transverse ligament' part of the posterior tibiofibular ligament has been excluded. It is a modified male sellar surface, which is convex anteroposteriorly; mediolaterally (left to right) it presents a medial convexity, a central concavity and a rather flattened lateral convexity. Reconstructions provided by A J Palfrey and Linda K Ziemer of the Department of Anatomy, Charing Cross Hospital Medical School, London.



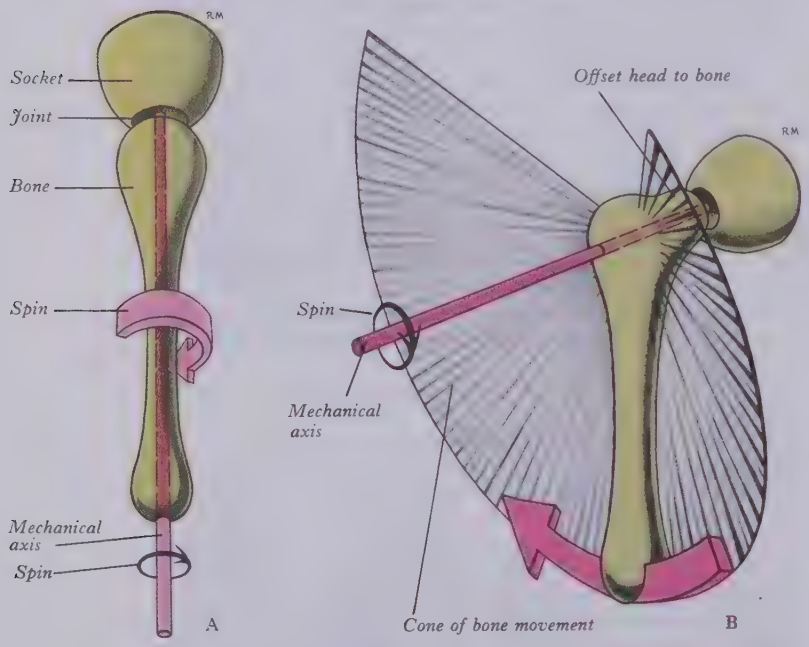
4.6B A variety of geometric figures to which reference is commonly made in simple classifications of synovial joints. However, such comparisons are rough approximations only—no synovial joint possesses articular surfaces which are truly plane, cylindrical, spherical, conical or ellipsoid. Commonplace simple and compounded ovoids are included for comparison.

Mechanical Axes of Bones



Bones are irregular, their articular surfaces bearing no simple or symmetrical relation to their form. Hence comparison of movements of individual *bones* may be misleading in terms of *joint mechanics*. To aid accurate comparison the concept of the *mechanical axis* has been introduced. This is made clearer in 4.10A and B. In A a hypothetical, symmetrical long bone is shown with a terminal joint in mid-range of movement. A rod through the bone, ending perpendicular to the articular centre, is its mechanical axis and can represent the bone when *articular movements* are considered; in this special case of symmetry axis coincides with shaft. In 4.10B, however, the bone is not symmetrical, the joint again is in mid-range and its mechanical axis is as shown; mechanical axis and shaft diverge widely. Corresponding *articular movements* hence result in similar displacements relative to the mechanical axis, but consequent movements of the shaft appear dissimilar. (See below for varieties of 'spin' and 'swing'.) Despite the usefulness of a mechanical axis in some analyses, in others it is less so because of arbitrary choice of a 'central articular point', difficult to define with precision. Mechanical axis selection might be better defined as that of *most habitual conjunct rotation*, the limit of which is the *close-packed* position of the joint concerned (vide infra). In

4.7 The two fundamental geometric types of articular surfaces. A. Ovoid, which may be convex (male) or concave (female). Note that the compound solid body illustrated presents different ovoid profiles in two planes at right angles and that the curvatures of the two may be different. B. Sellar or saddle-shaped surfaces, which are concavoconvex. In practice both types of surface may vary from only slightly to highly curved. Thus ovoid surfaces may be 'almost flat' or 'almost spherical' but the majority show intermediate grades of curvature and much variation in change of radius from place to place. Sellar surfaces may also be compound and have a marked asymmetry, e.g. at the talocrural and patellofemoral joints.

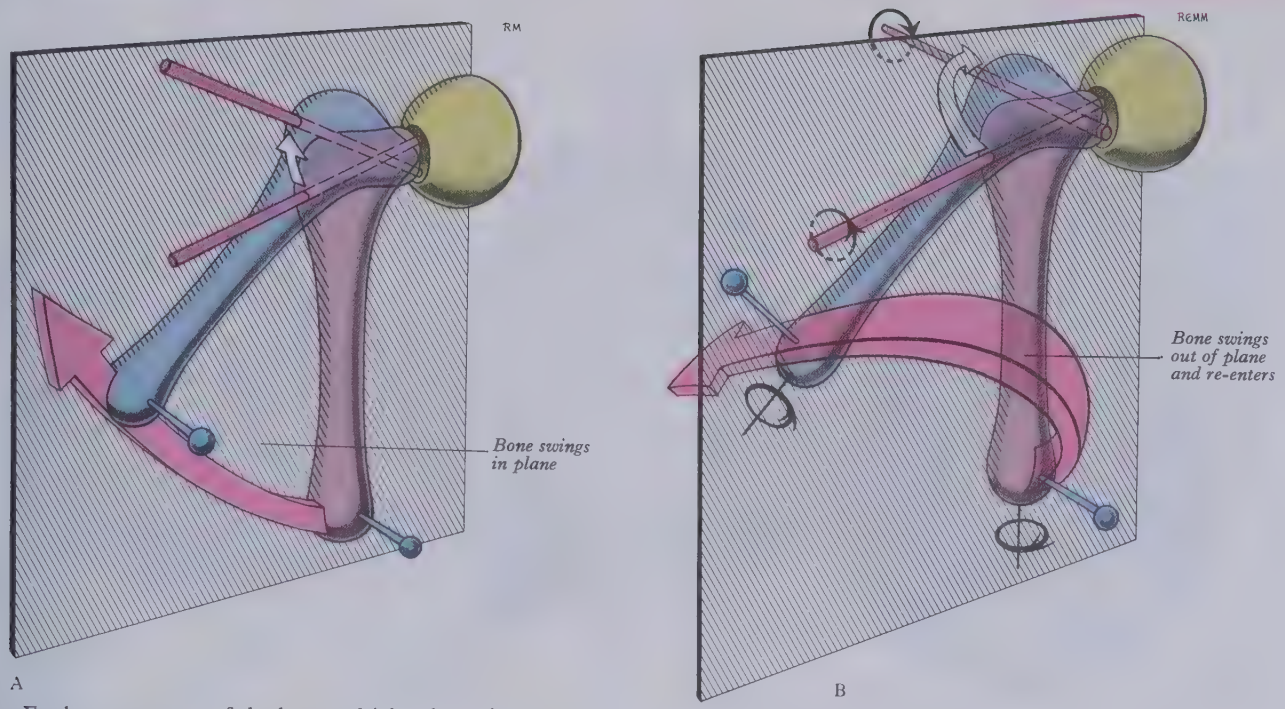


4.8 Geometric paths across ovoid surfaces, and three-sided figures enclosed by such paths. A. A chord (the shortest path between two points) and one example of an arc (any longer path between the points). B. A triangle enclosed by three chords. C. A trigone, a three-sided figure in which one or more sides is an arc.

4.9A Profile of a section through an ovoid surface showing that it may be considered as a series of segments of circles of changing radius. The (dashed) line joining the centres of the circles is the evolute of the profile.

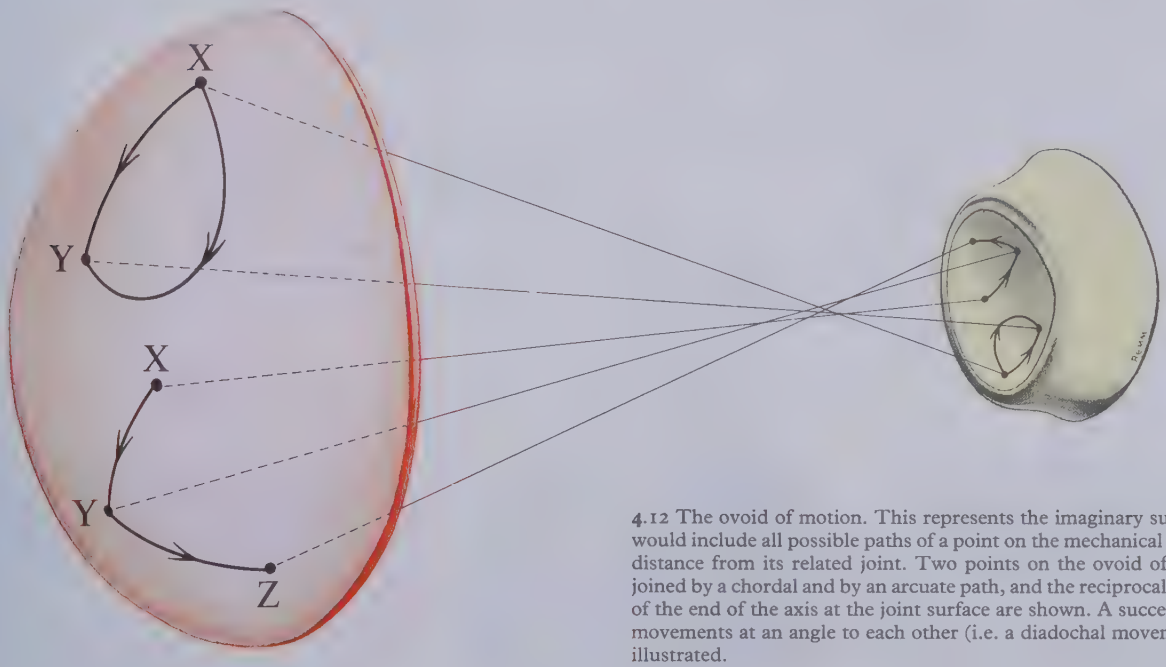
4.9B A small section of an ovoid profile (red) in various positions, in relation to a more extensive profile (black). The two fit perfectly (i.e. are fully congruent) in only one position.

4.10 The mechanical axis: (A). in a hypothetically simple, symmetrical long bone, with a terminal joint; a 'spin' is occurring around this axis; (B) in a bone with an offset head; a similar 'spin' is occurring between the articular surfaces, but the shaft of the bone traces part of the surface of a cone.



spheroidal, multi-axial joints definition of a *single* mechanical axis may also be an insufficient datum for the many combinations possible.

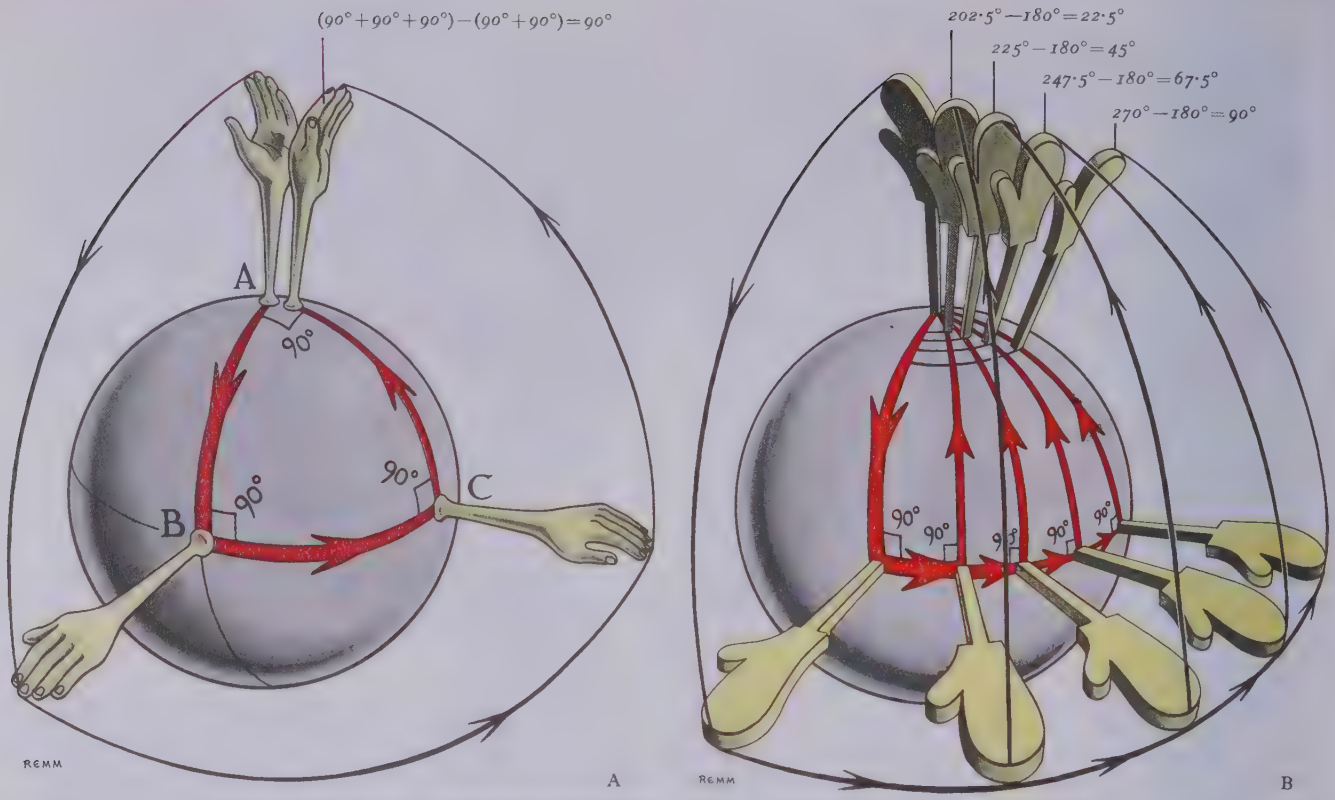
Movements of Bones



Apart from passive accessory movements due to external forces (p. 481), all others are rotations; since this term is often used in a restricted sense (p. 477), new terms become necessary. Any bone solely rotating around its stationary mechanical axis is said to show pure *spin*; *any* point on the bone, outside the axis, describes an arc (of a circle), with the axis as its centre (4.10). All other displacements of bone and axis are *swings*, which may be *pure* (4.11A) or *impure* when spin also occurs (4.11B). (In a spheroidal joint what is virtually pure spin is theoretically possible around many alternative 'mechanical axes'.)

Another useful concept is the so-called *ovoid of motion*: during any swing a point on the mechanical axis, distant from its related joint, describes a curved path in space and all such possible paths (4.12) are on part of an ovoid's surface (as would be expected, since they are generated from such an articular surface). Area and shape of such *ovoids of motion* vary for individual bones and articular surfaces. During any particular swing, therefore, a point on the mechanical axis moves from X to Y on the ovoid of motion either along a chord (a *cardinal swing*) or by a longer route from X to Y (an *arcuate swing*). Synchronously the articular end of the axis traces a reciprocal chord or arc across its opposing articular surface. A consequence of such swings is related to presence or absence of associated spin: during a cardinal swing along a chord (an unusual movement) there is *no associated spin*; in an arcuate swing there must be some spin which is functionally significant (vide infra). Similarly, spin occurs if a movement involves two chords in series at an angle to each other (one form of *diadochal movement*), e.g. X to Y and Y to Z in 4.12.

In some apparently simple swings of bones, spin was long undetected; but its occurrence can be predicted mathematically as a consequence of articular curves and is in most instances verifiable by careful inspection or cineradiography. Diagrams may assist comprehension: in Fig.4.13A three points, A, B and C, are on the surface of a sphere, AB, BC, and CD being shortest distances (chords) between them. AB and AC are 'lines of longitude' meeting the equator at 90° at B and C. A model limb moves successively along chords A→B, B→C, C→A; between initial and final positions it has 'spun' 90° (by which the sum of angles of 'triangle' ABC *exceeds* 180°). Fig. 4.13B shows intermediate 'lines

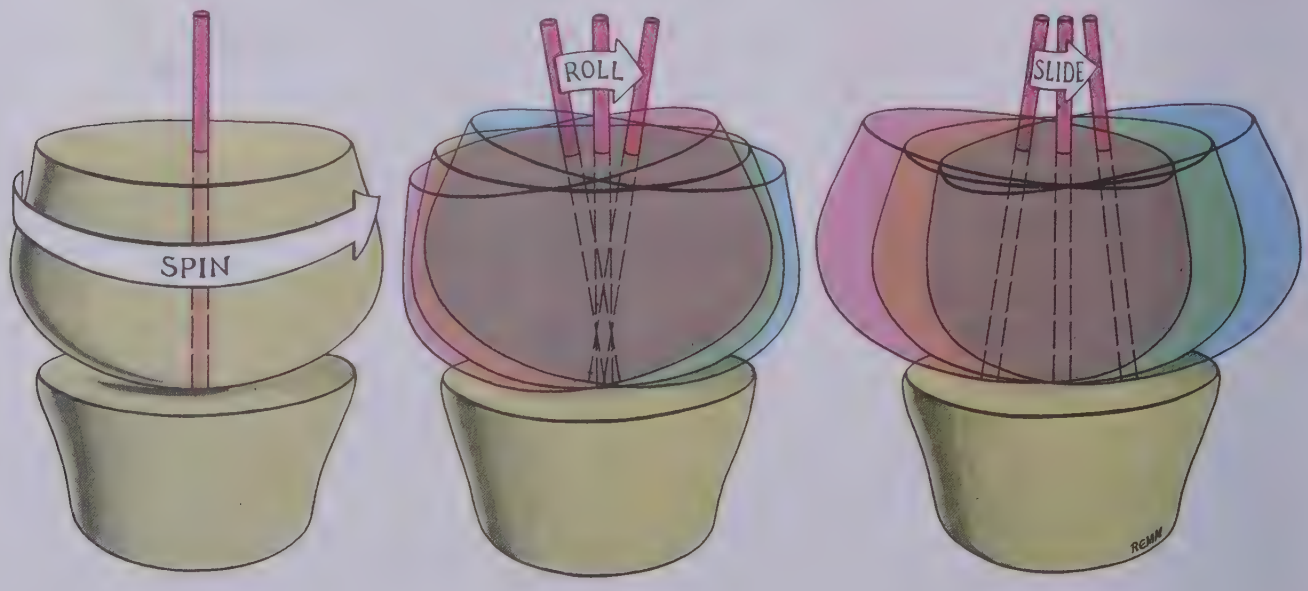


4.11 Further movements of the bone and joint shown in 4.10B. A. A cardinal swing. Note that the mechanical axis moves in one plane. (Its proximal end traces a chordal path at the joint and its distal end a chordal path on the ovoid of motion, see 4.12). There is no spin. B. An arcuate swing. Note that the bone moves out of the plane illustrated and then returns to it. The ends of the mechanical axis trace arcuate paths at the joint and on the ovoid motion. There is an associated spin or conjunct rotation around the *mechanical axis* (and a rotation around the *long axis* of the *bone shaft*).

4.12 The ovoid of motion. This represents the imaginary surface which would include all possible paths of a point on the mechanical axis at some distance from its related joint. Two points on the ovoid of motion are joined by a chordal and by an arcuate path, and the reciprocal movements of the end of the axis at the joint surface are shown. A succession of two movements at an angle to each other (i.e. a diadochal movement) is also illustrated.

of longitude'; in each case spin equals the sum of the three angles minus 180°. This relation holds mathematically for all ovoid or sellar surfaces. Spin is imparted during the B→C movement (i.e. along a second chord at an angle to the first). An arcuate path may be analysed as a series of chords which change angle. These spins, inevitable in certain swings, are *conjunct rotations* and characteristic of sellar and most ovoid joints. *Habitual* movements at *all* joints always involve some demonstrable conjunct rotation; an important consequence will be best appreciated after consideration of related movements and 'fit' of articular surfaces (vide infra).

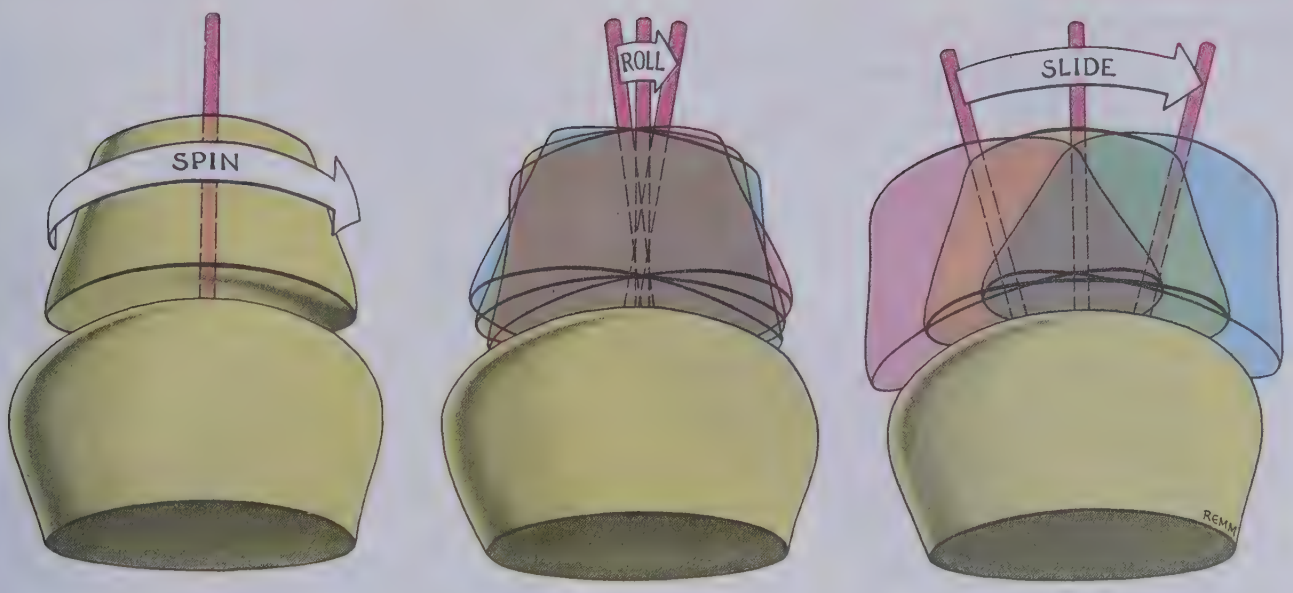
Beyond these basic arthrokinematics of *conjunct rotations* it must be added that other rotations (due to interplay of gravity, external forces and muscle action) are *adjunct*. Adjunct rotations occur only in joints with two or more degrees of freedom, involving either a bone undergoing *no* conjunct rotation or one in which it must be considered. In the first, factors causing adjunct rotation may generate *pure spin*; in the second, effects of adjunct rotation may be in the *same sense* (e.g. both 'clockwise'), i.e. additive, increasing rotation and hence termed a *cospin*. Alternatively, adjunct rotations may be in *opposite sense*, reducing or nullifying effects of conjunct rotation and hence termed *antispins*. Thus a bone starting one or a succession of arcuate swings which, if unmodified, would involve some conjunct rotation may also be subjected to *nullifying antispin*: the latter may be *gradual*, applied throughout movement or *sudden*, near its end. Therefore, while



4.13 The 'spin' or conjunct rotation which accompanies a diadochal movement. A model hand and arm moves over the surface of a sphere, first along a line of longitude, then one of latitude to return along a line of longitude. A. The arm traverses three chordal paths which enclose a 'triangle' with three right angles (i.e. the sum of the angles = 270°). Note that as it passes along the line of latitude from B to C, a spin of 90° is imparted. B. This illustrates how the amount of spin imparted during a diadochal movement varies with the length and angulation of the second stage of the movement.

the *path* of the bone is a more or less complex *arcuate* swing, it is modified to become *quasichordal* because there is no net spin.

Movements at Articular Surfaces



The 'fit' of ovoid surfaces (p. 478) is precise only at one end of the joint's most common excursion, a feature of the close-packed position discussed below. In all other positions surfaces are not fully congruent, the joint is 'loose-packed'. Changes in congruity are illustrated in the shoulder joint in **4**.17.

Where articular surfaces are not fully congruent movements can be analysed into spin, slide and roll, which must first be considered at a convex (male) surface moving on a stationary concave (female) surface, and vice versa (**4**.14,15). In most natural

A Spin. B Roll. C Slide.

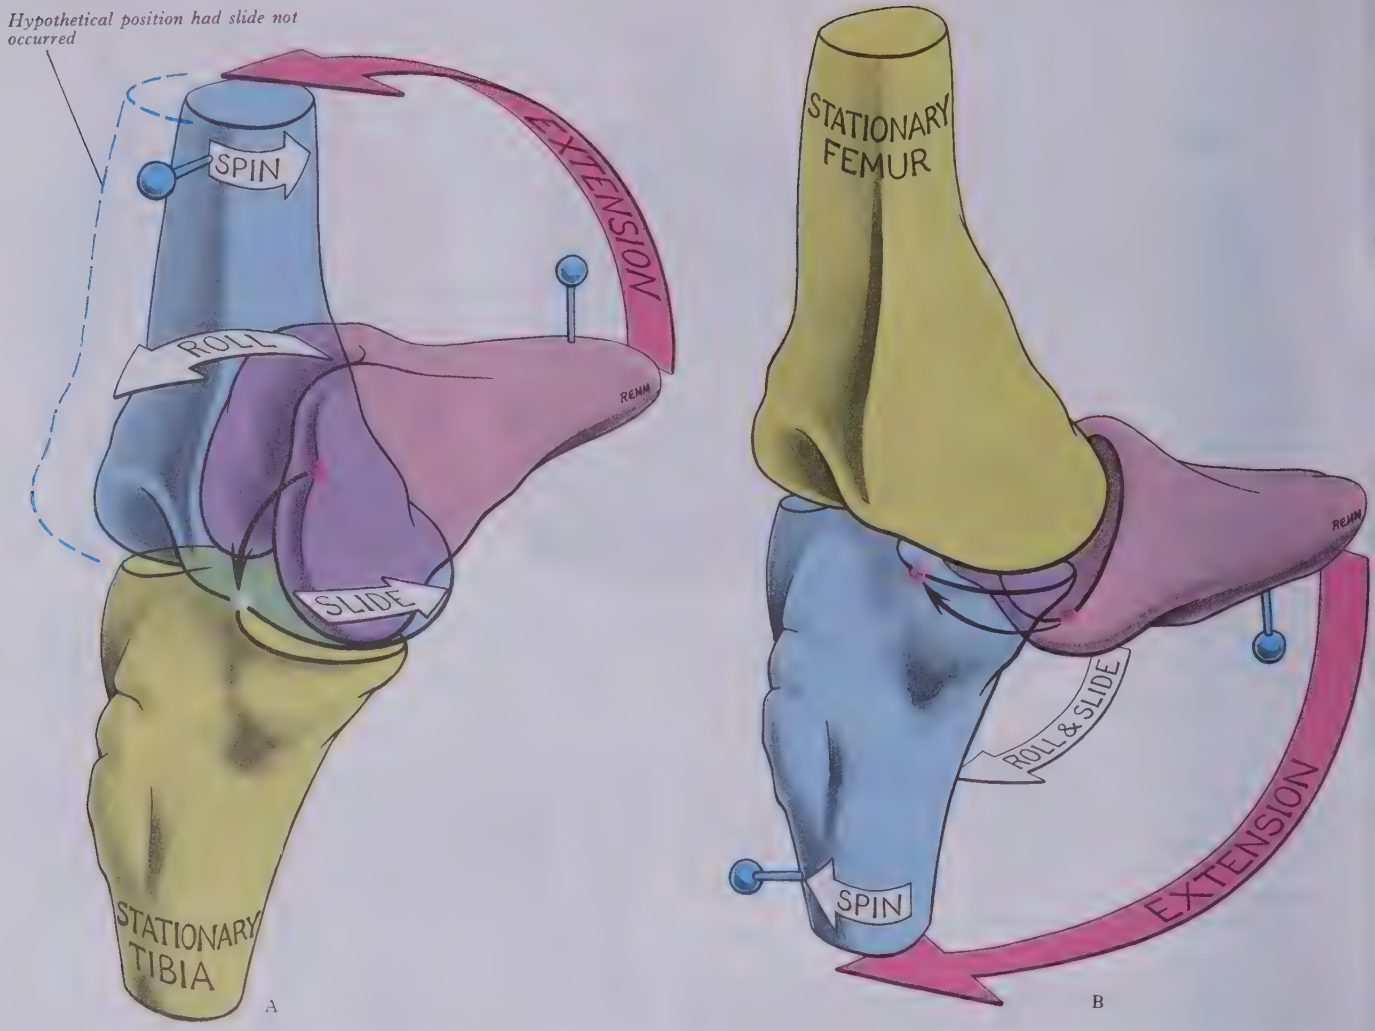
4.14 An analysis of the types of movement which occur (usually in combination) between articular surfaces when a male surface moves over a stationary female surface.

A Spin. B Roll. C Slide.

4.15 Articular movements. A female surface moves on a stationary male surface.

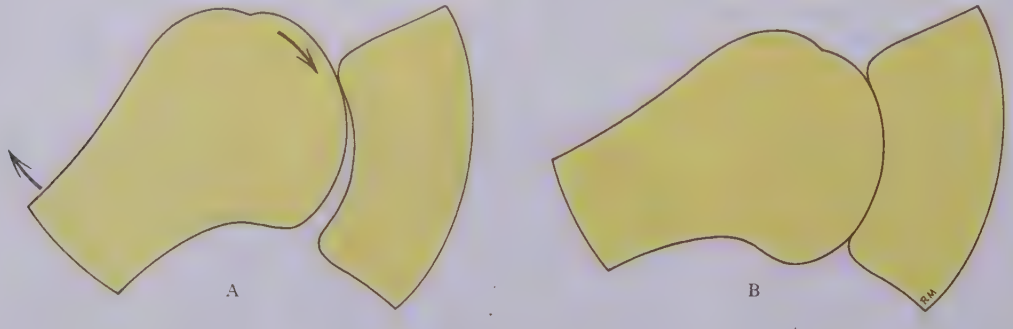
movement these are combined (**4.16**). With a moving convex surface, slide and roll are simultaneous but *opposite*; with a moving concave surface they are in the *same* direction; both combinations increase possible angulation, without a comparable increase in articular surface area. The significance of these movements and variations in congruity is best considered with the basic states of 'loose' and 'close-pack' (vide infra).

Joint Positions



Ovoid or sellar surfaces are fully congruent in only one position, at one extreme of *most habitual articular movement* (e.g. full extension at knee, wrist and interphalangeal joints, dorsiflexion at ankle, abduction with lateral rotation at shoulder). As full congruence is approached, other changes occur: attachments of fibrous capsule and ligaments increasingly separate and tense. The conjunct rotation of all natural movements adds to this by imposing spiral twist in them. In final **close-packing**, therefore, surfaces are fully congruent, in maximal contact and tightly compressed or 'screwed-home', fibrous capsule and ligaments being maximally spiralized and tensed; no further movement is possible. Close-packed surfaces cannot normally be separated by external force (as they may in other positions); bones can be regarded as temporarily locked, as if no joint existed. This extreme is only assumed when special effort is required; the rigidity and stresses generated expose articular structures maximally to trauma. Close-packing is a final, limiting position; any force which tends to further change is resisted by reflex contraction of appropriate muscles. Movement *just short* of close-packing is physiologically most important. Ligaments and articular cartilage are to a small degree elastically deformable and in the final stages the articular position is an equilibrium between the external torque applied (often gravity) and resistance to deformation of tissues by the tense, twisted capsule and compressed cartilages. In symmetrical standing, knee and hip joints approach close-packed positions sufficiently to maintain an erect posture with minimal muscular energy (Joseph 1960, 1975).

In all other positions articular surfaces are not congruent and parts of the capsule are lax; the joint is **loose-packed**. Capsules are lax enough near mid-range of many movements to allow separation of surfaces by external forces. Congruence in which a convex surface has a smaller radius than a concave is advantageous: firstly it allows combined spin, roll and slide, a feature of such joints; secondly contact area is greatly reduced and variable, which may diminish friction and erosion; thirdly small cuneiform intervals between surfaces around contact areas contain synovial fluid, their shape perhaps a factor in maintaining efficient lubrication and nutrition of avascular articular cartilages; finally, combination of sliding and rolling increases effective range of movement. With slide or roll alone, this could be achieved only by more extensive surfaces (**4.16** and p. 433).



According to MacConaill & Basmajian (1977) positions of close- and loose (least)-pack of joints are as follows:

Joint	Close-packed position	Least-packed position
Shoulder	Abduction + lateral rotation	Semiabduction
Ulnohumeral	Extension	Semiflexion
Radiohumeral	Semiflexion + semipronation	Extension + supination
Wrist	Dorsiflexion	Semiflexion
Metacarpophalangeal (2–5)	Full flexion	Semiflexion + ulnar deviation
Interphalangeal (fingers)	Extension	Semiflexion
First carpo-metacarpal	Full opposition	Neutral position of thumb
Hip	Extension + medial rotation	Semiflexion
Knee	Full extension	Semiflexion
Ankle	Dorsiflexion	Neutral position
Tarsal joints	Full supination	Semipronation
Metatarsophalangeal	Dorsiflexion	Neutral position
Interphalangeal (toes)	Dorsiflexion	Semiflexion
Intervertebral	Dorsiflexion	Neutral position

Opinions may vary in connection with a few of the statements in the above table. For example a 'closed-packed' position may possibly occur in occasional joints at *both* extremes of the range of movement. It is also most difficult to assess the situation in small tarsal, carpal and the first carpometacarpal joints. Intervertebral movements are, of course, the result of integrated simultaneous changes at *all* elements constituting the intervertebral articular complex; i.e. massive symphyses (including the discs), equally massive syndesmoses and the relatively small synovial zygapophysial joints. It is doubtful whether 'intervertebral' should appear in the table.

4.16 Analysis of the articular movements which are combined during extension at the knee joint. (Right knee viewed from medial aspect; patella, menisci and other structural features omitted.) A. With a stationary tibia, i.e. moving male femoral condylar surfaces. B. With a stationary femur, i.e. moving female tibial condylar surfaces. Notice that in each case elements of slide, roll and spin occur together. In A the roll and slide are in opposite directions, whereas in B they are in the same direction. See text for further description.

4.17 Congruence of articular surfaces. A. In loose-packed positions of a joint, e.g. the shoulder, the surfaces are not congruent (this has been over-emphasized for clarity). B. The close-packed position of the joint, with close-fitting or full congruence of the surfaces.

However, most of the positions cited here do, it is true, correspond with postures adopted when maximal stress is encountered.

General concepts as set out above have much clarified joint mechanics but aspects of joint lubrication, maintenance of articular cartilage and detailed mechanics of many joints await resolution (Freeman 1973).

Accessory movements. Movements actively performed at any joint do not always include all that its structure permits. Certain movements, voluntarily impossible or limited in range, can only be produced maximally when resistance to active movements occurs (accessory movements, first type), e.g. only when a solid object is grasped in the hand can fingers be *maximally* rotated at metacarpophalangeal joints (see p. 515). (However, a moderate degree of rotation of the *non-grasping* fingers towards the centre of the palm during flexion and its converse during extension is commonplace.) Some movements can be produced only passively (accessory movements, second type), their widest range obtained when the muscles of a joint are relaxed, e.g. when the supported arm is passively abducted at the shoulder, the

humerus can be distracted from the glenoid cavity, a feature of many joints when loose-packed. Such movements are commonly termed 'passive' but all movements, active or not, can be made passively when the muscles concerned are relaxed; the term 'accessory' will be used for all movements impossible in the absence of resistance (Salter 1955).

Limitation of movements is due to several factors, of which tension in ligaments is prominent, as is obvious in attempted hyperextension of the unfixed cadaveric knee or hip. Increasing ligamentous tension, balanced by increased compression between opposed articular surfaces, are integral factors in producing close-packing, limiting most habitual movements. But tension of antagonistic muscles is equally important, involving both *passive elastic components* of muscles (and other structures around the joint) and *reflex contraction* when stimulation of mechanoreceptors in articular and periarticular tissues reaches a critical level. Muscles as limiting factors are exemplified in flexion at the hip; with knee extended it is much more limited in range; with knee flexed hamstring muscles are relaxed allowing flexion of thigh to the abdominal wall, such *approximation of the soft parts* being a third factor in some movements, e.g. flexion at elbow and knee. Contact (occlusion) of teeth obviously limits mandibular elevation.

In synovial joints, where bones are connected only by ligaments and muscles, parts of articular surfaces are in constant apposition in all positions. (Some maintain that 'apposition' implies a fine film of synovial fluid, of 10 μm or *less*, between adjacent surfaces.) Apposition is assisted by atmospheric pressure and cohesion between surfaces; but these are subsidiary to balanced contraction of muscle groups around the joint. When these contract, the force generated is vectorially resolvable into components (p. 567). Some maintain or alter positions of bones ('swing' and 'spin' components) and oppose internal and external resistances, including gravity. Another component is *transarticular* ('shunt' component), which increases compression between articular surfaces and helps apposition in various postures and movements (p. 567). Effects of external compressive or tensile forces, including gravity, vary with posture of the body and its members in space and the direction of applied force. Thus gravity or load-bearing may sometimes provide a *distractive force*, tending to separate conarticular surfaces, or may exert a largely *translatory/swing* force between them. They often exert a considerable *compressive force* at surfaces.

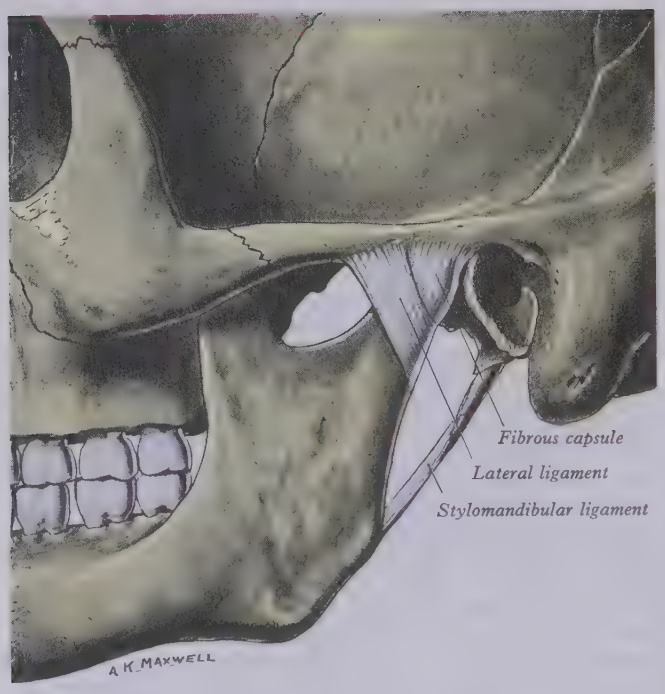
The preceding remarks are merely an introduction to the main concepts of current kinesiology. Brief references to myokinetics are on p. 567. For further analyses the references quoted should be consulted. Readers with greater facility in mathematics and physics will be interested in attempts to present a 'generalized mechanics of articular swing', ranging from Aristotelian and Newtonian physics to the relativity theory and quantum mechanics (MacConaill 1978 a,b,c)!

Blood supply and lymphatics. Joints receive blood from peri-articular arterial *plexuses* whose numerous rami pierce capsules to form subsynovial vascular plexuses. Some synovial vessels end near articular margins in an anastomotic fringe, the *circulus articularis vasculosus* (p. 299). A lymphatic plexus in the synovial subintima drains along blood vessels to the regional deep lymph nodes.

Nerve supply. Movable joints are innervated in general by nerves supplying their muscles, probably establishing local reflex loops involved in movement and posture. Although the branches concerned vary, each innervates a specific capsular region but their territories freely overlap. The region tautened by muscular contraction is usually innervated by nerves supplying antagonists (Gardner 1948). For example, the hip joint's capsule, on stretch inferiorly in abduction, is here supplied by the obturator nerve, tension in it thus producing reflex contraction of adductors, usually enough to prevent damage. However this is not so at the shoulder, where the axillary nerve innervates the antero-inferior capsular region.

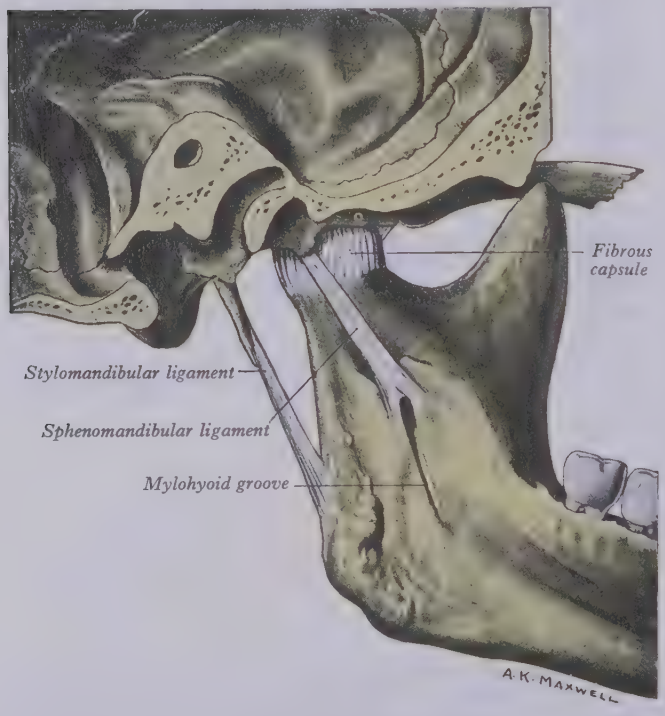
Myelinated fibres in articular nerves have Ruffini endings, lamellated articular corpuscles and some like the neurotendinous organs of Golgi. Simple endings are numerous at attachments of capsule and ligaments; they are terminals of non-myelinated and finely myelinated fibres believed to mediate pain (Gardner 1950). Ruffini end organs are variably orientated in the knee joint's capsule, principally in its flexor region; they respond to stretch and adapt slowly. Lamellated corpuscles, less numerous than Ruffini endings, are sited laterally and adapt rapidly; they respond to rapid movement and vibration; both register speed and direction of movement. Golgi end organs, with the largest myelinated nerve fibres (10–15 μm diameter), are like those at neuromuscular junctions and slow to adapt (Boyd & Roberts 1953, Boyd 1954, Skoglund 1956); they mediate position sense (Stopford 1921, Mountcastle & Powell 1959, Gardner 1967) and are concerned in stereognosis, i.e. recognition of shape in objects held (Renfrew & Melville 1960). Many non-myelinated fibres are sympathetic, ending near vascular non-striated muscle and believed to be vasomotor or vasosensory, although evidence is sparse.In synovial membrane no special end organs or even simple endings occur, except near blood vessels. The membrane is relatively insensitive to pain (Kellgren & Samuel 1950, Barnett et al 1961). For a review concerned with receptors and sensation see Wyke (1981); for histological and functional details and classification of articular nerve endings see p. 914.

THE INDIVIDUAL ARTICULATIONS



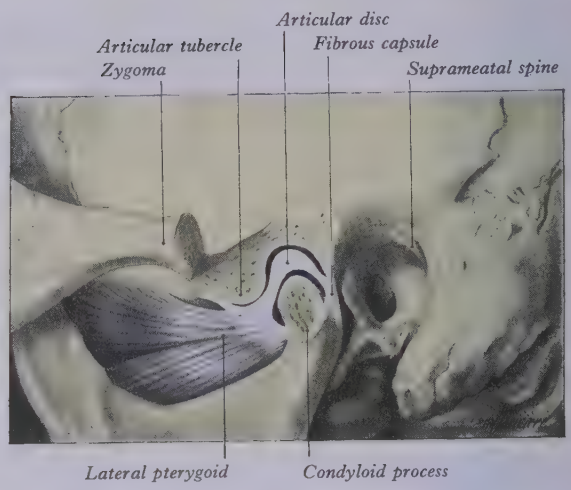
Temporomandibular Joints

Each joint involves the temporal articular tubercle and anterior part of the mandibular fossa above and mandibular condyle below. Articular surfaces are covered by white fibrocartilage in which collagen fibres predominate and cartilage cells are few. An articular disc divides the joint, usually completely, into upper and lower parts. (Sometimes, however, the disc is perforated.) Commonly described as 'condylar', they are preferably termed *ellipsoid*, right and left joints forming a *bicondylar* articulation.



The fibrous capsule is attached *above* anteriorly to the articular tubercle, posteriorly to the lips of the squamotympanic fissure and between these to the edges of the mandibular fossa; *below* to the mandibular neck. *Above* the articular disc the capsule is loose and it is taut *below* it. **Synovial membrane** lines the capsule, above and below the disc (but does not cover the disc); thus, on each side it lines the nonarticular surfaces of superior and inferior synovial compartments. Below the disc the capsular synovial membrane is reflected upwards along the mandible's neck and lateral pterygoid tendon to reach the condylar articular cartilage.

The lateral temporomandibular ligament (4.18), close to the capsule, is attached above to the tubercle on the zygoma's root, below to the lateral surface and posterior border of the mandibular neck, its fibres sloping *down* and *back* deep to the parotid gland.



The sphenomandibular ligament (4.19), medial to and separate from the capsule, is a flat, thin band descending from the sphenoidal spine and widening to reach the lingula of the mandibular foramen. Superolateral to it are the lateral pterygoid muscle and auriculotemporal nerve; inferior to this it is separated from the mandibular neck by maxillary vessels, below which the inferior alveolar vessels and nerve and a parotid lobule separate it from the mandibular ramus; here the vessels and nerve to the

4.18 The left temporomandibular joint: lateral aspect.

4.19 The left temporomandibular joint: medial aspect.

4.20 Sagittal section through the left temporomandibular joint.

mylohyoid pierce the ligament with the medial pterygoid muscle inferomedial. It is separated from the pharynx by fat and pharyngeal veins and, near its upper end, it is crossed by the chorda tympani. Some fibres traverse the medial end of the petrotympanic fissure to the anterior malleolar process as a vestige (the anterior ligament of the malleus) of the dorsal end of Meckel's cartilage (p. 1227). The role of this vestigial ligament in *mandibular* mechanics is negligible.

The articular disc (4.20,21A,B,C), an oval plate of fibrous tissue shaped like a peaked cap, completely divides the joint. Its upper surface is sagittally concavoconvex to fit the articular tubercle and fossa, its inferior concave surface adapted to the mandibular head. Its circumference blends with the fibrous capsule and, in front, the tendon of lateral pterygoid (p. 581). Medial and lateral, short, strong bands pass from its margins to the medial and lateral condylar poles, ensuring that disc and condyle move together in protraction and retraction. Posteriorly in the disc a venous plexus separates upper and lower layers, the *upper* of fibro-elastic tissue attached to the fossa's posterior margin, the *lower* of non-elastic fibrous tissue attached to the back of the condyle. Though variable, the disc is thickest behind its centre, in the deepest part of the mandibular fossa. Rees (1954) has described two thick regions (anterior and posterior bands) with thinner zones between, subdivisions being from before backwards: anterior extension, anterior band, intermediate zone, posterior band and the bilaminar region mentioned above (4.21A,B,C). The description of the articular disc given by Rees and followed above (also in 4.21,22) is widely quoted; however it was derived from fixed cadaveric material and perhaps undue emphasis is placed on anteroposterior zonal organization alone. Mediolateral variations are equally relevant. An interesting analysis with some alternative proposals concerning the design, formation, possible functional roles and derangements of the disc have been provided by Osborn (1985). He emphasizes the largely fibrous nature of the highly non-congruent articular surfaces and views the interposed disc as a visco-elastically deformable pad co-extensive with the cranial articular surface (i.e. much more extensive than the mandibular condyle). Compression forces (increased during chewing, biting, grinding) *thin* an area of disc between condyle and the posterior slope of the articular eminence, thereby 'squeezing out' material to form a thickened zone, the *annulus* of Osborn, which surrounds the thin area—a recess for the mandibular condyle. (It may be noted that the anterior and posterior thickened bands shown in 4.21, after Rees, are in fact continuous medial and lateral to the mandibular condyle.) The question of whether the shape of the disc is genetically determined, produced mainly by biomechanical constraints or both is also discussed. The supposedly non-elastic nature of the inferoposterior (mandibular) lamina of the disc is also questioned (see also below). Postnatal development of the disc up to 21 years, described by Wright & Moffet (1974), showed at no stage any chondrocytes in the disc, which is flat at birth and develops its sigmoid profile as the articular eminence enlarges. From the fifth decade it so often shows macroscopic evidence of degeneration (fraying, thinning and perforation) that this can be regarded as 'normal' ageing. Weisengreen (1975) found such degeneration in 40% of 183 individuals between 40 and 90 years. The disc, often incomplete, is variably perforated.

The stylomandibular ligament (4.18), a specialized band of deep cervical fascia (p. 582), stretches from the apex and adjacent anterior aspect of the styloid process to the mandible's angle and posterior border. It can be considered only accessory to the joint and of uncertain function.

Innervation is from the auriculotemporal and masseteric

branches of the mandibular nerve, **arteries** from superficial temporal and maxillary arteries. Klineberg & Wyke (1973) have detailed the distribution of mechanoreceptors in the joint and suggested their role in mastication.

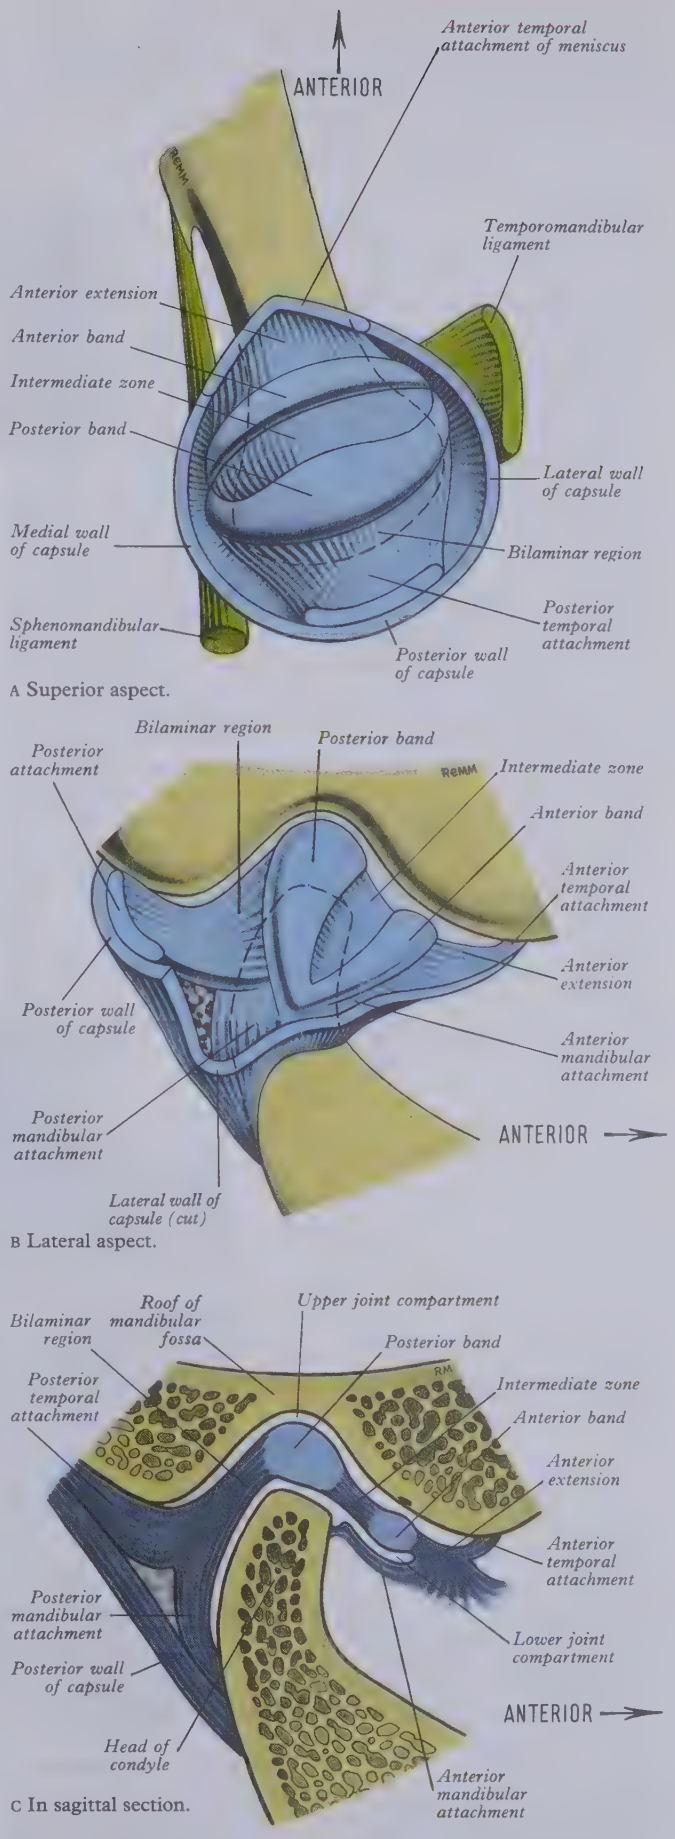
Movements. The mandible can be depressed or elevated, protruded or retracted and, since both joints always act together but may differ in actual movement, some rotation (around a vertical axis, vide infra) may occur. These actions involve gliding, spin, roll and angulation. (The last is another variety of rotation around a dynamic transverse axis, vide infra.)

In the *position of rest* upper and lower teeth are slightly apart; in closure they are apposed, the *occlusal position*. When the mouth opens the mandibular 'condyles' rotate on a common horizontal axis and also glide forwards and downwards on the inferior surfaces of their articular discs, which slide in the same direction on the temporal bones due to their attachments to the mandibular heads and to contraction of the lateral pterygoids drawing heads and discs on to the articular tubercles. Discal sliding ceases when their posterior fibro-elastic attachments to the temporal bones are stretched to their limit. Further hinging and gliding of the condyles brings them into articulation with the most anterior parts of the discs as the mouth opens fully. In *closure* movements are reversed: each head glides back and hinges on its disc, still held by the lateral pterygoid, which relaxes to allow the disc to glide back and up into the mandibular fossa. The full cycle is shown in 4.22, derived from observations by Rees (1954). Osborn (1985) presents alternative interpretations; he regards the fibrous articular surfaces as particularly susceptible to trauma during the arthrokinematic roll, spin and glide executed when the joint is maximally loaded. The deformable visco-elastic articular disc's primary function is to permit these activities while reducing the risk of trauma. The *disc* is thought to be stabilized by its inherent visco-elasticity; increasing loads thicken its annulus (vide supra) and prolapse is prevented. Activity of the lateral pterygoid and presence of elastic tissue in the posterior bilaminar zone are regarded as secondary features in disc stabilization. An unusual proposition is that while the disc is *self-stabilizing* its other principal role is to *destabilize* the mandibular condyle and allow complex free movement under load. The elastic tissues may act to withdraw tissues and thus prevent entrapment between the articular surfaces during mouth closure. In *protrusion* the teeth are parallel to the occlusal plane but variably separated, the lower carried forwards by both lateral pterygoid muscles. In *retraction* the mandible is returned to the position of rest. In rotatory movements of mastication (in the occlusal *plane*, but clearly not in *occlusion*), one head with its disc glides forwards, rotating around a vertical axis immediately behind the opposite head, then glides backwards rotating in the opposite direction, as the opposite head comes forward in turn. This alternation swings the mandible from side to side (Sarnat 1951).

Measurement of mandibular movements is of clinical interest; in adults incisors may separate by 50–60 mm, maximal lateral displacement and protrusion being about 10 mm, with much individual variation. Adult range is reached earlier in females (*c.* 10 years) than in males (*c.* 15 years) in accord with postnatal development of the articular profiles (Wright & Moffet 1974), adult form being reached between six and 12 years.

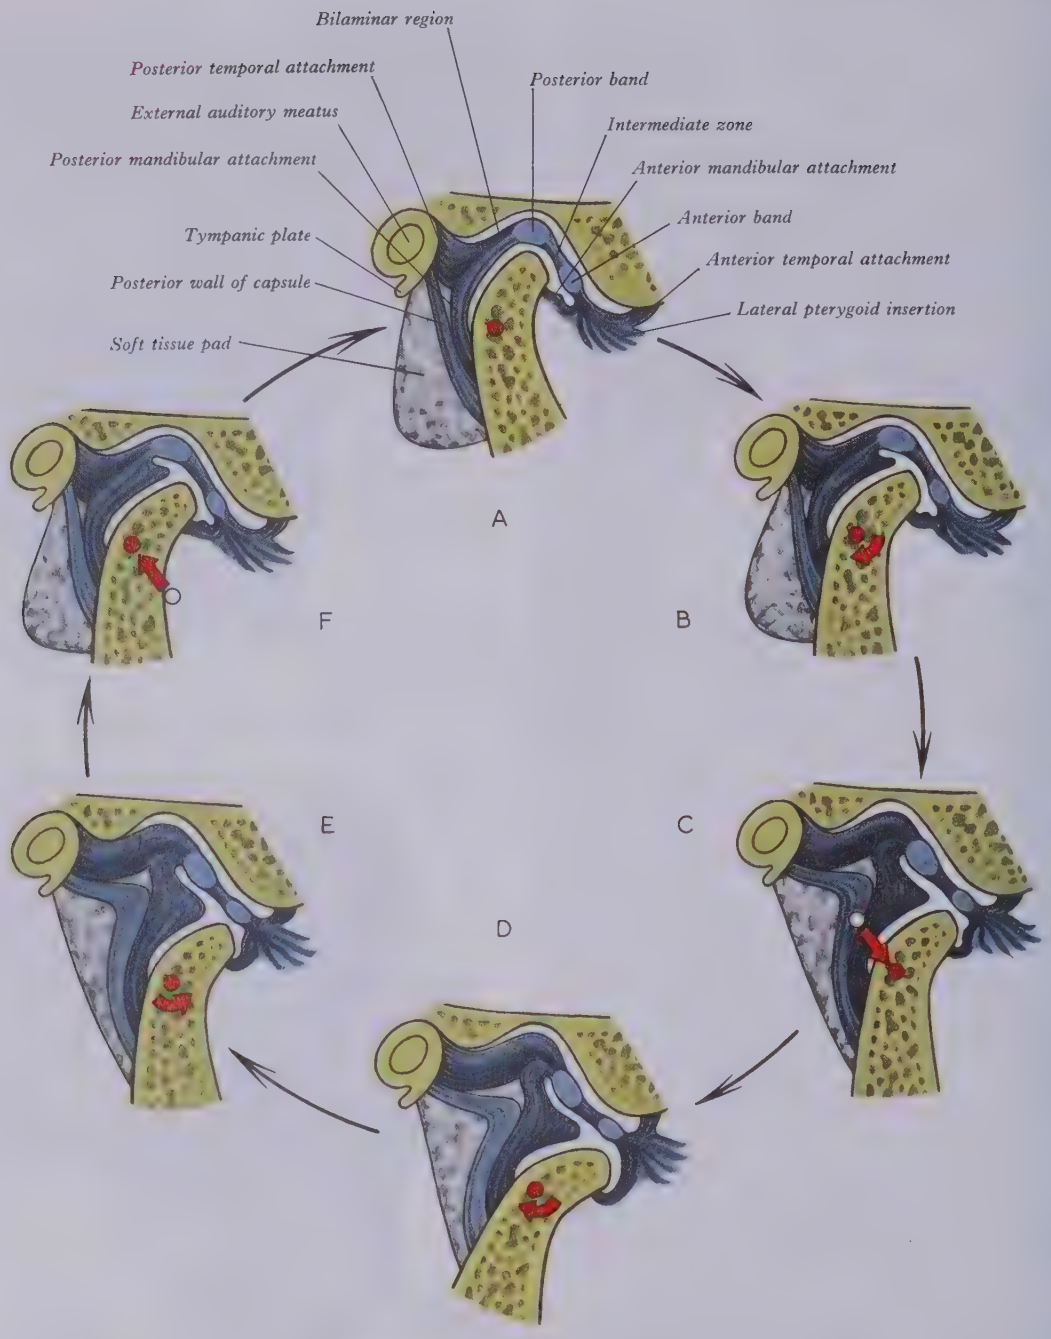
Muscles Producing Movements

Depression: lateral pterygoids, aided when the mouth is widely open or against resistance, by digastric, geniohyoid and mylohyoid muscles.



Elevation: temporalis, masseter, medial pterygoid, of both sides. In closure each mandibular head is retracted by the posterior fibres of the temporalis before elevation. The temporales maintain the position of rest (Latif 1957).

Protrusion: lateral and medial pterygoid muscles.



Retraction: temporales (posterior fibres), assisted by middle and deep parts of the masseters, digastric and geniohyoid muscles.

Lateral movements: medial and lateral pterygoid of each side, acting alternately.

Such a list, though useful, obscures the complex integrations of simultaneous contraction and lengthening of many muscles.

4.21 Form, subdivisions and thickness variations of the intra-articular disc in the temporomandibular joint. See text for details and for alternative interpretations.

4.22 Changing relationships of the condyle of the mandible, the articular disc and the articular surface of the temporal bone during one complete opening (A→D) and closing (D→A) cycle of the mouth.

4.21 and 4.22 are based upon Rees (1954) with permission of the late Professor J J Pritchard, on behalf of the late Leonard A Rees and the *British Dental Journal*. See also alternative hypotheses proposed by Osborn (1985).

Alternative descriptions of mandibular movements have been proposed (Kraus et al 1969). Successive positions of an indicator point on the mandible form a three-dimensional *envelope of movement; border movements* are those at its surface, *free movements* when the point moves within it and *contact movements* when maxillary and mandibular teeth remain apposed. For a more detailed analysis of biting, chewing and deglutition see Kraus et al (1969); and for a mathematical model relating patterns of human mandibular movement to biomechanical constraints see Baragar & Osborn (1984).

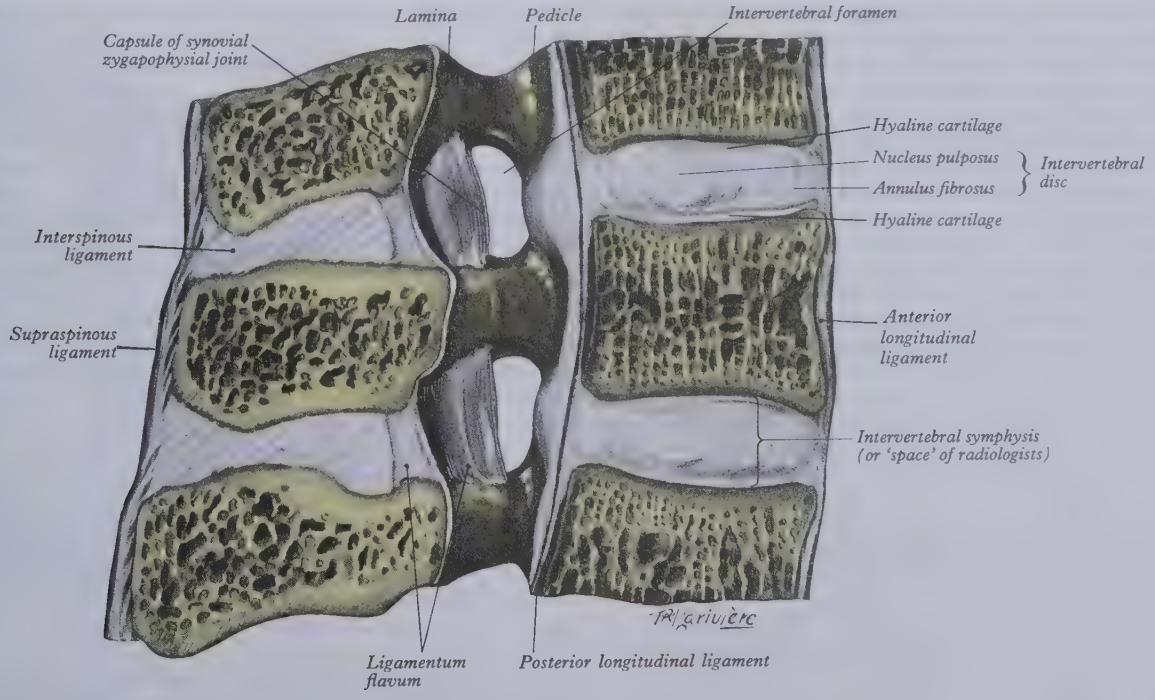
An unresolved controversy concerning forces transmitted at temporomandibular joints must be noted. A proposal that they carry no load, or are subject to little transarticular compression, has been supported by Wilson (1920), Scott (1955), Steinhardt (1958) and others; while later views (e.g. Smith & Savage 1959, Turnbull 1970) oppose this. Most observations involve vertebrates other than mammals; few reliable experimental data are available for man according to Gingerich (1971). Analysis both theoretical and involving electromyography (integrated and quantitative) in man, however, favours a force-transmitting function (Barbenel 1972, 1974), supported by observations by Crompton & Hiiemae (opossum, 1969) and by Buckland-Wright (cat, 1978). In view of the complex activities at these joints, both views may be correct at times. It is only in 'hinge' movements of limited extent, as in biting, that controversy need exist.

Applied Anatomy. The mandible is dislocated only forwards. With the mouth open, the condyles are on the articular eminences and sudden violence, even muscular spasm (a convulsive yawn), may displace one or both into the infratemporal fossa. Reduction involves depressing the jaw posteriorly, at the same time elevating the chin. Downward pressure overcomes spasm in masseteric,

temporal and pterygoid muscles; elevation of the chin forces the condyles backwards. Derangement of a disc may follow trauma, by overclosure with backward displacement of a condyle or malocclusion; clicking and pain on movement result. In operations, rami of the facial nerve overlying the joint must be preserved. Changes in occlusion may lead to remodelling of temporomandibular articular surfaces (Moffet et al 1964).

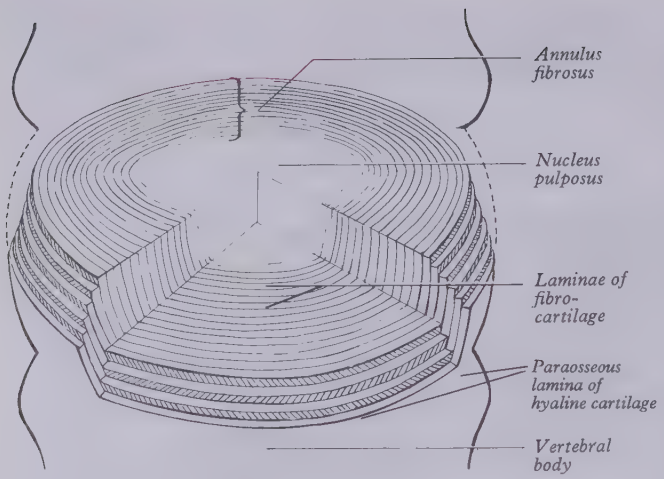
JOINTS OF THE VERTEBRAL COLUMN AND THORAX

All vertebrae, from second cervical to first sacral, articulate by cartilaginous joints between their bodies, synovial joints between their articular processes (zygapophyses) and fibrous joints between their laminae and also between their transverse and spinous processes.



Joints of Vertebral Bodies

Vertebral bodies are united by anterior and posterior longitudinal ligaments and by fibrocartilaginous intervertebral discs between laminae of hyaline cartilage, together forming symphyses.



The anterior longitudinal ligament (4.23A), a strong band, extends along the anterior surfaces of the vertebral bodies. It is broader caudally, thicker and narrower in thoracic than in cervical and lumbar regions; also relatively thicker and narrower opposite vertebral bodies than at the levels of intervertebral symphyses. Attached to the basilar occipital bone, it extends to the atlantal anterior tubercle, thence to the front of the body of the axis and thereafter continues caudally to the front of the upper sacrum. Its longitudinal fibres, strongly adherent to intervertebral discs, hyaline cartilage laminae and margins of adjacent vertebral bodies, are but loosely attached at intermediate levels of the bodies, where the ligament fills their anterior concavities, flattening the vertebral profile (4.23A). At these various levels ligamentous fibres blend with the subjacent periosteum, perichondrium and periphery of annulus fibrosus. It has several layers, most superficial fibres being longest and extending over three or four vertebrae, intermediate between two or three, the deepest from one body to the next. Laterally short fibres connect adjacent vertebrae.

The posterior longitudinal ligament (4.23A,24A) is in the vertebral canal on the posterior surfaces of the vertebral bodies, attached to the body of the axis and continued to the sacrum; above it is continuous with the membrana tectoria (p. 494). Its smooth, glistening fibres, attached to intervertebral discs, laminae of hyaline cartilage and adjacent margins of vertebral bodies, are separated between attachments by basivertebral veins and the venous rami draining them into anterior internal vertebral plexuses. At cervical and upper thoracic levels the ligament is broad and uniform in width, but in lower thoracic and lumbar regions (4.24A) it is denticulated, narrow over vertebral bodies and broad over discs (strictly symphyses). Its superficial fibres bridge three or four vertebrae, the deeper extending between adjacent vertebrae as *perivertebral ligaments* close to and, in adults, fused with annuli fibrosi of the intervertebral discs. These layers are more distinct in the immediate postnatal years.

Intervertebral discs (4.23A,B), between adjacent surfaces of vertebral bodies from axis to sacrum, are their chief bonds. Discal outlines correspond with the bodies which they connect, thickness varying in different regions and parts of the same disc. They are thicker anteriorly in cervical and lumbar regions, contributing here to anterior convexity, but nearly uniform in the thoracic region, anterior concavity here being largely due to vertebral bodies. Discs are thinnest in upper thoracic, thickest in lumbar regions and adherent to thin layers of hyaline cartilage on superior and inferior vertebral surfaces (p. 315); together disc and hyaline cartilages form an *intervertebral symphysis*. Except for their peripheries, supplied from adjacent blood vessels, discs are avascular and supported by diffusion through the trabecular bone of adjacent vertebrae. Vascular and avascular parts differ in

4.23A Median sagittal section through part of the lumbar region of the vertebral column. Note the boundaries of intervertebral foramina. For contrasting details concerning the direction of fibre bundles in the interspinous ligaments see text and Heylings (1978).

4.23B Simplified schema of the main structural features of an intervertebral disc. The fibrocellular structure of the nucleus pulposus is omitted. For clarity the number of fibrocartilaginous laminae has been greatly reduced, since they are in fact of microscopic dimensions. Note alternating obliquity of collagen fascicles in adjacent laminae. (Modified after Inoue 1973.)

reaction to injury (Smith & Walmsley 1951). Discs are connected to anterior and posterior longitudinal ligaments; at the thoracic level they are tied laterally by intra-articular ligaments to the heads of ribs articulating with adjacent vertebrae. Intervertebral discs (excluding the first two vertebrae) form a fifth of the postaxial vertebral column, cervical and lumbar regions having, in proportion to length, more discs than the thoracic and hence being more pliant (Harris 1939). Each disc consists of an outer laminated *annulus fibrosus* and an inner *nucleus pulposus* (4.23A,B).

The *annulus fibrosus* has a narrow outer collagenous zone and a wider inner fibrocartilaginous zone. Its laminae, convex peripherally seen in vertical section, are incomplete collars connected by fibrous bands overlapping one another. (The internal vertical concavity of the laminae conforms to the surface profile of the nucleus pulposus.) Posteriorly, laminae join in a complex manner; fibres in the rest of each lamina are parallel and run obliquely between vertebrae; fibres in contiguous laminae criss-cross, (4.23B) thus limiting rotation in both directions. Predominantly *vertical* posterior fibres have been described (Zaki 1973), predisposing to herniation. Obliquity of fibres in deeper zones varies in different laminae (Inoue 1973). Johnson et al (1985) have described elastic fibres in a small number of human lumbar annuli fibrosi. Hickey et al (1981) have described fetal collagen fibril diameters in these structures; they also include elastic fibres.

The *nucleus pulposus*, better developed in cervical and lumbar regions, is nearer the disc's posterior surface. At birth it is large, soft, gelatinous and of mucoid material with a few multinucleated notochordal cells, invaded also by cells and fibres from the inner zone of adjacent annulus fibrosus. Notochordal cells disappear in the first decade, followed by gradual replacement of mucoid material by fibrocartilage (Sylven 1951), derived mainly from the annulus fibrosus and the hyaline cartilaginous plates adjoining vertebral bodies. The nucleus pulposus, hitherto distinct, now becomes less differentiated from the remainder of the disc (Walmsley 1953, Peacock 1952, Tondury 1958). In lumbar discs cellularity (6000 cells/mm^3 overall) is highest in peripheral annulus fibrosus and in hyaline cartilage nearest to the vertebral bodies, with a glucose diffusion coefficient of 2.5 cm^2 per second, comparable with values for cartilage elsewhere (Maroudas et al 1975). However, nutritional conditions may be more critical, especially in large lumbar discs. With these changes the nucleus pulposus becomes amorphous and sometimes discoloured. Its water-binding capacity and elasticity diminish (Puschel 1930), because these properties are due to its mucopolysaccharide and protein component (Hendry 1958). When the disc is not loaded, pressure in the nucleus pulposus is low at all ages (Nachemson 1960). Pech & Haughton (1985) have recently used cadaveric intervertebral discs to show the high correlation between appearances in X-rays and by magnetic resonance (MR).

Applied Anatomy. In young adults intervertebral discs are so strong that violence first damages bones. It is impossible to damage a healthy disc except by forcible flexion. After the second decade, however, degenerative changes in discs may result in necrosis, sequestration of the nucleus pulposus, softening and weakening of the annulus fibrosus. Then comparatively minor strains may cause *either* internal derangement with eccentric displacement of the nucleus pulposus *or* external derangement; it then bulges or bursts through the annulus fibrosus, usually posterolaterally. In the former unequal tension in the joint causes muscle spasm and sudden violent pain, acute *lumbago*; in the latter a herniated nucleus may press on adjacent nerve roots with resultant referred pain, *sciatica*. Such derangements are usually in the lower lumbar region, especially at the lumbosacral joint, and sometimes at the levels of C.5–7. Motor effects, with loss of power and reflexes may ensue.

Joints of Vertebral Arches

Joints between vertebral articular processes (zygapophyses) are synovial and vary in shape with vertebral level (p. 316); the laminae, spines and transverse processes are connected through syndesmoses constituted by ligamenta flava, interspinous, supraspinous and intertransverse ligaments and the ligamentum nuchae. Some authorities prefer to group these various fibrous structures as accessory ligaments of the zygapophysial joints; others, as here, classify them as officially recognized, named syndesmoses.

ZYGAPOPHYSIAL JOINTS

These joints are of the simple (cervical and thoracic) or complex (lumbar) synovial variety. Their mating surfaces are carried on mutually adapted zygapophyses and are clothed with hyaline articular cartilage. Their size, shape and topology varies with spinal level and are described with individual vertebrae in *Osteology*.

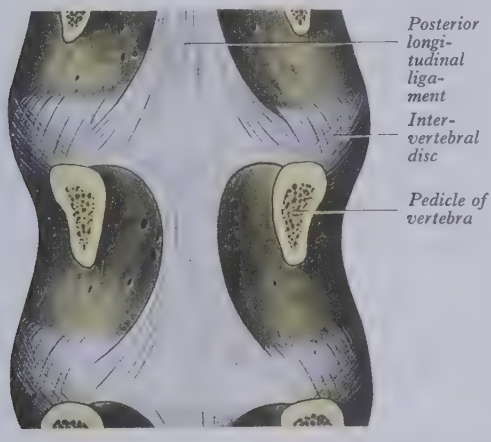
Articular capsules are thin and loose and attached peripheral to the articular facets of adjacent zygapophyses; they are longer and looser in the cervical region. (See Intervertebral Foramen below.)

Zygapophysial lumbar specializations. Engel & Bogduk (1982) studied 82 lumbar zyapophysial joints and identified three types of intracapsular structure. These were: (1) *adipose tissue fat pads* either superoventral, inferodorsal or both; (2) *fibro-adipose 'menisci' (meniscoids)* at the superior or inferior pole, or both; (3) *connective tissue rims* either ventral, dorsal or both. The rims are inflexions of fibrous capsule; the fat pads are similar to those in many other joints; the meniscoids are remarkable in possessing an expanded, vascularized, fibro-adipose base, attached to and sometimes perforating the capsule, an adipose core, poorly vascularized, and a firm flattened fibrous apex. They project into the crevices between non-congruent articular surfaces but their function is conjectural; they are possibly significant clinically. *All* specimens presented at least one of these features and more than 50% presented two or more features.

INTERVERTEBRAL SYNDESMOSES

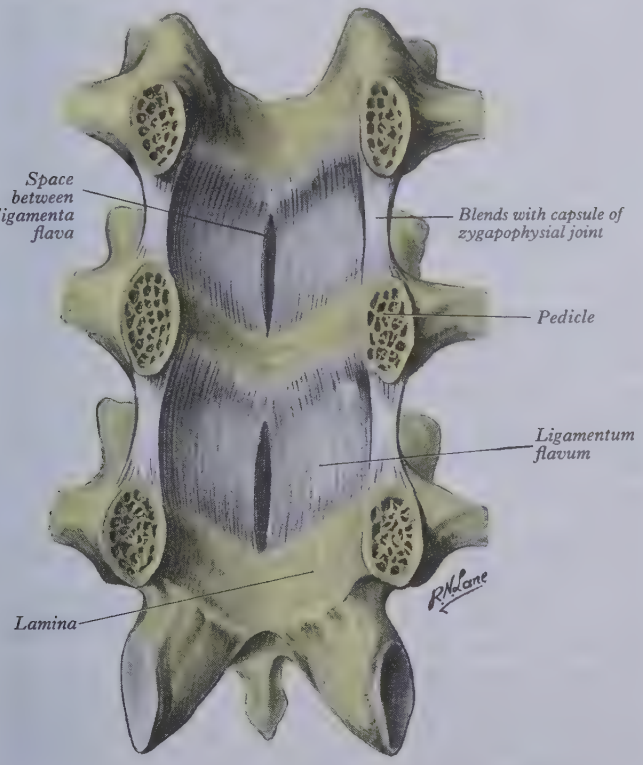
Ligamenta flava (4.23A,24B) connect laminae of adjacent vertebrae in the vertebral canal. Their attachments extend from zygapophysial capsules to where laminae fuse to form spines; here their posterior margins meet and are partially united, intervals being left for veins connecting internal to posterior external vertebral venous plexuses. Their predominant tissue is yellow elastic tissue, whose almost perpendicular fibres descend from the lower anterior surface of one lamina to the posterior surface and upper margin of the one below it. The ligaments are thin, broad and long in the neck, thicker in the thoracic region, thickest at lumbar levels. They brake separation of the laminae in spinal

flexion, obviating abrupt limitation, and assist restoration to an erect attitude after flexion, perhaps protecting discs from injury.



The supraspinous ligament (4.23A), a strong fibrous cord connecting spinous process apices from the seventh cervical to the sacrum, is thicker and broader at lumbar levels and intimately blended with neighbouring fascia. Its most superficial fibres extend over three or four vertebrae, the deeper spanning two or three, the deepest connecting adjacent spines and here continuous with interspinous ligaments. Between the seventh cervical spine and external occipital protuberance it is expanded as the ligamentum nuchae. Heylings (1978) considers supraspinous ligaments to cease at the fifth lumbar spine.

The ligamentum nuchae, a bilaminar fibro-elastic intermuscular septum, is often considered homologous with, but structurally distinct from, supraspinous and interspinous ligaments in the neck. In structure, its dense bilateral fibro-elastic laminae are separated by a tenuous layer of areolar tissue; the laminae are blended at its dorsal free border. The latter is superficial and extends from the external occipital protuberance to the seventh cervical spine. From this the fibro-elastic laminae are attached to the median part of the external occipital crest, the posterior atlantal tubercle and the medial aspects of the bifid spines of cervical vertebrae, as a septum for bilateral attachment of cervical muscles and their sheaths. In bipeds it is the reduced representative of a much thicker, complex elastic ligament which, in quadrupedal mammals, aids suspension of the head and modifies its flexion, functioning like ligamenta flava.



Interspinous ligaments (4.23A), thin and almost membranous, connect adjoining spines, their attachments extending from root to the apex of each. They meet ligamenta flava in front and the supraspinous ligament behind. Narrow and elongated in the thoracic region, broader, thicker and quadrilateral at lumbar levels, they are poorly developed in the neck. (Some observers allocate all cervical bundles as part of the ligamentum nuchae; others regard them, although tenuous, as distinct interspinous fasicles.) Their fibres are usually described as obliquely dorsocaudal. In a study of 28 cadavers Heylings (1978) found them obliquely *dorsocranial* at lumbar levels.

Intertransverse ligaments between transverse processes consist at cervical levels of a few, irregular fibres, largely replaced by intertransverse muscles; in the thoracic region they are cords intimately blended with adjacent muscles; in the lumbar region they are thin and membranous.

Intervertebral joints (symphyses, syndesmoses and synovial) are all innervated by adjoining spinal (and sympathetic) nerves, particularly by their dorsal divisions.

4.24A The lumbar region of the posterior longitudinal vertebral ligament.

4.24B The ligamenta flava of the lumbar region: anterior aspect.

Intervertebral Foramina

Closely related to some of the main intervertebral articulations are the principal routes of entry and exit to and from the vertebral canal, the **intervertebral foramina**. (Minor routes occur between the median, often partly fused, margins of the ligamenta flava, vide supra.) Between the axis and sacrum, despite some quantitative and structural regional variations, essentially they conform to the same general plan; because of their construction, contents and susceptibilities to multiple disorders, they are loci of great biomechanical, functional and clinical significance. The specializations cranial to the axis and at sacral levels are described with the individual bones and articulations. **The boundaries** of a generalized intervertebral foramen are: *anteriorly*, from above downwards, periosteum of the posterolateral aspect of the superior vertebral body (thin compact osseous shell over red bone marrow containing cancellous bone); posterolateral aspect of the intervertebral symphysis (including the disc), the curved collagen fascicles here may be regarded as the outer lamina of the annulus fibrosus or as extensions of perivertebral ligaments (distinctions of little importance), finally a small (variable) periosteum-covered posterolateral part of the body of the inferior vertebra (structure as above); *superiorly*, the compact bone of the deep arched inferior vertebral notch of the vertebra above; *inferiorly*, the compact bone of the shallow superior vertebral notch of the vertebra below; *posteriorly* a part of the ventral aspect of the fibrous capsule of the zygapophysial synovial joint. Cervical intervertebral foramina are distinct in having superior and inferior vertebral notches of almost equal depth; also in accord with the direction of the pedicles they face *anterolaterally* and external to them, in the same direction, is the complex transverse process and foramen transversarium (p. 317). The thoracic and lumbar intervertebral foramina face *laterally* and their transverse processes are posterior. The first to tenth thoracic foramina have additionally as anteroinferior boundaries the articulations of the head of a rib, the capsules of double synovial joints with the demifacets on adjacent vertebrae and the intra-articular ligament between the costocapitular ridge and the intervertebral symphysis. Note that the lumbar foramina lie *between* the two principal lines of vertebral attachment of the psoas major muscle. The walls of each foramen are, as noted, clothed throughout by collagen, either periosteal, perichondrial, annular or capsular. **Contents** are: a segmental mixed spinal nerve and its sheaths, from two to four recurrent meningeal (sinuvertebral) nerves (pp. 1124, 1125), variable spinal arteries (for origins, branches and distribution see p. 765), and plexiform venous connections between internal and external vertebral venous plexuses (p. 811). These structures, particularly the

nerves, may be affected by trauma or one of the numerous disorders of the tissues bordering the foramen: i.e. fibrocartilage of the annulus fibrosus, in earlier decades the nucleus pulposus, the highly vascular red bone marrow occupying the cancellous bone of the vertebral bodies; the compact bone of the pedicles; the capsules, synovial membranes, articular cartilages (and at lumbar levels fibro-adipose meniscoids, fat pads, fibrous labra, p. 490) of the synovial zygapophysial joints; and additionally at thoracic levels tissues of the complex synovial costocapitular joints.

Movements of the Vertebral Column

Range of movement between vertebrae is restricted by the limited deformation of intervertebral symphyses (particularly the discs), whose greater thickness at cervical and lumbar levels increases individual ranges. It is also limited by the topography of the zygapophysial joints and by concomitant changes in tension of the ligamentous syndesmoses. Although movements between individual vertebrae are small, their summation gives a wide total range to the vertebral column in flexion, extension, lateral flexion, rotation and circumduction.

In *flexion* the anterior longitudinal ligaments become relaxed and the anterior parts of intervertebral discs are compressed; at its limit the posterior longitudinal ligament, ligamenta flava, interspinous and supraspinous ligaments and posterior fibres of intervertebral discs are tensed; interlaminar intervals widen, inferior articular processes glide on superior processes of subjacent vertebrae and their capsules become taut. Tension of extensor muscles is also important in limiting flexion, e.g. when carrying a load on the shoulders. Flexion is most extensive at the cervical level.

In *extension* the opposite events occur; it is limited by tension of the anterior longitudinal ligament, anterior discal fibres and approximation of spines, zygapophyses and compression of posterior discal fibres. Marked in cervical and lumbar regions, it is much less at thoracic level, partly because discs are thinner and also due to effects of thoracic skeleton and musculature. In full extension the axis of movement has been described as behind the articular processes, moving forwards as the column straightens and passes into flexion, reaching the centre of the vertebral bodies in full flexion (Wiles 1935).

In *lateral flexion* intervertebral discs are laterally compressed and contralaterally tensed and lengthened, motion being limited by tension of antagonist muscles and ligaments. It is always combined with rotation. Lateral movements occur in any part of the column but are greatest in cervical and lumbar regions.

Rotation involves twisting of vertebrae relative to each other, with torsional deformation of intervening discs. Although slight between individual vertebrae, it summates along the column, its upper part being turned to one or other side. Movement is slight at cervical level, greater in the upper thoracic and least in the lumbar region. *Circumduction* is limited and merely a succession of preceding movements.

Extent and direction of vertebral movements are guided by articular facets. Although often described as *plane*, they are never truly flat but *ovoid*, opposing surfaces being reciprocally concave and convex. In the *cervical* region upward inclination of the superior articular facets allows free flexion and extension; the latter is usually greater and checked above by locking of the posterior edges of the superior atlantal facets in the occipital condylar fossae and below by slipping of the seventh cervical inferior processes into grooves inferoposterior to the first thoracic superior articular processes. Flexion stops where the cervical convexity is straightened, checked by apposition of the projecting lower lips of vertebral bodies with shelving surfaces on subjacent bodies. Cervical lateral flexion and rotation are always combined; superomedial inclination of superior articular facets imparts rotation during lateral flexion. In the *thoracic* region, especially above, all movements are limited, reducing interference with respiration; lack of upward inclination of superior articular facets prohibits much flexion, extension being checked by contact of the inferior articular margins with laminae and of spines with each other. Thoracic rotation is freer; its axis is in the vertebral bodies in the mid-thoracic region, in front of them elsewhere, so that rotation involves some lateral displacement (Davis 1959, Davis et al 1965). Direction of articular facets would allow free lateral flexion but this is limited in the upper thoracic region by resistance of ribs and sternum. Rotation is usually combined with slight lateral flexion to the same side. Lumbar extension is wider in range than flexion and some lateral flexion and rotation can also occur. Range of rotation is limited by absence of a common centre of curvature for right and left articular facets (Putz 1976). Functional transition between thoracic and lumbar regions is usually between the eleventh and twelfth thoracic vertebrae (p. 322), where zygapophysial joints of the vertebral arches usually fit tightly, slight compression locking them and preventing all but flexion.

Muscles producing vertebral movements. The spinal column is moved both by intrinsic muscles attached to it and by muscles attached to other bones, acting indirectly. Gravity also always plays a part.

Flexion: longus cervicis, scaleni, sternocleidomastoid and rectus abdominis of both sides.

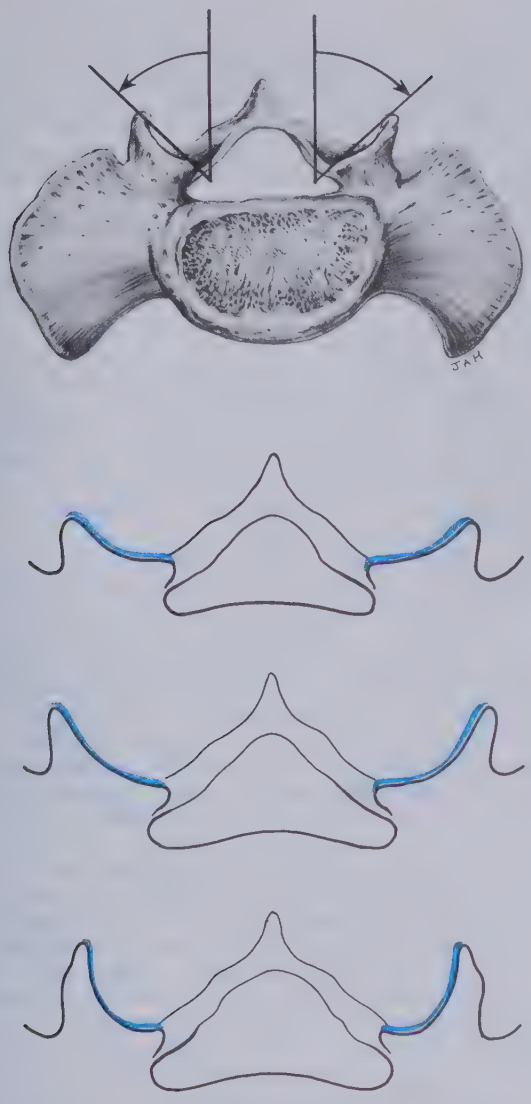
Extension: the erector spinae complex, splenius, semispinalis capitis and trapezius of both sides.

Lateral flexion: longissimus and iliocostocervicalis, oblique abdominal muscles and flexors on the side of *lateral* flexion.

Rotation: rotatores, multifidus, splenius cervicis and oblique abdominal muscles.

Extension, principally lumbar, occurs commonly from a stooping position. Initial extension is mainly at hips and knees; continuous lumbar extension is delayed, with little or no activity in erector spinae. In lifting heavy weights there is considerable compression of lumbar intervertebral discs initially, with large rises in thoracic and abdominal pressure, which may resist flexion (Davis 1963, Davis et al 1965). Pal & Rontal (1986) have recently studied the mechanics of weight transmission via the vertebral arches. In contrast with the usual view, that the major, almost only, factor is contributed by vertebral bodies and intervertebral discs, they find that, on the basis of areal and other measurements, the vertebral arches and their zygapophysial joints are, at cervical levels, also a considerable factor in weight transmission. For an extensive view of lumbar backache see Wyke (1980).

Lumbosacral Joints



Articulations between the fifth lumbar and first sacral vertebrae resemble those of others. Their bodies are united by a symphysis including a large intervertebral disc, deeper ventrally (its anterior margin at the sacrovertebral angle, p. 329) with anterior and posterior longitudinal ligaments adherent to it. Their zygapophysial joints are separated by a wider interval than those above. They have ligamenta flava, interspinous and supraspinous ligaments. The fifth lumbar vertebra is attached to ilium and sacrum by the iliolumbar ligament. These joints vary much in geometry (p. 325, 4.25).

The iliolumbar ligament (4.56), attached to the tip and antero-inferior aspect of the fifth lumbar transverse process, sometimes has a weak attachment to the fourth. It radiates laterally and is attached by two main bands to the pelvis: a lower one, the *lumbosacral ligament*, from the inferior aspect of the fifth lumbar transverse process to the anterosuperior lateral surface of the sacrum, blending with the ventral sacro-iliac ligament; and an upper, partial attachment of quadratus lumborum, passing to the iliac crest anterior to the sacro-iliac joint, continuous above with the thoracolumbar fascia. Innervation is from dorsal divisions of spinal nerves.

THE SACROCOCCYGEAL JOINT

This is a symphysis between the sacral apex and coccygeal base, united by a fibrocartilaginous disc, remnants of hyaline cartilage and ventral, dorsal and lateral ligaments.

The fibrocartilage, a thin disc between contiguous surfaces of the sacrum and coccyx, is somewhat thicker in front and behind than laterally. Its surfaces carry hyaline cartilage varying from thin veils to small islands. Occasionally the coccyx is more mobile, the joint being synovial.

4.25 The method employed by Čihák (1970) to measure the inclinations of articular surfaces of the lumbosacral zygapophysial joints (above). The lower profiles depict three degrees of increasing curvature and inclination. For quantitative data derived from 132 human sacra consult the original paper.

The ventral sacrococcygeal ligament (4.56) consists of irregular fibres descending on the pelvic surfaces of both sacrum and coccyx, attached like the anterior longitudinal ligament.

The superficial dorsal sacrococcygeal ligament is flat and passes from the margin of the sacral hiatus to the dorsal coccygeal surface (4.57). It roofs the lower sacral canal.

The deep dorsal sacrococcygeal ligament passes from the back of the fifth sacral vertebral body to the dorsum of the coccyx and corresponds to the posterior longitudinal ligament.

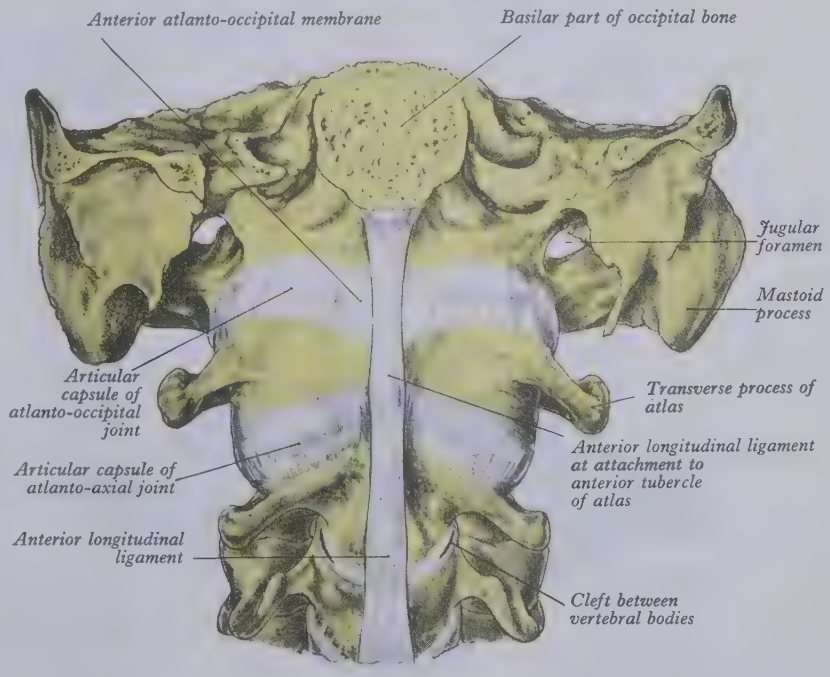
A lateral sacrococcygeal ligament on each side, like an intertransverse ligament, connects a coccygeal transverse process to an inferolateral sacral angle, completing a foramen for the fifth sacral spinal nerve.

The intercornual ligaments connect sacral and coccygeal cornua on each side. A fasciculus also connects the sacral cornua to the coccygeal transverse processes.

Intercoccygeal Joints

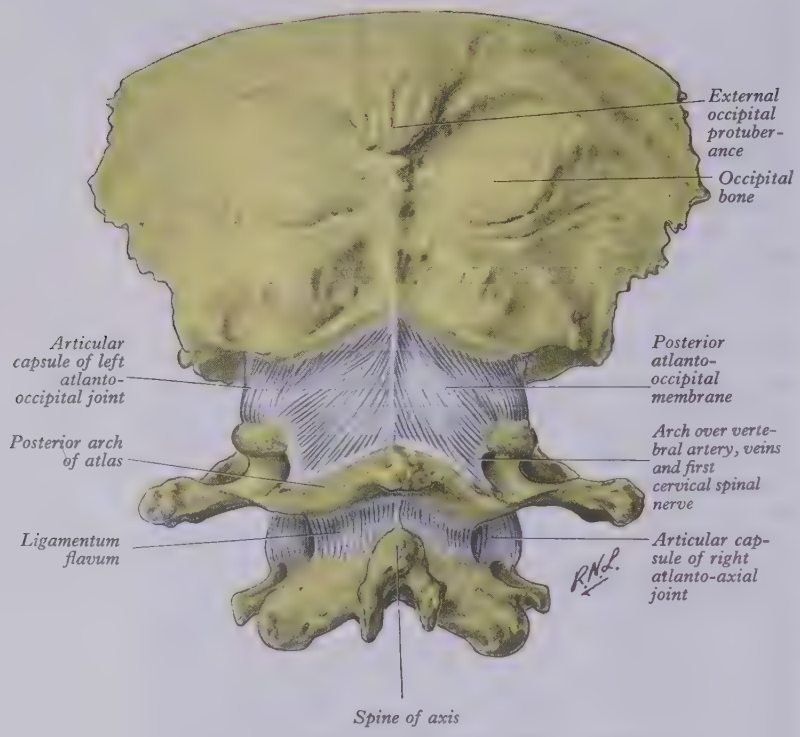
These are symphyses, with thin discs of fibrocartilage, between coccygeal segments in the young. Segments are also connected by extension of the ventral and dorsal sacrococcygeal ligaments. In adult males all segments are united comparatively early but in females union is later. In advanced age the sacrococcygeal joint is obliterated. Occasionally the joint between the first and second segments is synovial; the apex of the terminal segment is connected to overlying skin by white fibrous tissue.

Craniovertebral Joints



Articulation of the cranium and vertebral column is by means of paired atlanto-occipital joints and the ligaments between the axis and occipital bone; it is appropriate that the joints between atlas and axis at which the head rotates are also included here.

ATLANTO-AXIAL JOINTS

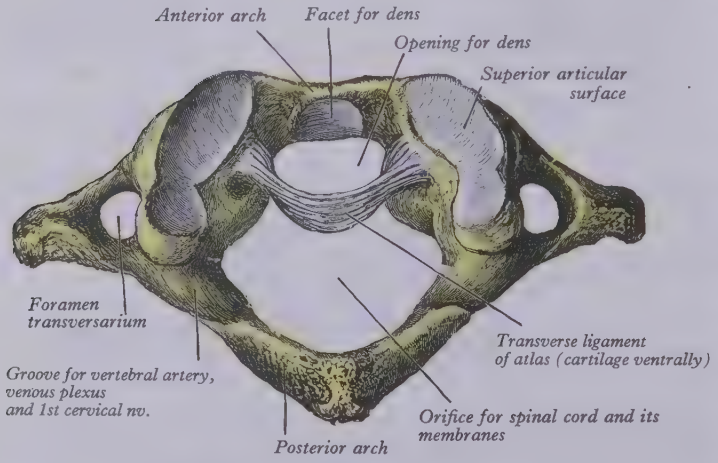


Articulation of atlas to axis is at three synovial joints, a pair between inferior atlantal and superior axial facets and a median complex between the axial dens and atlantal anterior arch and transverse ligament.

The lateral atlanto-axial joints are often classified as planar but the cartilaginous *articular surfaces* are ovoid, the atlantal slightly concave, the axial reciprocally convex (pp. 317, 318). According to Kapandji (1970) both facets are transversely cylindrical, engaging like wheels. Fibrous capsules are thin, loose, attached at their articular margins and lined by synovial membrane. Each has a posteromedial *accessory ligament* attached below to the axial body near the base of its dens, above to the lateral atlantal mass near the transverse ligament. The vertebrae are connected in front by the anterior longitudinal ligament (4.26), here a strong and wide band fixed above to the lower border of the anterior atlantal arch, below to the front of the axial body. It thickens into a median cord connecting the anterior atlantal tubercle to the axial body. They are joined by a broad, thin membrane (4.27) attached above to the lower border of the atlantal arch, below to upper edges of the axial laminae in series with ligamenta flava; it is pierced laterally by the second cervical spinal nerves.

The median atlanto-axial joint is a pivot between the axial dens and a ring formed by the atlantal anterior arch and transverse ligament; it has *two* synovial cavities which act in concert. A facet on the anterior dental surface articulates with one on the posterior aspect of the anterior atlantal arch, having a weak, loose fibrous capsule lined by synovial membrane. Posteriorly is a larger

4.26 Atlanto-occipital and atlanto-axial joints: anterior aspect. On each side a small cleft has been opened between the lateral part of the upper surface of the body of the third cervical vertebra and the bevelled, inferior surface of the body of the axis. (See also p. 317.)



4.27 Atlanto-occipital and atlanto-axial joints: posterior aspect.

synovial cavity (or bursa) between the *cartilaginous* anterior surface of the transverse ligament and the posterior grooved aspect of the dens (4.30), often continuous with one of the atlanto-occipital joints.

The transverse atlantal ligament (4.28,29,30), a thick strong band across the atlantal ring, holds the dens against the anterior arch. Attached to a small, medial tubercle on each atlantal lateral mass, it is broader centrally and bears an anterior thin layer of articular cartilage. From its superficial fibres median longitudinal bands ascend and descend, the upper to the superior surface of the basilar occipital bone between the apical ligament of the dens and membrana tectoria; the lower band, which may be absent, reaches the posterior axial surface. The whole complex forms the *atlantal cruciform ligament*. The transverse ligament divides the ring into unequal parts (4.28), the posterior and larger surrounding spinal cord and meninges, the anterior containing the dens, whose neck is embraced posteriorly by the ligament, retaining it in position even when all other ligaments are divided.

Movement at the atlanto-axial joints are simultaneous at all three, consisting basically of atlantal rotation on the axis and limited by alar ligaments (p. 495). The opposed lateral facets are both slightly convex in anteroposterior axes. Therefore, when gliding back or forwards on the lower facet, the upper also descends, stretch of capsule being diminished by descent of its upper attachments, making capsular laxity unnecessary. The lateral atlanto-axial joints support the head via the atlas, the pivot guides rotation. Kapandji (1974) has analysed these and other cervical movements, emphasizing the slight helical component in lateral atlanto-axial motion, as described above.

Muscles producing rotation: obliquus capitis inferior, rectus capitis posterior major and splenius capitis of one side, and contralateral sternocleidomastoid.

4.28 The atlas vertebra, with the transverse ligament.

ATLANTO-OCCIPITAL JOINTS

Each joint has a facet on its corresponding lateral atlantal mass which is adapted to an opposed occipital condyle: it is ellipsoid in type and *articular surfaces* are reciprocally curved. Atlantal facets are concave, tilted medially and centrally constricted, the surface partially, sometimes completely, divided (Singh 1965). The bones are connected by articular capsules and anterior and posterior atlanto-occipital membranes.

Fibrous capsules surround the occipital condyles and superior atlantal articular facets, thickened posterolaterally but thin and sometimes deficient medially, where the synovial cavities often connect with the bursa between dens and transverse atlantal ligament (Cave 1934).

The anterior atlanto-occipital membrane (4.26), broad and of densely woven fibres, connects the anterior margin of the foramen magnum to the upper border of the anterior atlantal arch; laterally it blends with the capsular ligaments; it is strengthened by the anterior longitudinal ligament to form a median cord between the basilar occipital bone and anterior atlantal tubercle (4.26).

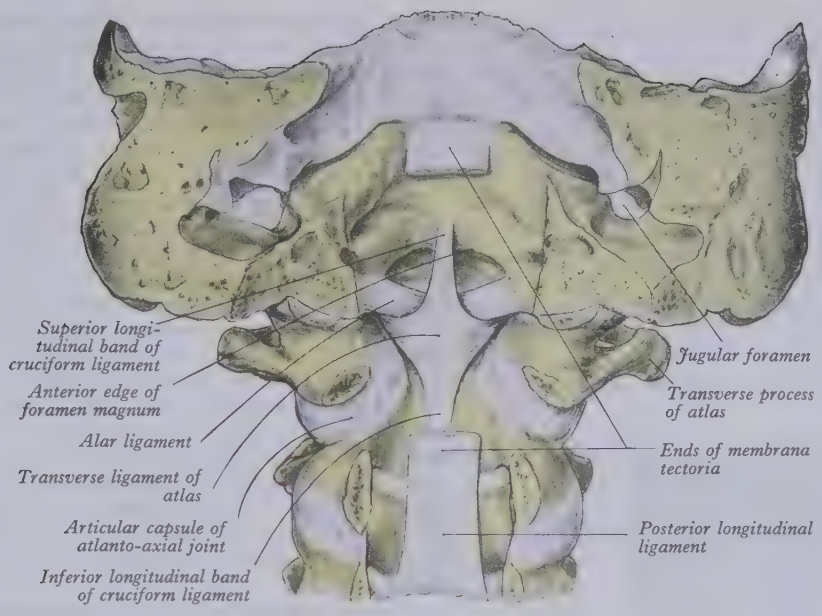
The posterior atlanto-occipital membrane (4.27), broad but thin, connects the posterior margin of the foramen magnum to the upper border of the posterior atlantal arch. It arches over the grooves for the vertebral arteries, completing openings for entrance of the arteries and exit of venous plexuses and the first cervical spinal nerves. The ligamentous border arching over artery, veins and nerve is sometimes ossified.

In movements at the atlanto-occipital joints their long (topographical) axes run anteromedially; because of this and their articular curvatures, the profiles of *both* joints are parts of the surface of *one* ellipsoid, its long axis transverse. Hence joints act as one around transverse and anteroposterior axes of movement but *not* around the vertical, therefore permitting flexion/extension and slight lateral flexion.

Muscles Producing the Movements

Flexion: longus capitis and rectus capitis anterior.

Extension: recti capitis posteriores major et minor, obliquus capitis superior, semispinalis capitis, splenius capitis and trapezius (cervical part).



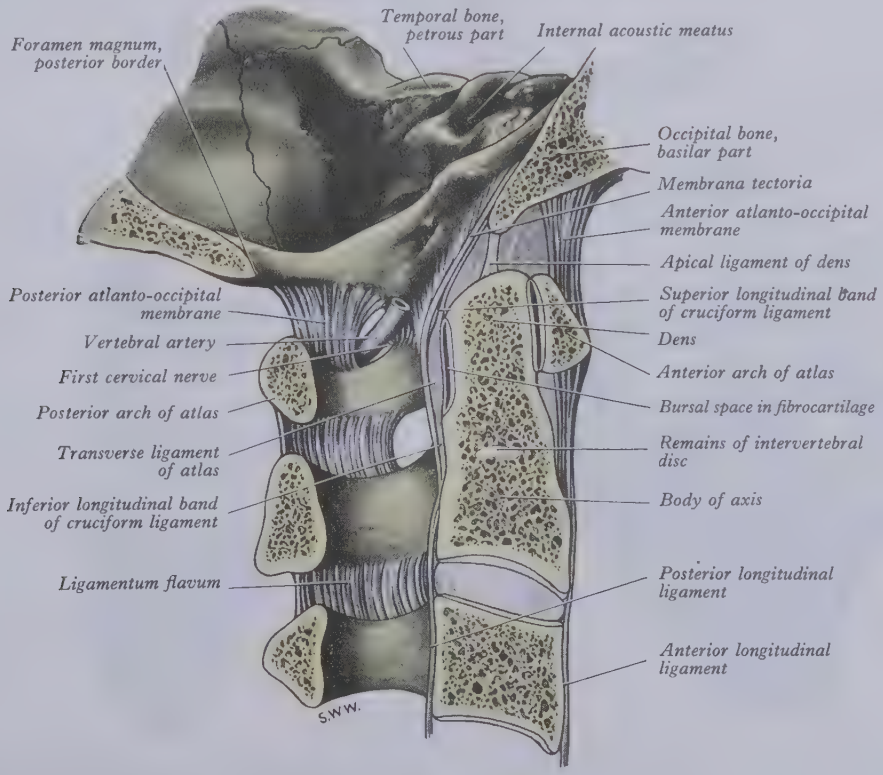
Lateral flexion: rectus capitis lateralis, semispinalis capitis, splenius capitis, sternocleidomastoid and trapezius (cervical part).

Ligaments Connecting Axis and Occipital Bone

The membrana tectoria, paired alar and median apical ligaments extend between axis and occipital bone.

The membrana tectoria (4.29,30), inside the vertebral canal, is a broad strong band covering the dens and its ligaments as a prolongation of the posterior longitudinal ligament (p. 489). Its superficial and deep laminae are both attached to the posterior surface of the axial body, the superficial lamina expanding as it ascends to the *upper* surface of the basilar occipital bone, and is attached in front of the foramen magnum, blending with the cranial dura mater; the deep lamina has a median band, extending also to the basilar occipital, and two lateral bands which ascend medial to the atlanto-occipital joints to the margins of the foramen magnum.

The alar ligaments (4.29), strong rounded cords, start on each side of the apex of the dens and ascend laterally to rough impressions on the medial sides of the occipital condyles. They



4.29 Posterior aspect of the atlanto-occipital and atlanto-axial joints, after removal of the posterior part of the occipital bone and the laminae of the upper cervical vertebra. The atlanto-occipital joint cavities have been opened.

relax in extension, tauten in flexion, thus limiting movement. They would prevent rotation of the head, were it not for a slight descent of the atlas which relaxes the ligaments enough to compensate for rotational tension. Rotation to the right is checked by tension of those fibres of the right ligament attached to the dens in front of the axis of movement and fibres of the left ligament attached behind the axis, and vice versa in left rotation.

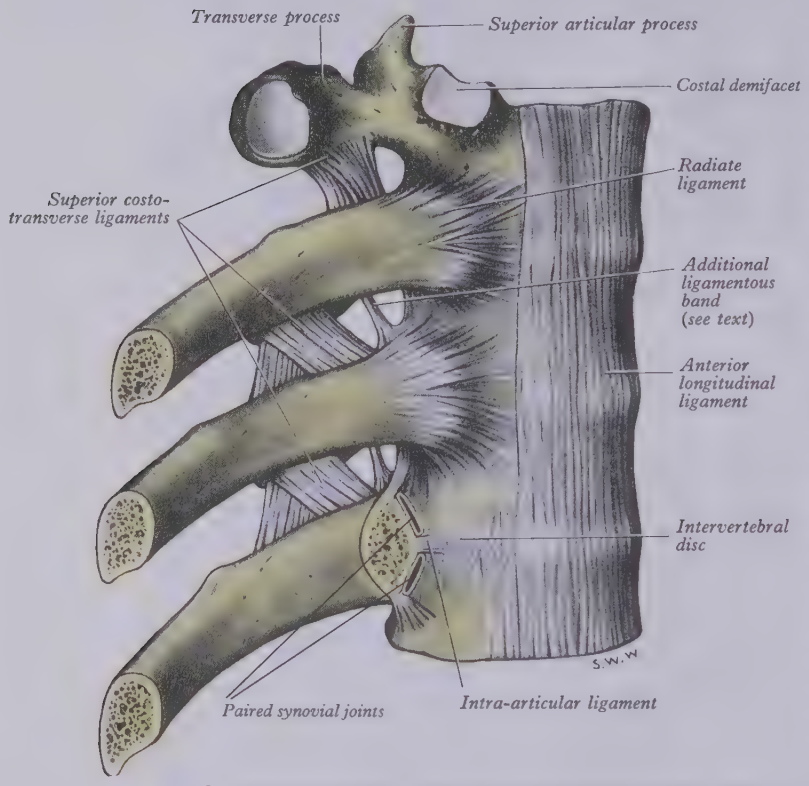
The apical ligament of the dens (4.30) extends from its apex to the anterior margin of the foramen magnum between the alar ligaments; it blends with deep fibres of the anterior atlanto-occipital membrane and the upper vertical band of the cruciform ligament. It is said to be the core of the centrum of the pro-atlas and contains traces of notochord (Ganguly & Roy 1964). The ligamentum nuchae (p. 491) also connects cervical vertebrae with the cranium.

Applied Anatomy. Dislocation of atlas from axis, with rupture of the transverse ligament and consequent spinal injury, occurs in death by hanging which may, however, fracture the axis or tear the disc between it and the third cervical vertebra. Dislocation of atlas on axis may follow pathological softening of the cruciform ligament or disease in the lateral atlanto-axial joints (e.g. rheumatoid arthritis, Bogduk et al 1984).

4.30 Median sagittal section through the occipital bone and the first to third cervical vertebrae.

Costovertebral Joints

Articulations of the ribs with the vertebral column connect costal heads to vertebral bodies (costocorporeal) and costal necks and tubercles to transverse processes (costotransverse).



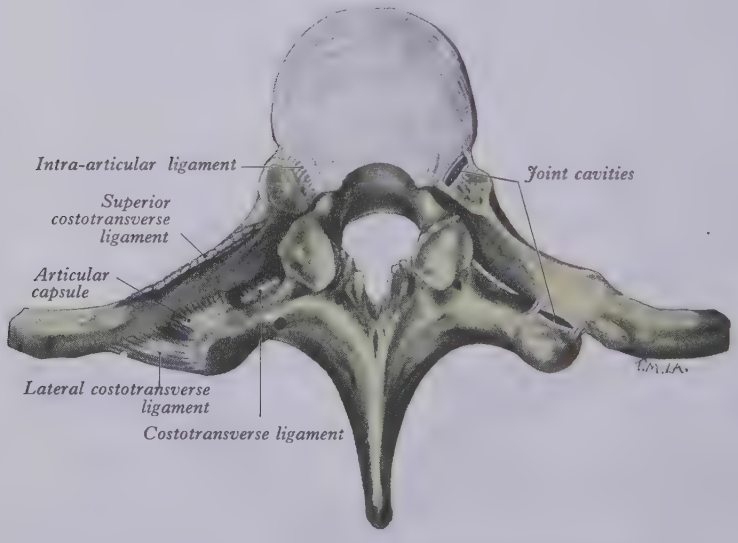
JOINTS OF COSTAL HEADS

Heads of typical ribs articulate with facets (often termed demifacets) on the margins of adjacent thoracic vertebral bodies and with intervertebral discs between them (4.31). The first and tenth to twelfth ribs articulate with a single vertebra by a simple synovial joint; in the others an intra-articular ligament bisects the joint. Double synovial compartments result, the joint being classified as both compound and complex. Often inaccurately described as plane, their articular surfaces are slightly ovoid and the upper and lower synovial articulations are obtusely angled to each other (4.31). Ligaments are capsular, radiate and intra-articular.

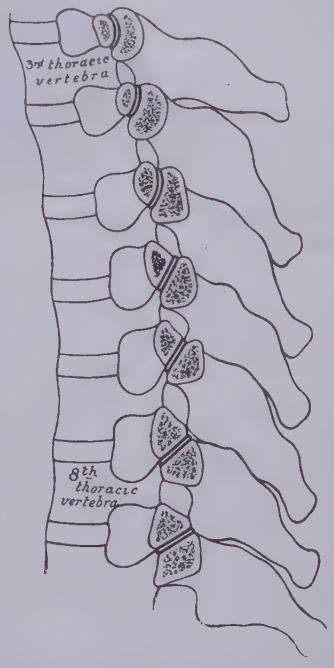
The fibrous capsules connect costal heads to the circumference of articular surfaces formed by intervertebral discs and demifacets of adjacent vertebrae; some of their upper fibres traverse their intervertebral foramina to blend with the backs of intervertebral discs (strictly symphyses); posterior fibres are continuous with costotransverse ligaments.

Radiate ligaments connect the anterior parts of each costal head to the bodies of two vertebrae and their intervertebral disc. Each is attached to the head just beyond its articular surface. Superior fibres ascend to the vertebral body above, inferior to the body below; intermediate fibres, shortest and least distinct, are horizontal and attached to the disc. In the first rib's joint the radiate ligament is attached to the seventh cervical and first thoracic vertebrae. In joints of the tenth to twelfth ribs, articulating with single vertebrae, the ligament is attached to this and the one above.

The intra-articular ligament is a short, flat band, attached laterally to the crest between the costal articular facets and medially to the intervertebral disc, dividing the joint; from the first and tenth to twelfth joints the ligament is absent.



4.31 Costovertebral joints: right anterolateral aspect. In the lowest joint shown most of the radiate ligament and the anterior part of the head of the rib have been excised to show the two joint cavities and the intra-articular ligament between them.



COSTOTRANSVERSE JOINTS

The facet of a costal tubercle articulates reciprocally with the transverse process of its corresponding vertebra (4.32). The eleventh and twelfth ribs lack this articulation; in the upper five or six joints articular surfaces are reciprocally curved but below this flatter (4.33). Their ligaments are capsular, costotransverse, superior and lateral costotransverse. **The fibrous capsule** is thin and attached to articular peripheries; it has a synovial lining.

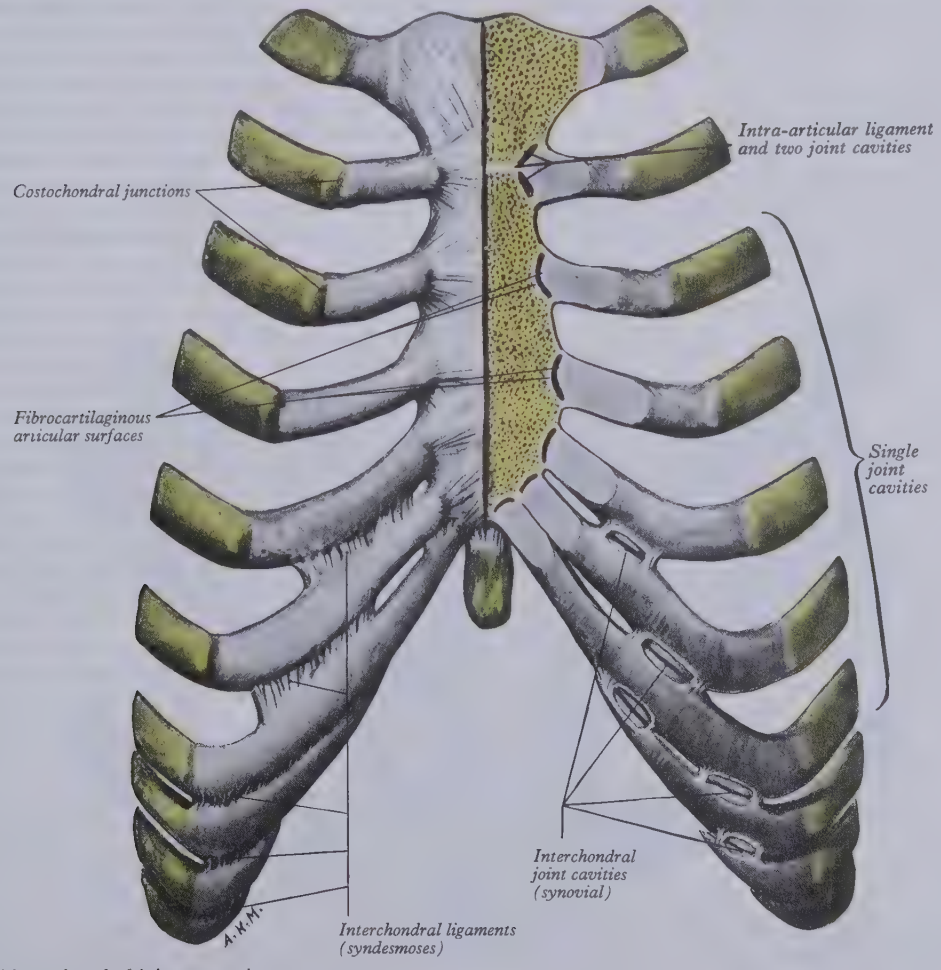
The superior costotransverse ligament has an anterior layer attached between the crest of the costal neck and lower aspect of the transverse process above (4.31); laterally it blends with the internal intercostal membrane and it is crossed by intercostal vessels and nerve; its posterior layer is attached dorsally on the costal neck, ascending posteromedially to the transverse

4.32 Costovertebral joints: superior aspect. On the left the free demifacet superior to the intra-articular ligament is apparent on the rib's head. On the right the inferior costovertebral and costotransverse synovial cavities have been opened.

4.33 Section through the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper with less curved facets on the lower transverse processes.

process above; laterally it blends with the external intercostal muscle. The first rib has no such ligament; the shaft of the twelfth, near its head, is connected to the base of the first lumbar transverse process by a *lumbocostal ligament* in series with the superior costotransverse ligaments. An **accessory ligament**, usually present and medial to the superior costotransverse, is separated from it by the dorsal ramus of a thoracic spinal nerve and accompanying vessels (4.31). Variable in attachments, such bands usually pass from a depression medial to a costal tubercle to the inferior articular process immediately above; some fibres also pass to the base of the transverse process.

The costotransverse ligament fills the *costotransverse foramen* between costal neck and its adjacent corresponding transverse process. Its numerous short fibres extend back from the posterior rough surface on the costal neck to the anterior surface of the transverse process. In the eleventh and twelfth ribs it is rudimentary or absent.



The lateral costotransverse ligament, short, thick and strong, passes obliquely from the apex of a transverse process to the rough nonarticular part of the adjacent costal tubercle. The ligaments of upper ribs *ascend* from their transverse processes; they are shorter and more oblique than those of the lower ribs, which *descend*.

Movements at costotransverse joints. Costal heads are so firmly tied to vertebral bodies by radiate and intra-articular ligaments that only slight gliding can occur; strong ligaments binding costal necks and tubercles to transverse processes also limit movements at costotransverse joints to slight gliding, guided by the shape and direction of articular surfaces (4.33); those on tubercles of the upper six ribs are oval and vertically convex, fitting corresponding concavities on the anterior surfaces of transverse processes; hence up and down movements of tubercles involve rotation of costal necks on their long axes. Articular surfaces of the seventh to tenth tubercles are almost flat, facing down, medially and backwards; opposing surfaces are on the upper aspects of transverse processes. Hence when these tubercles ascend they also move posteromedially. Both sets of joints move simultaneously and in the same directions; the costal neck moves as if at a single joint, the two articulations forming its ends. In the upper six ribs the neck moves slightly up and down but its chief movement is one of rotation on its long axis, downward rotation of its ventral aspect being associated with depression and upward rotation with elevation of the shaft and anterior end of the rib. In the seventh to tenth ribs the neck ascends posteromedially or descends anterolaterally, increasing or diminishing the infrasternal angle; slight rotation accompanies these movements. The muscles involved in respiration are considered on p. 594.

Sternocostal Joints

Costal cartilages join small concavities on the lateral sternal borders (*chondrosternal articulations*, 4.34). Perichondrium and periosteum are continuous. The first costal cartilage joins by an unusual variety of synarthrosis (see p. 467; this is often inaccurately called a synchondrosis) while the second to seventh articulate by synovial joints; articular cavities are often absent, particularly in lower joints. Articular surfaces are *fibrocartilaginous* and this tissue also unites costal cartilages to sternum where cavities are absent (Gray & Gardner 1943). Ligaments involved are capsular, radiate sternocostal, intra-articular and costoxiphoid. According to Sick & Koritke (1976) the seventh costosternal joint may be synovial or 'symphysial'.

Fibrous capsules surround the second to seventh sternocostal joints. They are thin, blended with sternocostal ligaments and

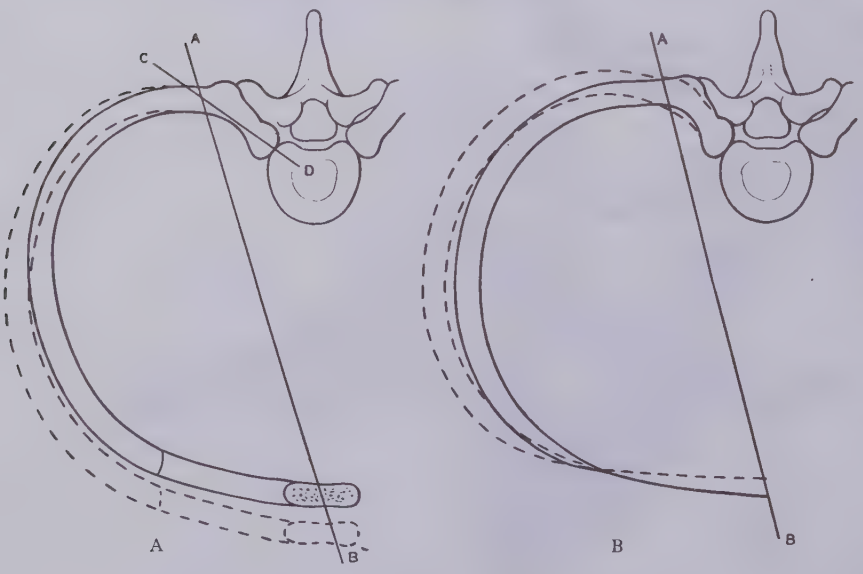
4.34 Sternocostal and interchondral joints: anterior aspect.

strengthened above and below by fibres connecting cartilages to sternum.

Radiate sternocostal ligaments are broad, thin bands radiating from the front and back of sternal ends of cartilages of true ribs to corresponding sternal surfaces. Their superficial fibres intermingle with adjacent ligaments above and below, with those of the opposite side and with tendinous fibres of pectoralis major, forming a thick fibrous membrane around the sternum, more markedly in its lower part.

Intra-articular ligaments are constant only between second costal cartilages and sternum. The second costal cartilage's ligament extends from the costal cartilage to the fibrocartilage uniting manubrium and sternal body and is therefore intra-articular. Occasionally the third sternal cartilage is connected with the first and second sternal segments by a similar ligament. Fibrocartilaginous strands may occur in the third and lower joints. Articular cavities may be absent at all ages.

Costoxiphoid ligaments connect anterior and posterior surfaces of the seventh costal cartilage (and sometimes sixth) to the same surfaces of the xiphoid process. They vary in length and breadth, the posterior being less distinct.



Movements. Slight gliding movements occur at sternocostal joints, sufficient for respiration (p. 594).

Interchondral Joints

Contiguous borders of the sixth to ninth costal cartilages articulate by apposition of small oblong facets, each articulation being enclosed in a thin *fibrous capsule*, lined by synovial membrane with lateral and medial *interchondral ligaments* (4.34). Sometimes the fifth cartilage, more rarely the ninth, articulate at their inferior borders with adjoining cartilages, this connection being more often by ligamentous fibres. Articulation between the ninth and tenth cartilages is never synovial and sometimes absent (p. 467). For further comments on chondral arthroses see p. 335.

Costochondral Junctions

The costal cartilages are persistent, unossified anterior parts of cartilaginous models preceding fully developed ribs. Artificially separated from its rib a costal cartilage has a rounded end, the rib a depression. Across junctions periosteum and perichondrium are continuous and the collagen of the osseous and cartilaginous matrices blend. No movement occurs there.

4.35 A. Diagram showing the axes of movement (AB and CD) of a vertebrosternal rib. The interrupted lines indicate the position of the rib in inspiration. B. Diagram showing the axis of movement (AB) of a vertebrochondral rib. The interrupted lines indicate the position of the rib in inspiration.

Sternal Joints

The manubriosternal joint between the manubrium and sternal body is usually a symphysis, the bony surfaces covered by hyaline cartilage and connected by a fibrocartilage which may ossify in the aged. In more than 30% the central part of the disc is absorbed and the joint *appears* synovial; similar cavitation may occur in the symphysis pubis (see p. 467, 517). The two are also connected by a fibrous membrane enveloping the whole bone. In 10% of all over 30 years the manubrium is joined to the sternal body by bone but the intervening cartilage may be only superficially ossified; it is in the aged that this is complete. Early synostosis has been attributed to a persistent synchondrosis in place of a symphysis (Ashley 1954). In the newborn union is by collagenous and elastic fibres without chondrocytes.

Movements. The symphysis permits a small range of angulation between longitudinal axes of manubrium and corpus sterni and also limited anteroposterior displacement. A study of these movements in 62 male athletes yielded (standing position) mean values of 162.7° (full inspiration) and 164.7° (full expiration) for the manubriosternal angle (Constantinescu 1974). Both movements contribute to respiratory excursions of the sternum.

The xiphisternal joint between xiphoid process and corpus sterni is also a symphysis, usually transformed to a synostosis by the fortieth year but it sometimes remains unchanged even in old age.

Mechanism of the Thorax

Each rib has its range and direction of movement contributing to thoracic respiratory excursions. Each acts as a lever, its fulcrum immediately lateral to its costotransverse articulation; hence, when the shaft is elevated, the neck is depressed and vice versa; since the lever's arms differ much in length, slight movement at the vertebral end is much magnified at the anterior end.

Anterior costal ends are lower than posterior; therefore when shafts are raised they move forwards. The mid-shaft is below the ends so that when the shaft is raised it also spreads laterally. Further, each rib is part of a curve greater than that of the rib above; therefore costal elevation increases transverse thoracic diameter at higher levels. (Modifications of rib movements at vertebral ends are described on p. 497.) Modifications also result from attachments of anterior costal ends with different movements of vertebrosternal, vertebrochondral and vertebral ribs.

Vertebrosternal ribs (4.35A). The first moves little, except in deep respiration about an oblique axis through the neck; the shaft rises laterally in inspiration, its inferomedial surface becoming more directly inferior, an impossible movement if the cartilage is calcified, as it may be; first ribs and manubrium then move as a unit about a transverse axis through their costotransverse joints. The second rib also moves little in quiet respiration; elevation of third to sixth ribs thrusts their anterior ends up and forwards, mostly by backward rotation at their necks; this also moves the sternum similarly at the manubriosternal joint, increasing the anteroposterior thoracic diameter. As this action ceases, an elevating force raises the middle parts of their shafts, everting their lower borders, opening the costochondral angle and increasing the transverse thoracic diameter. Measurements of sternal respiratory movements reveal large excursions, especially in fit adult males (Constantinescu 1974). Between full inspiration and expiration the suprasternal notch may move 31 mm, excursions at the superior (34 mm) and inferior (37 mm) ends of the corpus sterni being increased by changes in the sternal angle.

Vertebrochondral ribs (4.35B), including the seventh, assist thoracic respiratory enlargement and they also increase upper abdominal space for the viscera displaced by diaphragmatic descent, although abdominal relaxation accounts in part for this. Costal cartilages, through their joints, push each other up, the final thrust forcing the lower sternum up and forwards. Elevation of their anterior ends is limited by the very slight rotation possible at their necks. Elevation of shafts is accompanied by outward and backward movement, the former everting their anterior ends and

opening the infrasternal angle, while backward movement retracts anterior ends and counteracts the forward thrust of elevation, most noticeably in the lower ribs which are shortest. The result is an increase in transverse and diminution in median anteroposterior diameters of the upper abdomen, while its lateral anteroposterior diameters are increased.

Vertebral ribs have free anterior ends and costovertebral joints without intra-articular ligaments and may move a little in all directions. As other ribs rise they are depressed and fixed by the quadrati lumborum to aid diaphragmatic action of the diaphragm. The muscles which produce these movements are discussed on p. 594.

JOINTS OF THE UPPER LIMB

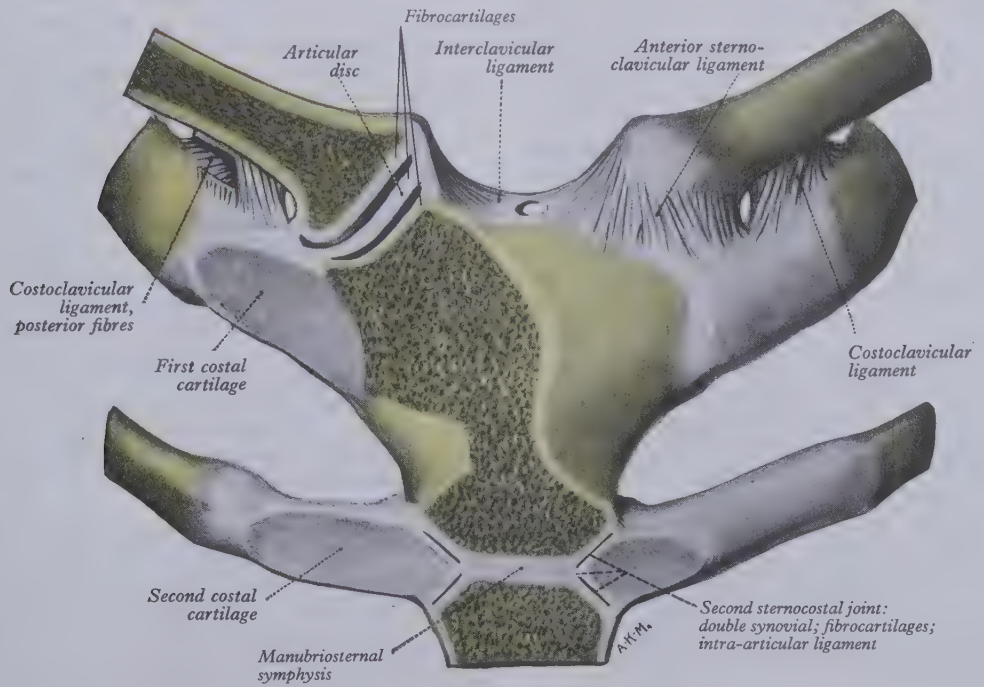
The Sternoclavicular Joint

Involved in the sternoclavicular joint are the sternal end of the clavicle and the sternal clavicular notch, together with the adjacent superior surface of the first costal cartilage (4.36). The clavicular *articular surface*, much the larger, is covered by *fibrocartilage*, thicker than the fibrocartilaginous lamina on the sternum. Convex vertically but anteroposteriorly slightly concave, it is therefore sellar; the sternal clavicular notch is reciprocally curved but the two surfaces are not fully congruent. (For their variations see p. 405.) The joint is divided by an articular disc. Its ligaments are capsular, anterior and posterior sternoclavicular, interclavicular and costoclavicular.

The fibrous capsule is thickened in front and behind; but above and especially below it is little more than loose areolar tissue.

The anterior sternoclavicular ligament is broad, attached above to the anterosuperior aspect of the clavicle's sternal end, and passes inferomedially to the upper anterior aspect of the manubrium, spreading to the first costal cartilage.

The posterior sternoclavicular ligament, a weaker band posterior to the joint, descends inferomedially from the back of the clavicle's sternal end to the back of the upper manubrium.



The interclavicular ligament, continuous above with deep cervical fascia, unites the superior aspects of the sternal ends of both clavicles; some fibres are attached to the superior manubrial margin. When present, *suprasternal ossicles* (p. 332) are in this ligament.

The costoclavicular ligament is like an inverted cone but short and flattened, with anterior and posterior laminae attached to the upper surface of the first rib and costal cartilage, ascending to the margins of an impression on the inferior clavicular surface at its medial end. Fibres of the anterior lamina ascend laterally and shorter fibres of the posterior lamina ascend medially (4.36); they fuse laterally and merge medially with the capsule. Between them a bursa suggests separate functions (Cave 1961). Probably each is tensed at opposite extremes of clavicular axial rotation.

The articular disc, flat and almost circular, between the sternal and clavicular surfaces, is attached above to the superoposterior border of the clavicular articular surface, below to the first costal cartilage near its sternal junction and by the rest of its circumference to the capsule. Thicker peripherally, especially in its superoposterior part, it divides the joint into a larger superolateral part and a smaller inferomedial one. The capsule around the former is more lax, movements between clavicles and discs being more extensive than those between discs and sternum. Movement is considered below (p. 500). Sellar shape of the surfaces permits *angulation* in approximately anteroposterior and vertical planes and some rotation (about the clavicular long axis) or *spin* (30° according to Kapandji 1970), which is conjunct. Close-packing probably coincides with maximum posterior spin associated with full scapular rotation (vide infra). Some anteroposterior translation also occurs.

Arteries to the joint are branches from the internal thoracic and suprascapular arteries; *nerves* are from the anterior supraclavicular nerve and the nerve to the subclavius. For details of vascularization consult Sick & Ring (1976).

Applied Anatomy. The joint's strength depends on ligaments, especially its disc. This and the usual transmission of forces *along* the clavicle make dislocation rare and fracture far more common.

4.36 Sternoclavicular joints: anterior aspect; left joint intact and right in coronal section.

The Acromioclavicular Joint

This articulation (4.40,42), between the clavicle's acromial end and the medial acromial margin, is approximately plane; but either surface may be slightly convex, the other reciprocally concave. *Both* are covered by *fibrocartilage*, the clavicular being a narrow, oval area facing inferolaterally and overlapping a corresponding facet on the medial acromial border. The long axis is anteroposterior. Ligaments are capsular, acromioclavicular and coracoclavicular.

The fibrous capsule completely surrounds the articular margins and is strengthened above by the acromioclavicular ligament.

The acromioclavicular ligament, quadrilateral and above the joint, extends between upper aspects of the clavicle's acromial end and the adjoining acromion. Its parallel fibres interlace with the trapezial and deltoid aponeuroses.

An articular disc often occurs in the joint's upper part, partially separating articular surfaces (de Palma 1957). More rarely it completely divides the joint.

Movements at this joint (vide infra) are like those of the sternoclavicular. Axial rotation of the clavicle is said to be about 30° (Kapandji 1970). The two joints together permit about 60° of scapular rotation. Angulation with the scapula occurs in any direction. Spin and angulation both tense the coracoclavicular ligament at their extremes; spin tightens the capsule by spiralization. According to MacConaill & Basmajian (1977) close-packing occurs when the angle between the superior scapular border and clavicular shaft reaches about 90°. This 'opening' (*ouverture*) of the angle tenses the conoid part of the coracoclavicular ligament (Kapandji 1970); further scapular rotation is due to rotation at the sternoclavicular joint.

The coracoclavicular ligament (4.37) interconnects clavicle and scapular coracoid process. Though separate from the acromioclavicular joint it is a most efficient accessory ligament, maintaining apposition of clavicle to acromion. Its *trapezoid* and *conoid parts*, usually separated by fat or, frequently, a bursa, connect the medial horizontal part of the coracoid process and lateral end of the subclavian groove of the clavicle; these adjacent areas may even be covered by cartilage to form a *coracoclavicular joint* (Lewis 1959).

The *trapezoid part*, the anterolateral fasciculus, is broad, thin and quadrilateral, ascending slightly from the upper coracoid surface to the trapezoid line on the inferior clavicular surface. It is almost *horizontal*, its anterior border free, its posterior joined to the conoid part, forming an angle projecting backwards.

The *conoid part*, the posteromedial fasciculus, a dense almost *vertical* triangular band, has its base attached to the clavicle's conoid tubercle and its inferior apex attached posteromedially to the conoid tubercle at the root of the coracoid process in front of the scapular notch.

Arterial supply is from suprascapular and thoraco-acromial arteries, *nerve supply* from suprascapular and lateral pectoral nerves.

Applied Anatomy. In acromioclavicular dislocation the coracoclavicular ligament is torn and the scapula falls away from the clavicle. Owing to the flatness and orientation of the joint surfaces, dislocation readily recurs.

MOVEMENTS OF THE SHOULDER GIRDLE

Clavicular movements at their sternoclavicular and acromioclavicular joints are always associated with those of the scapula, which, in turn, are usually accompanied by humeral movements. Therefore this account should be amplified by reference to pp. 502 and 503. The acromioclavicular joint allows the acromion, and hence the scapula, anteroposterior gliding and rotation on the clavicle; but scapular range is much increased by movements at the sternoclavicular joint. Analysis is clarified by considering *scapular movements*, primarily analysed as (1) elevation and depression, (2) protraction and retraction round the thorax, (3) rotation forwards or upwards, with its inferior angle as reference point, and its reverse.

1. *Scapular elevation and depression*, picturesquely exemplified by 'shoulder' shrugging, do not necessarily imply movement at the shoulder joint. In elevation slight angulation or swing occurs at the acromioclavicular joint but the clavicle's sternal end, rotating on an anteroposterior axis through the bone above the medial attachment of the costoclavicular ligament, slides down over the articular disc (*translation*); this is checked by antagonist muscles and tension in the costoclavicular ligament and lower capsule. It is effected by trapezius (upper part) and levator scapulae; since these tend to rotate the scapula in opposite directions, pure elevation can occur.

In the reverse movement slight angulation occurs at the acromioclavicular joint, but at the sternoclavicular joint the clavicle slides up on the disc, checked by antagonist muscles, the interclavicular and sternoclavicular ligaments and articular disc. This role of the interclavicular ligament, suspension of the depressed clavicle, has been confirmed by experiment (Bearn 1967). Usually gravity alone is sufficient, but serratus anterior (lower part) and pectoralis minor are, when necessary, active effectors.

2. *Forward movement (protraction)* round the thoracic wall occurs in pushing, thrusting and reaching movements, usually with some forward rotation. The acromion advances over the clavicular facet to the limit and the shoulder is simultaneously advanced by forward movement of the lateral end of the clavicle and posterior translation of its sternal end over the sternal facet, carrying the disc with it. Antagonist muscles and the anterior sternoclavicular and costoclavicular (posterior lamina) ligaments check backward slide of the sternal end. Serratus anterior and pectoralis minor are prime movers and maintain continuous apposition of the scapula, especially its medial border, in smooth gliding on the thoracic wall. The upper part of latissimus dorsi also acts like a strap across the inferior scapular angle in protraction and forward rotation.

In *scapular retraction*, bracing back the shoulders, movements are reversed and checked at the sternoclavicular joints by posterior sternoclavicular and costoclavicular (anterior lamina) ligaments. Trapezius and the rhomboids are prime movers, but gravity may also produce retraction when the weight of the trunk is taken by the arms in leaning forwards, to a degree controlled by protractive musculature.

When force is applied at the end of an outstretched arm, e.g. in a fall on the hand, pressure transmitted to the glenoid cavity tends to drive the sloping acromial facet below the clavicle's acromial end but also tenses the trapezoid ligament, which resists the displacement; and, unless the fall is unexpected, even greater forces are available to resist dislocation.

3. *Forward rotation of the scapula* increases the range of *humeral elevation* by turning its glenoid cavity to face almost directly up (as in raising an arm above the head), a movement always associated with some humeral elevation and with protraction of the scapula. Scapular rotation entails movements at the sternoclavicular and the acromioclavicular joints: the sternoclavicular permits elevation of the clavicle's lateral end, a movement almost complete when the arm is abducted to 90°. The acromioclavicular joint moves in the first 30° of abduction when the conoid ligament becomes taut and thereafter is accompanied by clavicular rotation at the sternoclavicular joint around the bone's longitudinal axis, also with further depression of its medial end as the lateral end continues to rise. Some acromioclavicular movement also occurs in the final stages of humeral abduction (Inman et al 1944). Trapezius (upper part) and the serratus anterior (lower part) are prime movers.

Return rotation is usually by gravity, gradual active lengthening of trapezius and serratus anterior being sufficient to control it. When more force is needed the levator scapulae, rhomboids and in the initial stages pectoralis minor are prime movers in returning the scapula to a position of rest.

Muscles which are antagonists in one movement may combine as prime movers in another. Movements, not muscles, are represented in cerebral motor areas; muscles are not grouped unalterably in nervous control but can be variably combined as demands dictate. Thus serratus anterior and trapezius are opposed in scapular movement round the thorax but combine as prime movers in its forward rotation.

In all scapular movements subclavius probably steadies the clavicle by drawing it medially and downwards, although its

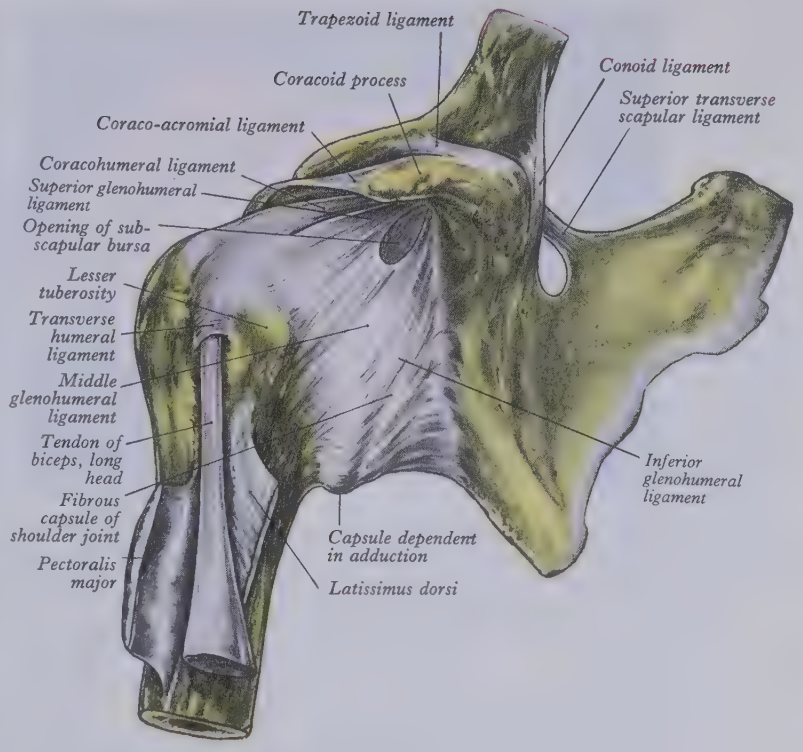
inaccessibility makes its role uncertain. Scapular movements on the thoracic wall are facilitated by areolar tissue between subscapularis and serratus anterior and the costal wall. With the arm pendant the shoulder girdle's normal posture relative to the trunk involves moderate activity in trapezius and serratus anterior (Basmajian 1967), which obviously must increase when the limb is loaded.

LIGAMENTS OF THE SCAPULA

The main scapular ligaments (4.37) are the coraco-acromial and superior transverse scapular; there may also be a weaker, variable inferior transverse (spinoglenoid) ligament.

The coraco-acromial ligament, a strong triangular band between coracoid process and acromion, is attached apically to the acromion anterior to its clavicular articular surface and by its base to the whole lateral coracoid border. With coracoid process and acromion it completes an *arch* above the humeral head. It may have two strong marginal bands with a thinner centre; when occasionally the pectoralis minor is inserted into the humeral capsule instead of the coracoid process, its tendon passes between the bands (p. 611). The subacromial bursa (p. 502 and 4.39) facilitates movement between the coraco-acromial arch and the subjacent supraspinatus muscle and shoulder joint, functioning as a secondary synovial articulation.

The superior transverse scapular (suprascapular) ligament makes the scapular notch into a foramen and is sometimes ossified. A flat fasciculus, it narrows towards its ends, attached to the base of the coracoid process and medial side of the scapular notch. The suprascapular nerve traverses the foramen; suprascapular vessels cross above the ligament.



A membranous *inferior transverse (spinoglenoid) ligament* may stretch from the scapular spine's lateral border to the glenoid margin forming an arch over the suprascapular nerve and vessels entering the infraspinous fossa; it is often absent.

The Humeral (Shoulder) Joint

This is a multi-axial spheroidal joint (3.181,4.37,38A,B,C,41,42) possessing three degrees of freedom between the roughly hemispherical humeral head and shallow scapular glenoid cavity, a construction allowing much movement but reducing security. Skeletally the joint is weak, and depends for support on surrounding muscles more than on its shape and ligaments. However, the coraco-acromial arch overhangs it (vide supra).

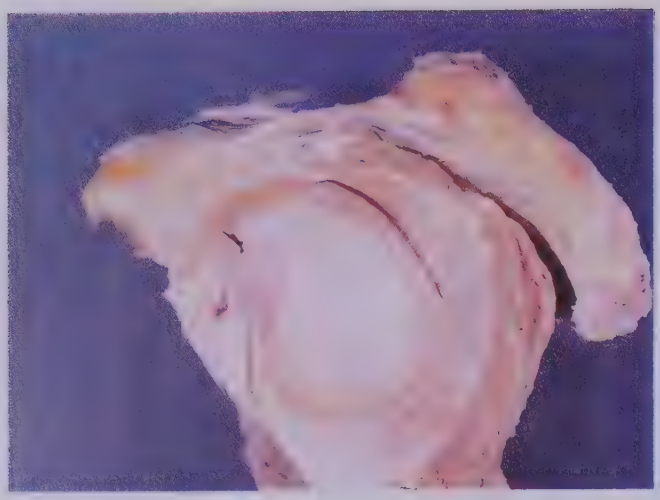
The *articular surfaces*, reciprocally curved, are really *ovoids* (see p. 480). Here, as in the hip, where ovoid surfaces are almost spherical they are often termed *spheroidal*. The humeral convexity much exceeds in area that of the glenoid concavity (4.38A,B) and only a minor part opposes the glenoid in any position, the remaining capitular articular surface being in contact with the capsule. The glenoid cavity (4.38A,C,39,40) is deepened by a fibrocartilaginous rim, the *glenoidal labrum*. Both articular surfaces are covered by hyaline cartilage: on the humerus it is centrally thickest, thinner peripherally; the reverse in the glenoid cavity. In most positions, their curvatures are not fully congruent, the joint being loose-packed (Saha 1961). Full congruence (close-packing) is reached with the humerus abducted and laterally rotated (see pp. 502, 503; and 4.5,17). When the arm is dependent, the anterior glenoid edge can be represented by a laterally concave line descending 3 cm from a point just lateral to the coracoid apex; it lies over the joint's lower half. The ligaments are the *glenoidal labrum, fibrous capsule, glenohumeral, coracohumeral* and *transverse humeral*.

The fibrous capsule (4.37,38) envelops the joint, attached medially to the glenoid margin outside the glenoidal labrum, and encroaching on the coracoid process to include the attachment of the long head of biceps. Laterally, it is attached to the humeral anatomical neck, i.e. near the articular margin, except inferomedially where it descends more than 1 cm on the humeral shaft. It is so lax that the bones can be distracted for 2 or 3 cm. This accords with a very wide range of movement. However, such unnatural separation requires relaxation of the upper capsule by abduction.

4.37 The right shoulder joint: anterior aspect.

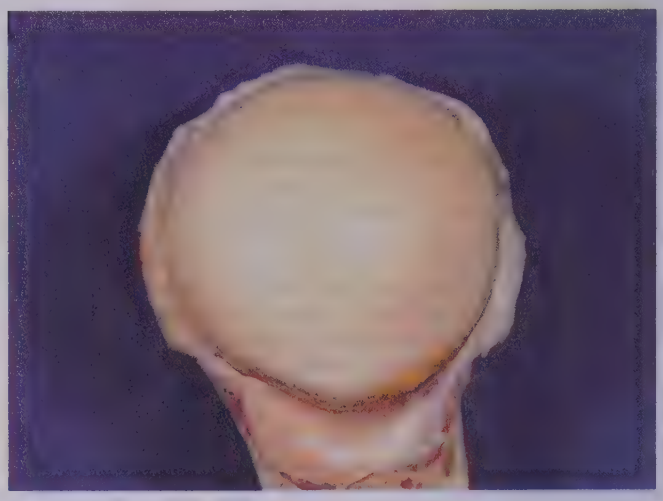
The fibrous capsule is supported by the tendons of supraspinatus (above), infraspinatus and teres minor (behind), subscapularis (in front) and by the long head of triceps (below). All but triceps blend with the capsule as the *rotator cuff* which reinforces the capsule and actively supports it unless the muscles are fully relaxed. The triceps is separated from the capsule by the axillary nerve and posterior circumflex humeral vessels as they pass back from the axilla (4.41). Inferiorly the capsule is hence least supported and also subjected to the greatest strain, being stretched tightly across the humeral head in full abduction.

The capsule usually has two or three openings: an anterior, below the coracoid process, connects the joint to a bursa behind the subscapular tendon; another, between the humeral tubercles (tuberosities), transmits the long bicipital tendon and its synovial sheath; a third, inconstant and posterior, connects the joint to a bursa under the infraspinatous tendon.



Three *glenohumeral ligaments*, best visible from within the joint (4.40), reinforce the capsule. At their scapular ends all are attached to the superomedial glenoid margin, blended with the glenoidal labrum. The *superior* passes along the medial edge of the bicipital tendon to attachment above the lesser humeral tubercle; the *middle* reaches the lower part of this tubercle; the *inferior* extends to the lower part of the humeral anatomical neck. The capsule is also strengthened in front by extensions from the tendons of pectoralis major and teres major.

Synovial membrane lines the capsule and covers parts of the anatomical neck. The long bicipital tendon traverses the joint in a synovial sheath which continues into the intertubercular sulcus as far as the humeral surgical neck (4.37,38).



The coracohumeral ligament (4.37), a broad thickening of the upper capsular region, descends laterally from the lateral border of the coracoid root to the front of the greater tubercle, blending with the supraspinatous tendon; its inferoposterior border blends with the capsule, the anterosuperior does not.

The transverse humeral ligament (4.37) is a broad band passing between the humeral tubercles, converting the intertubercular sulcus into a canal; its attachment is superior to the epiphysial line. It is simply a retinaculum for the long tendon of biceps.

The glenoidal labrum (4.39), a fibrocartilaginous rim round the glenoid cavity, is triangular in section, its base attached to the cavity's margin, its thin margin projecting as a continuation of the

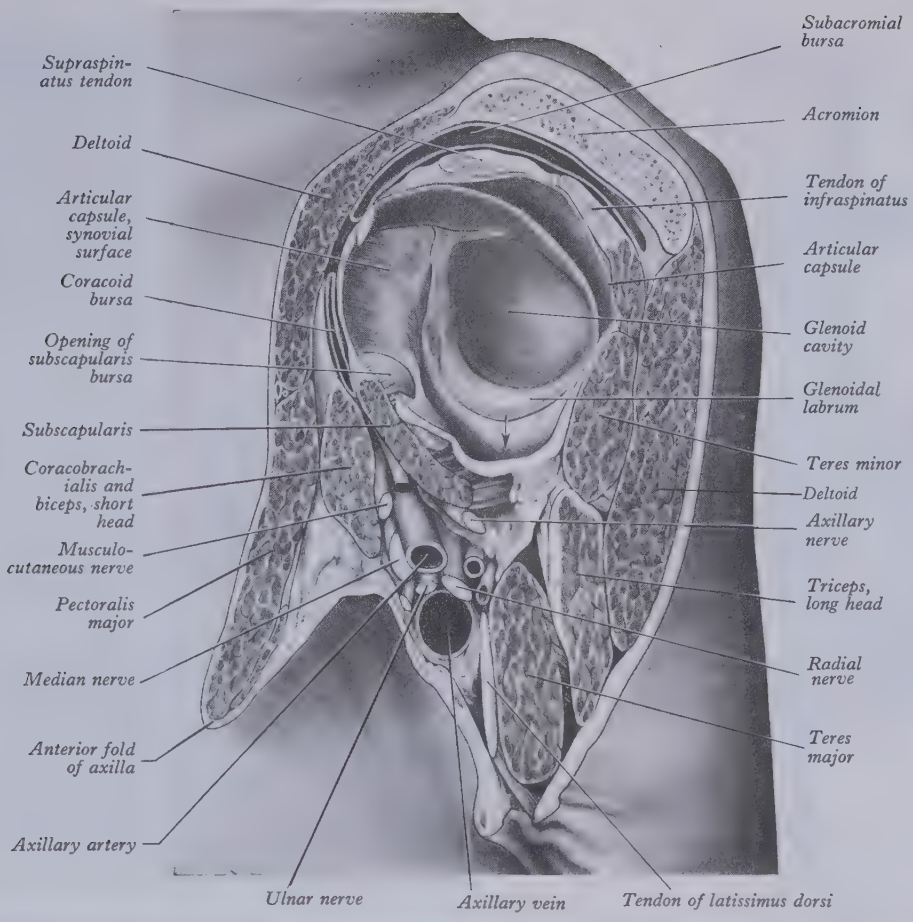
4.38 A,B Dissections from a preserved cadaver showing the articular surfaces and periarticular structures of the glenohumeral joint. A shows the glenoid cavity covered by articular cartilage and the glenoidal labrum; note the intracapsular part of the tendon of the long head of the biceps sectioned near the supraglenoid tubercle, the fibrous capsule intimately blended with 'rotator cuff' musculature, the subacromial bursa, and the superjacent coraco-acromial arch complex. B displays the much more extensive spheroidal articular surface of the head of the humerus and the pendant inferior part of the fibrous articular capsule. (Preparation by M C E Hutchinson and photography by Kevin Fitzpatrick, Guy's Hospital Medical School, London.)

curve of the glenoid. It blends above with two fasciculi from the long tendon of biceps. It deepens the cavity, may protect bone and probably assists lubrication (p. 471). Its attachment is sometimes partly deficient; synovial membrane may protrude through such gaps.

Many bursae adjoin the shoulder joint: (1) between the subscapular tendon and articular capsule (4.40), communicating with the joint between the superior and middle glenohumeral ligaments; (2) sometimes between the infraspinatous tendon and capsule, occasionally opening into the joint; (3) the *subacromial bursa* (4.39) between deltoid muscle and capsule, non-communicating but prolonged under the acromion and coraco-acromial ligament, and between them and supraspinatus; (4) on the superior acromial aspect; (5) frequently between the coracoid process and capsule; (6) sometimes behind coracobrachialis; (7) between teres major and the long head of triceps; (8) and (9) anterior and posterior to the tendon of latissimus dorsi.

4.38C Section through the shoulder joint. The synovial membrane is in blue.



Related *muscles* are: supraspinatus (above), long head of triceps (below), subscapularis (in front), infraspinatus and teres minor (behind), long bicipital tendon (intracapsular). Deltoid covers the joint in front, behind and laterally (4.39).

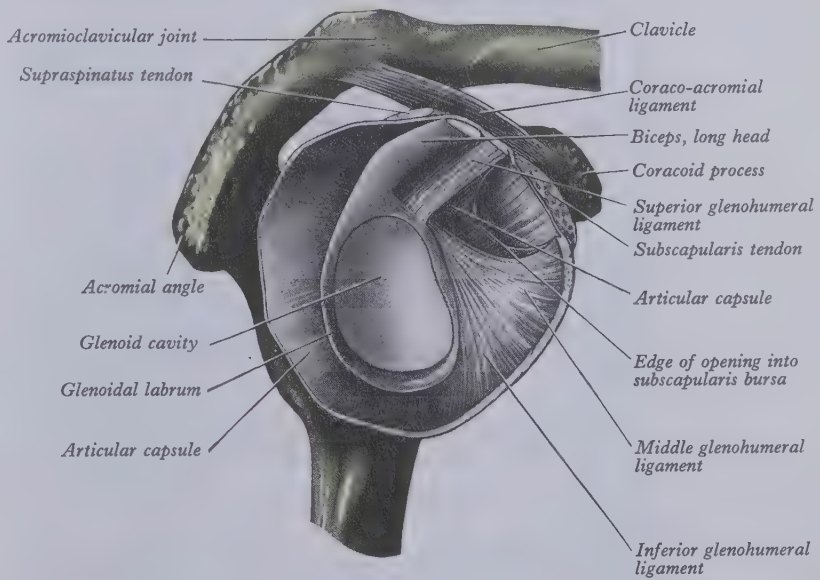
Arteries are from the anterior and posterior circumflex humeral and suprascapular vessels. *Nerves* are mainly from the posterior brachial cord and from suprascapular, axillary and the lateral pectoral nerves. The suprascapular supplies the posterior and superior, axillary antero-inferior and the lateral pectoral anterosuperior parts of the capsule (Gardner 1948B).

Movements. The shoulder, as a multi-axial spheroidal joint, is capable of any combination of swing and spin over a very wide range (p. 482), all movements analysable as rotations around three orthogonal axes, i.e. it has three degrees of freedom (p. 476). Classically, flexion–extension, abduction–adduction, circumduction and medial and lateral rotation (p. 476) are assigned to it. Laxity of the capsule, and a humeral head which is large relative to the shallow glenoid cavity, afford a wider range of movement than at any other joint. However, with the arm dependent, even when moderately loaded, the supraspinatus and tension in the upper capsule prevent downward displacement of the humerus (Basmajian 1962).

In analysis of shoulder movements it is preferable to refer humeral movement to the scapula, rather than to conventional anatomical planes, relevant axes being shown in 4.5A,B,C. When the arm hangs at rest the glenoid cavity faces almost equally forwards and laterally, and humeral capitular and scapular (topographical) axes correspond, although the humerus, relative to the anatomical position, is medially rotated (p. 477). *Flexion* carries the arm anteromedially on an axis through the humeral head orthogonal to the glenoid cavity at its centre. *Abduction and adduction* occur in a vertical plane orthogonal to that of flexion–extension, the axis being horizontal, through the humeral head, parallel to the glenoid plane (Flecker 1929). Pure abduction raises the arm *anterolaterally in the plane of the scapula*. However, when referred to the *trunk*, flexion and extension are in the paramedian plane, abduction and adduction in the coronal plane. Raising the arm vertically from flexion (in this sense) or raising it from abduction (in this sense) are both accompanied by humeral rotation in opposite directions. Whether 'scapular' or any other plane of abduction is described, these are selections from an infinite series. In scapular abduction points on the humeral surface pursue vertical chords but in rotation they are horizontal. In 'pure' flexion–extension, in a plane orthogonal to the scapular, the axis of movement (and the notional 'mechanical axis', p. 480) are regarded as projected from the centre of the glenoid cavity.

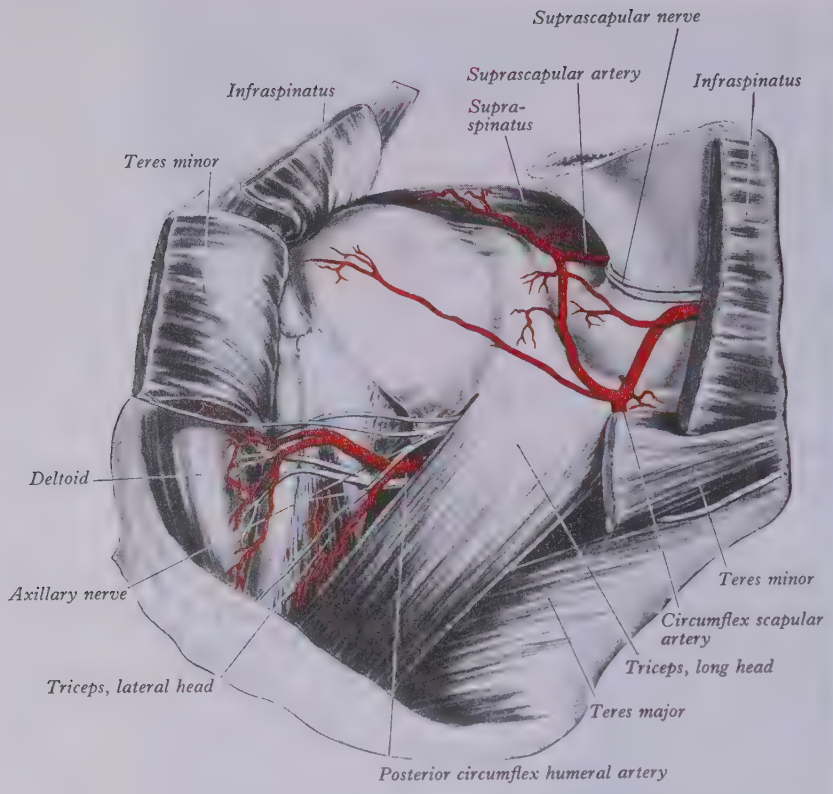
Glenohumeral abduction is about 90° (Kapandji 1970) but angles up to 120° have been stated (Inman et al 1944). About 60°

4.39 An obliquely coronal section through the left shoulder and shoulder joint, in the plane of the glenoidal labrum, dissected after removal of the upper limb. The arrow points into the dependent part of the articular capsule. Note: the relations of the axillary vessels to each other and to the branches of the brachial plexus as displayed in this dissected section may appear unfamiliar and the reader is referred to **6**.92 for a more usual view. Compare, also, with **4**.40.



further abduction occurs at the sterno- and acromioclavicular articulations. Contralateral vertebral flexion also aids in bringing the arm vertical. However, during active elevation movements at the glenohumeral and scapuloclavicular joints are simultaneous, except in the initial 25°–30°, when most and often all movement is glenohumeral. For every 15° of elevation, glenohumeral is said to be 10° and scapular 5°.

In flexion, however, the humerus swings at right angles to the scapular plane and scapular rotation cannot increase elevation (120°) obtainable in full flexion. If the fully flexed humerus is also abducted, elevation increases pro rata until, when the humerus reaches the scapular plane, i.e. when true abduction is reached, 180° of elevation becomes possible. In *rotation*, medial or lateral, the humerus revolves about one-quarter of a circle around a vertical axis; range is greatest when the arm is pendent, least when it is vertical. When assessing rotational range at the glenohumeral joint, the forearm should be flexed to a right angle at the elbow, preventing misinterpretation due to superadded pronation or supination in the pendent limb. In *circumduction*, a succession of the foregoing movements, the distal end of the humerus describes the base of a cone, its apex at the humeral head, but this glenohumeral movement can be much increased by scapular movements; the combination is exemplified in acts of slinging objects with force.



Because of the offset position of the humeral head relative to the shaft's longitudinal topographical axis, flexion and extension involve almost pure 'spins' in the glenoid cavity (p. 480). Other movements are an infinite variety of cardinal or arcuate swings or successions of these (pp. 478, 480).

The peculiar relation of the long bicipital tendon to the shoulder joint may serve several purposes. By its connection with both shoulder and elbow the muscle harmonizes their actions as an elastic ligament during all their movements. It helps to prevent the humeral head impinging on the acromion when the deltoid contracts (vide infra) and to steady it in movements of the arm.

A wide range of *accessory movements* (p. 484) occurs at the shoulder joint. The humeral head can be translated in any direction relative to the glenoid cavity and, in abduction when accessory movements are most free, the articular surfaces can be separated by traction.

4.40 Interior of the right shoulder joint: anterolateral aspect.

4.41 Posterior aspect of the left shoulder joint. An oblique section has been made through the spine of the scapula and the acromion has been removed. Parts of the infraspinatus and teres minor have been excised and their tendons have been turned forwards.

Muscles producing the movements may be divided into (1) those acting on the pectoral girdle and (2) those acting on the glenohumeral joint.

(1) **Muscles acting on the pectoral girdle** have been considered on p. 500.

(2) **Muscles acting at the glenohumeral joint** are principally deltoid, pectoralis major, latissimus dorsi and teres major. All converge on the humerus, acting at mechanical advantage on a joint which, owing to glenoid shallowness and capsular laxity, is relatively unstable, a condition counteracted by the short muscles attached nearer to it, viz. subscapularis, supraspinatus, infraspinatus and teres minor (the '*rotator cuff*'), which function as postural muscles retaining the humeral head and glenoid in correct alignment and resisting skid during active movements.

Flexion: pectoralis major (clavicular part, p. 611), deltoid (anterior fibres) and coracobrachialis assisted by biceps. The sternocostal part of pectoralis major is a major force in flexion forwards to the coronal plane *from the full extension*.

Extension: deltoid (posterior fibres) and teres major, from the pendent position. When the fully flexed arm is extended against resistance, latissimus dorsi and the sternocostal part of pectoralis major act powerfully until the arm reaches the coronal plane.

Abduction: deltoid, but initially its effect is mainly upward and, unless opposed, would so displace the humerus. Subscapularis, infraspinatus and teres minor are the opposing force exerting downward traction; these three and deltoid constitute a 'couple' to produce abduction in the scapular plane. Supraspinatus assists in effecting and maintaining this movement but its precise role is controversial.

Medial rotation: pectoralis major, deltoid (anterior fibres), latissimus dorsi, teres major and, with the arm pendent, subscapularis.

Lateral rotation: infraspinatus, deltoid (posterior fibres) and teres minor.

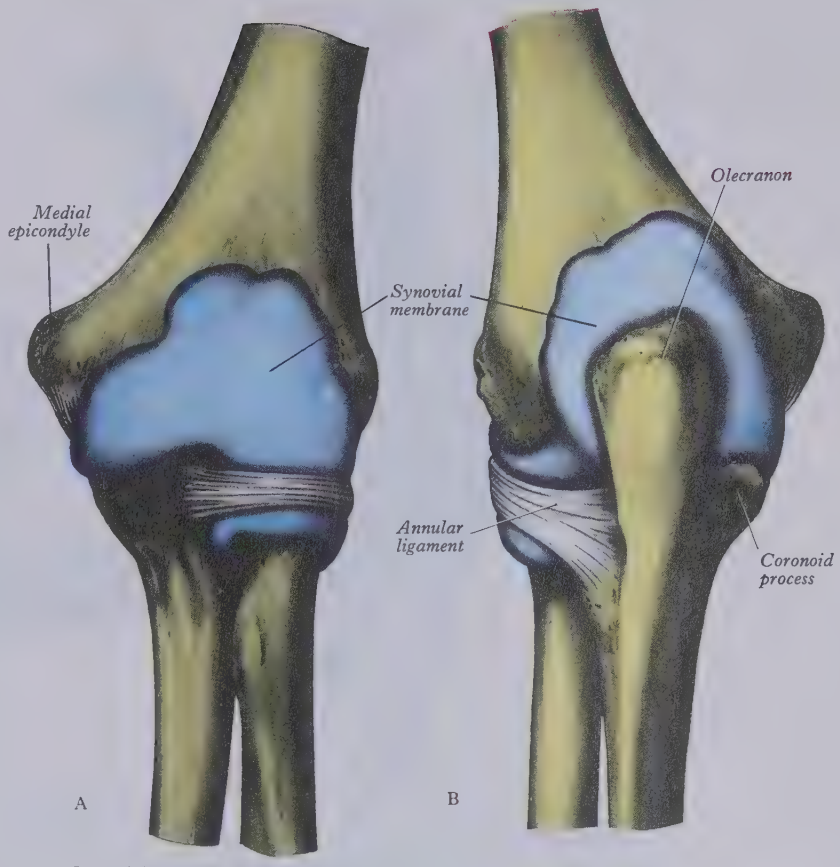
Applied Anatomy. Owing to the joint's shallowness it is the most frequently dislocated, usually with the arm abducted, the humeral head pressing against the antero-inferior aspect of the

capsule, where it is thinnest and least supported. The tear is almost always here, dislocation being primarily subglenoid. (Further degrees are subcoracoid and subclavicular.) If, after reduction, abduction is prevented, dislocation cannot recur.

If the shoulder joint ankyloses, loss of movement is partly compensated by increased scapular mobility. When ankylosis is likely the humerus should be positioned as if the palm were to be placed on the back of the neck, i.e. abducted, to make full use of scapular mobility.

The Cubital (Elbow) Joint

This (4.43–48) includes two articulations: (1) *humero-ulnar*, between humeral trochlea and ulnar trochlear notch, and (2) *humeroradial*, between humeral capitulum and radial head. It is hence a *compound* synovial joint. Its complexity is increased by continuity with the superior radio-ulnar joint, this complex being the *cubital articulation*. The superior radio-ulnar joint will, however, be considered separately.



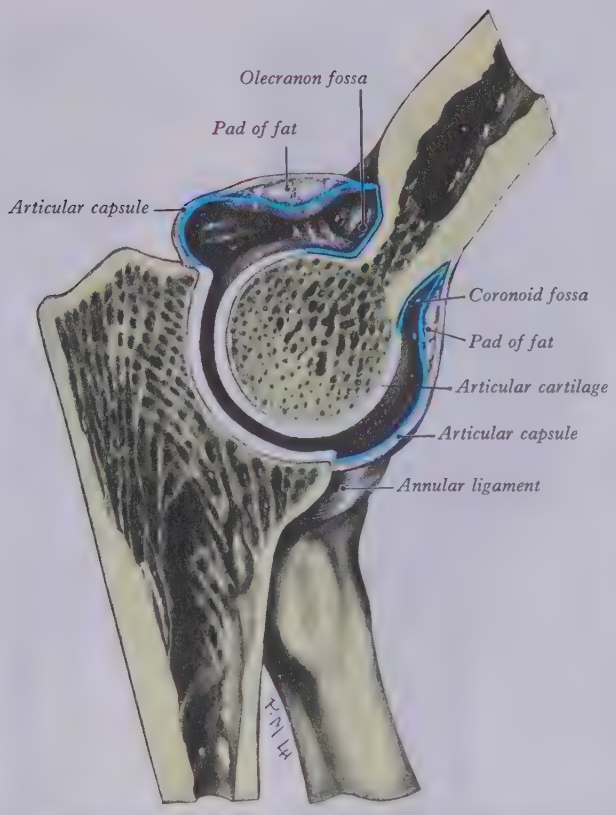
Articular surfaces are the humeral trochlea and capitulum, and the ulnar trochlear notch and radial head. The trochlea is not a simple pulley as its medial flange exceeds its lateral, thus projecting to a lower level so that the plane of the joint, about 2 cm distal to the inter-epicondylar line, is tilted inferomedially; the trochlea is also widest posteriorly and here its lateral edge is sharp. The trochlear notch is not wholly congruent with it; in full extension the medial part of its upper (olecranon) half is not in contact with the trochlea and a corresponding lateral strip loses contact in flexion. The trochlea has an asymmetrical sellar surface, largely concave transversely, convex anteroposteriorly; sections show that these profiles are compounded spirals. Consequently swing is accompanied (as in all hinge joints) by screwing and conjunct rotation (pp. 480, 482). Olecranon and coronoid parts of the trochlear notch are usually separated by a rough strip, devoid of articular cartilage and covered by fibro-adipose tissue and synovial membrane. The capitulum and the radial head are reciprocally curved; closest contact occurs with a semiflexed radius in mid-pronation. The rim of the head, more prominent medially, fits the groove between humeral capitulum and trochlea.

Since the humero-ulnar and humeroradial articulations form a largely uni-axial joint, ligaments are capsular and ulnar and radial collateral.

The articular capsule (4.44,45) is anteriorly broad and thin, attached proximally to the front of the medial epicondyle and humerus above the coronoid and radial fossae, and distally to the edge of the ulnar coronoid process and annular ligament (p. 507), being continuous at its sides with the ulnar and radial collateral ligaments. Anteriorly it receives numerous fibres from brachialis. Posteriorly the capsule is thin and attached to the humerus behind its capitulum and near its lateral trochlear margin, to all but the lower part of the olecranon fossa's edge, and to the back of the medial epicondyle. Inferomedially it reaches the olecranon's superior and lateral margins and is laterally continuous with the superior radio-ulnar capsule deep to the annular ligament (p. 507). It is related posteriorly to the tendon of triceps and to anconeus.

The synovial membrane (4.43,44) extends from the humeral articular margins, lines the coronoid, radial and olecranon fossae, the flat medial trochlear surface (3.136), the capsule's deep surface and the lower part of the annular ligament. Projecting between radius and ulna from behind is a crescentic synovial fold, partly dividing the joint into humeroradial and humero-ulnar parts; irregularly triangular, it contains extrasynovial fat (4.46). Between capsule and synovial membrane are three other pads of fat; the largest, at the olecranon fossa, is pressed into it by triceps during flexion; the other two, at the coronoid and radial fossae, are pressed in by brachialis during extension. They are all slightly displaced in contrary movements. Smaller synovial-covered tags of fat project into the joint near constrictions flanking the trochlear notch (p. 413), covering small non-articular areas of bone.

The ulnar collateral (medial cubital) ligament (4.45A), a triangular band, has thick anterior, posterior and inferior parts united by a thin region. The *anterior part* is attached by its apex to the front of the medial epicondyle and by its broad distal base to a proximal tubercle on the medial coronoid margin. The *posterior part*, also triangular, is attached low on the back of the medial epicondyle and to the olecranon's medial margin. Between these two bands intermediate fibres descend from the medial epicondyle to an inferior, *oblique band*, often weak, between olecranon and coronoid processes, converting a depression on the medial margin of the trochlear notch into a foramen, by which the intracapsular fat pad is continuous with extracapsular fat medial to the joint. The ulnar collateral ligament is related to triceps, flexor carpi ulnaris and the *ulnar nerve*. Along it, anteriorly, the attachment of flexor digitorum superficialis extends from the medial epicondyle to the medial coronoid border.



4.43 A. Synovial cavity of the left elbow joint, partially distended: anterior aspect. (Originally drawn from a specimen prepared by J C B Grant.) The fibrous capsule of the elbow joint has been removed but the thick part of the annular ligament has been left in situ. Note that the synovial membrane descends below the lower border of the annular ligament. B. Synovial cavity of the left elbow joint, partially distended: posterior aspect of the specimen represented in A. In A and B a small part of the ulnar (medial) collateral ligament may be seen.

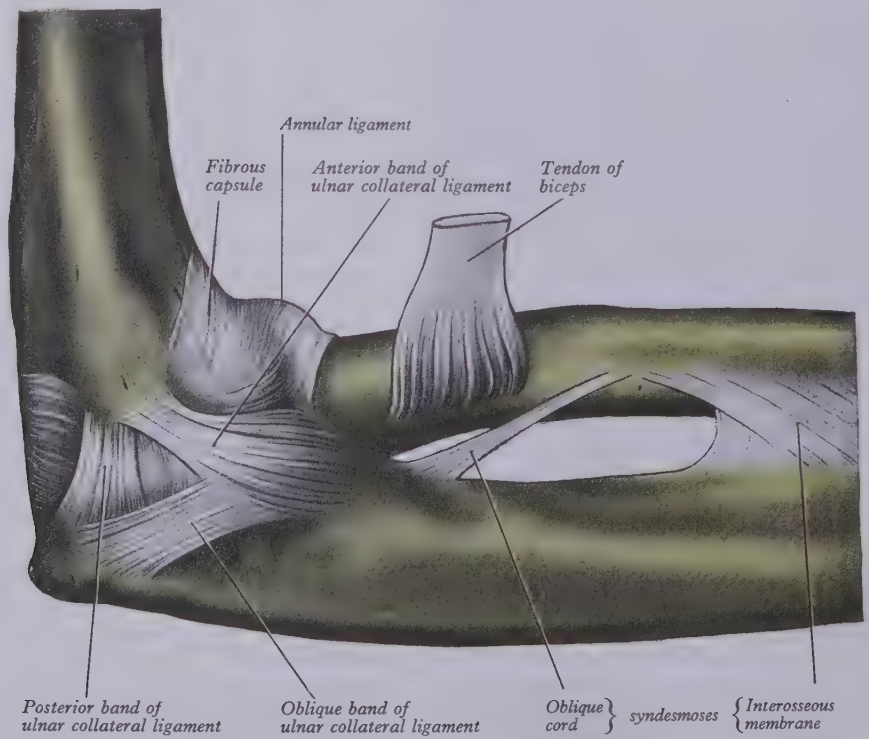
The radial collateral (lateral cubital) ligament (4.45B) is attached low on the lateral epicondyle and to the annular ligament, some of its posterior fibres crossing the ligament to the proximal end of the ulna's supinator crest. It is intimately blended with attachments of supinator and extensor carpi radialis brevis.

Muscles related to the joint are: (in front) brachialis, (behind) triceps and anconeus, (laterally) supinator and the common extensor tendon, and (medially) the common flexor tendon and flexor carpi ulnaris.

Articular arteries are from the numerous peri-articular anastomoses (6.97). *Articular nerves* are mainly from the musculocutaneous and radial, but the ulnar, median and sometimes anterior interosseous nerves also contribute. The musculocutaneous branch is from the nerve to brachialis and innervates an anterior part of the capsule; branches of the radial supply its posterior and anterolateral regions and come from the nerve to anconeus and the ulnar collateral branch to the medial head of triceps. The ulnar nerve supplies the ulnar collateral

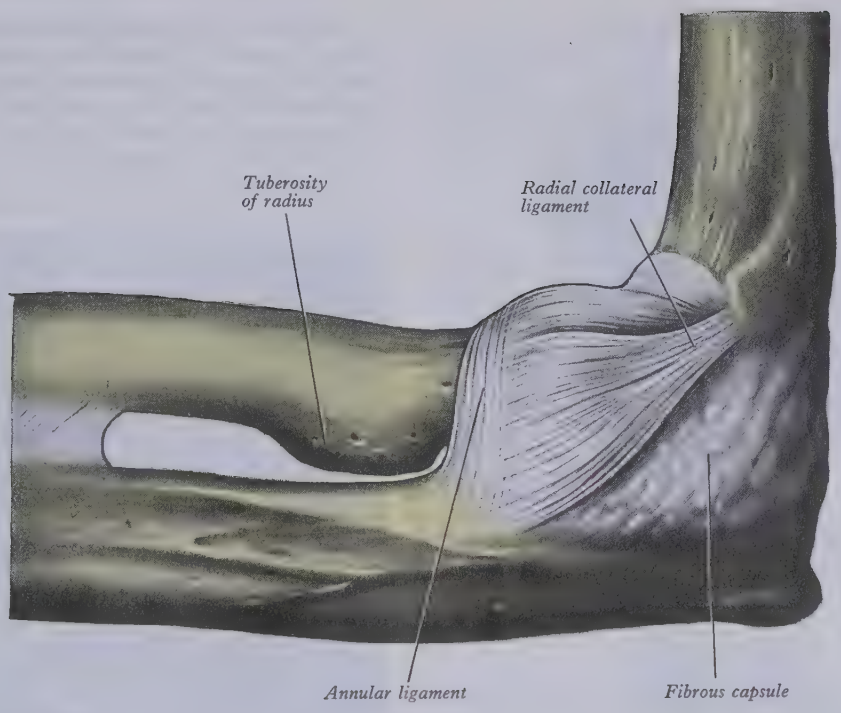
4.44 Sagittal section through the left elbow joint: medial aspect. The synovial membrane is shown in blue.

ligament behind the medial epicondyle (Gardner 1948b). These articular nerves accompany blood vessels supplying the synovial membrane, fat pads and epiphyses; they presumably contain vasomotor fibres as well as afferent fibres serving pain and proprioception.



Movements. Being a uni-axial joint the elbow allows flexion and extension, ulna moving on trochlea, radial head on capitulum. However, ulnar flexion–extension is not a pure swing but accompanied by slight conjunct rotation, the ulna being slightly pronated in extension, supinated in flexion. Since the capitulum is smaller than the radial facet, the head of the radius can be felt at the back of the joint in full extension, which is limited by tension in the capsule and muscles anterior to the joint (extension being the close-packed position) and the entry of the tip of the olecranon into the olecranon fossa; flexion is limited chiefly by apposition of soft parts; in full flexion the rim of the radial head and the tip of the ulnar coronoid process enter the radial and coronoid humeral fossae respectively.

When the forearm is fully extended and supinated, it diverges laterally forming with the upper arm a 'carrying angle' of about 163° (Steel & Tomlinson 1958); its ulnar border cannot contact the lateral surface of the thigh. The 'carrying angle' is caused partly by projection of the medial trochlear edge about 6 mm beyond its lateral edge and partly by obliquity of the coronoid's superior articular surface, which is not orthogonal to the ulna's shaft. Tilt of humeral and ulnar articular surfaces is approximately equal; hence the carrying angle disappears in full flexion, the two bones reaching the same plane. When the adducted arm is flexed the little finger meets the clavicle, due to the position of the resting humerus (p. 502); with the humerus rotated laterally, the hand reaches the front of the shoulder. The carrying angle is also masked by pronation of the extended forearm, which brings the upper arm, semipronated forearm and hand into line, increasing manual precision in full extension of the elbow or during extension.



Accessory movements are limited to slight ulnar screwing, abduction and adduction, and anteroposterior translation of the radial head on the humeral capitulum. In translation the radial head moves on the ulnar radial notch and the annular ligaments are slewed backwards and forwards, more so when the elbow is semiflexed.

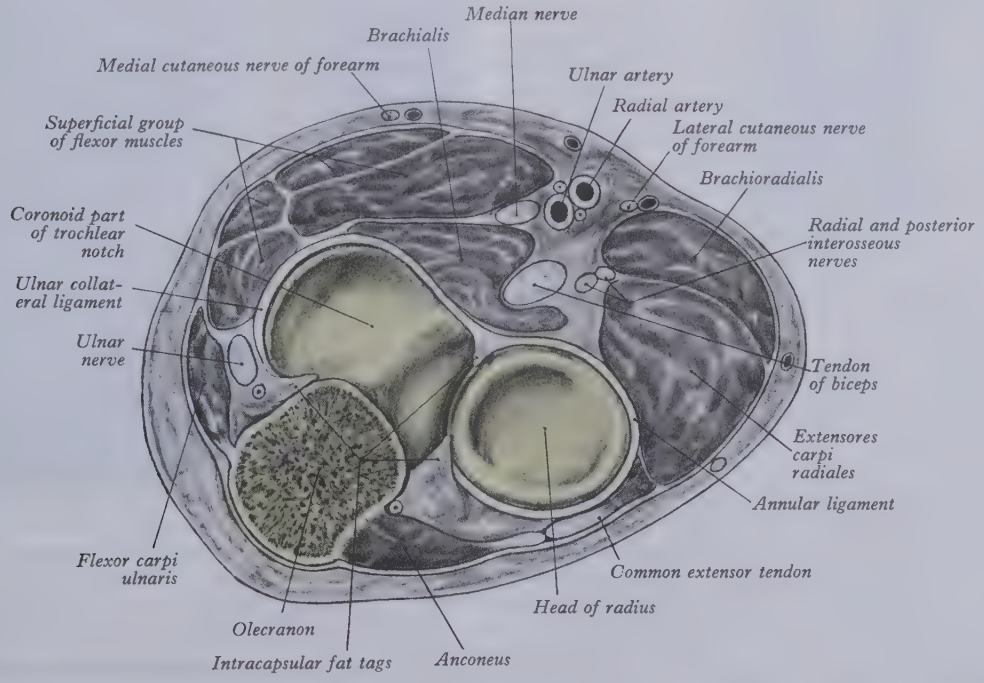
Muscles Producing the Movements

Flexion: brachialis, biceps and brachioradialis. In slow flexion or its maintenance against gravity, brachialis and biceps are principally involved, even for light loads. With increasing speed, activity in brachioradialis is increasingly prominent (MacConaill 1949, Basmajian 1959); due to its attachments it acts most effectively in mid-pronation. (See shunt muscle activity pp. 567, 568.) Against resistance pronator teres and flexor carpi radialis may act.

4.45A Left elbow joint: medial aspect.

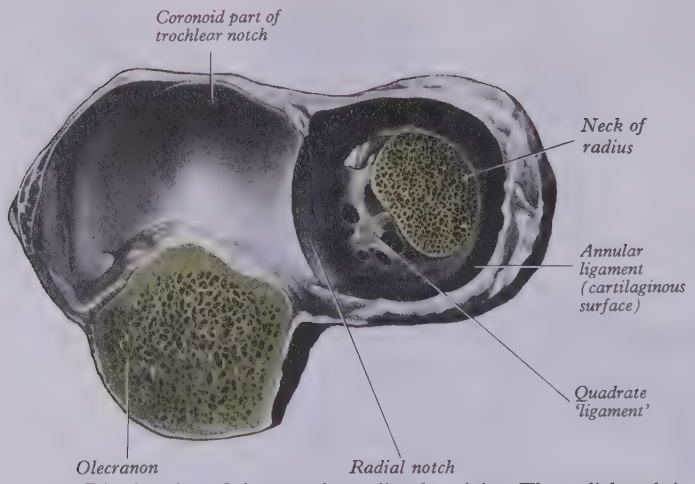
4.45B Left elbow joint: lateral aspect.

Extension: triceps, anconeus and gravity. In rapid extension brachioradialis again acts as a shunt muscle (pp. 567, 568).



Radio-ulnar Joints

The radius and ulna are connected by *proximal* and *distal radio-ulnar synovial joints* and by an intermediate interosseous membrane and ligament, a non-synovial *middle radio-ulnar joint*.



THE PROXIMAL RADIO-ULNAR JOINT

This a is uni-axial pivot between the circumference of the radial head and the osseofibrous ring made by the ulnar radial notch and annular ligament.

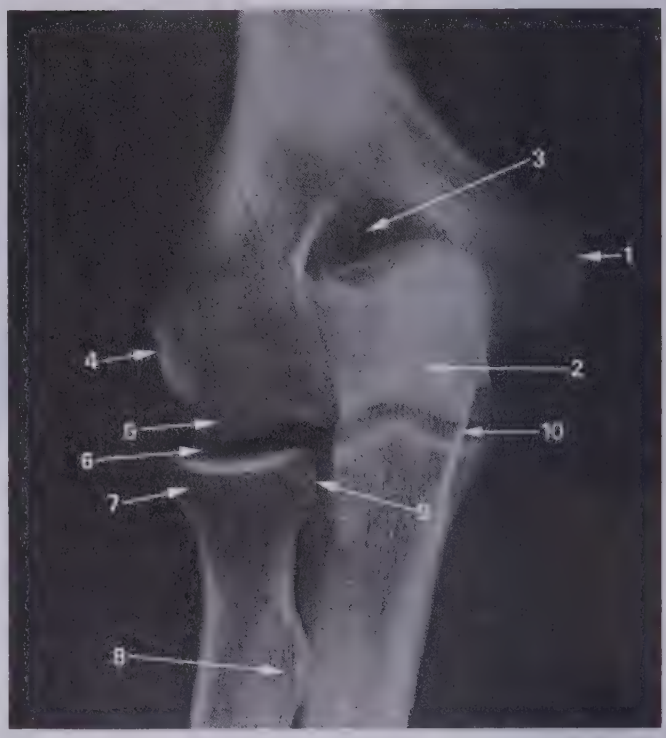
The annular ligament (4.45–47,49), a strong band, encircles the radial head, holding it against the ulna's radial notch. Forming about four-fifths of the ring, it is attached to the notch's anterior margin, broadens posteriorly and may divide into several bands and is attached to a rough ridge at or behind the notch's posterior margin; diverging bands may also reach the lateral margin of the trochlear notch above and proximal end of the supinator crest below. The proximal annular border blends with the cubital capsule, except posteriorly where the capsule passes deep to the ligament to reach the posterior and inferior margins of the radial notch. From the distal annular border a few fibres pass over reflected synovial membrane to

4.46 Transverse section of the right elbow joint to show the relations of the joint: superior aspect. Note the intracapsular fat 'tags' with meniscoid transverse-sectional profiles.

4.47 Distal socket of the superior radio-ulnar joint. The radial neck is transected and its head withdrawn. The socket consists of the chondrified aspect of the annular ligament, the articular cartilage of the radial notch of the ulna and the lax almost retiform quadrate 'ligament'. Section at the olecranon's base reveals, ventrally, the sellar articular surface of the coronoid part of the trochlear notch (humero-ulnar joint).

attach loosely on the radial neck. A thin, fibrous *quadrate ligament* covers the synovial membrane on the joint's distal surface (Martin 1958). The annular ligament's external surface blends with the radial collateral ligament and is an attachment of part of supinator. Posterior to it are anconeus and the interosseous recurrent artery. Internally the ligament is thinly covered by *cartilage* where it is in contact with the radial head; distally it is covered by synovial membrane, reflected up onto the radial neck.

THE MIDDLE RADIO-ULNAR UNION



The radial and ulnar shafts are connected by syndesmoses—an oblique cord and an interosseous membrane.

The oblique cord (4.49) is a small, inconstant, flat fascial band on the deep head of supinator, extending from the lateral side of the ulnar tuberosity to the radius a little distal to its tuberosity. Its fibres are at right angles to those in the interosseous membrane. Its functional significance is dubious.

The interosseous membrane (4.49) is a broad, thin, collagenous sheet, its fibres slanting distomedially between the radial and ulnar interosseous borders, its distal part attached to the posterior division of the radial border. Two or three posterior bands occasionally descend distolaterally across the other fibres. The membrane is proximally deficient, starting about 2 or 3 cm distal to the radial tuberosity. It is broader at mid-level and has an oval aperture near its distal margin conducting the anterior interosseous vessels to the back of the forearm. Between its proximal border and the oblique cord is a gap for the posterior interosseous vessels. The membrane augments attachments of the deep forearm muscles and connects the two bones. Its fibres appear to transmit to ulna and humerus forces acting proximally from hand to radius; however, it is only tense when the hand is midway between prone and supine positions and is relaxed in complete pronation and supination; the hand is usually pronated when subject to such forces. Moreover, the radius can transmit substantial forces directly to the humerus (Travill 1964). *Anteriorly* the membrane is related, in its proximal three-quarters, laterally to flexor pollicis longus and medially to flexor digitorum profundus, between them to the anterior interosseous vessels and nerve, and in its distal quarter to pronator quadratus; *posteriorly* are supinator, abductor pollicis longus, extensores pollicis brevis, pollicis longus and indicis and, near the carpus, the anterior interosseous artery and posterior interosseous nerve.

THE DISTAL RADIO-ULNAR JOINT

This is a uni-axial pivot between the ulna's convex distal end (head) and the concave ulnar notch of the radius; these surfaces are enclosed by a capsule and connected by an articular disc. The fibrous capsule is thicker in front and behind, proximally lax and lined by synovial membrane projecting proximally between radius and ulna as a *recessus sacciformis* in front of the distal part of the interosseous membrane (4.52).

A

B

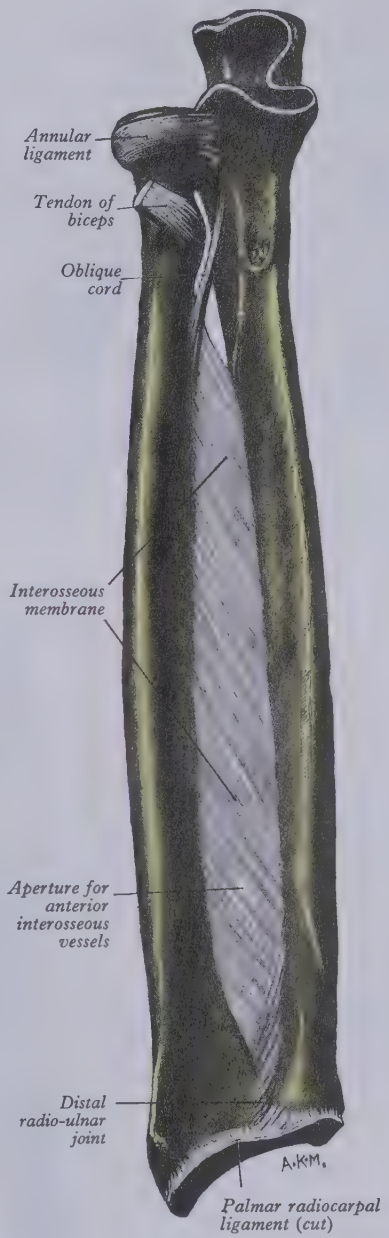
B. 1. Head of radius. 2. Profile of capitulum. 3. Profile of trochlea. 4. Olecranon.

The articular disc (4.52) is fibrocartilaginous (collagen and elastic fibres in the young) and is triangular, binding the distal ends of ulna and radius. Its periphery is thicker, its centre sometimes perforated. It is attached by a blunt, thick apex to a depression between the ulnar styloid process and distal articular surface and by its wider thin base to the prominent edge between the ulnar notch and carpal articular surface of the radius. Its margins are united to adjacent carpal ligaments, its surfaces smooth and concave; the proximal articulates with the ulnar head, the distal is part of the radiocarpal joint, articulating with the lunate bone and, when the hand is adducted, the triquetral. Mikić (1978) studied 180 wrist joints from 100 cadavers, ranging from fetuses to 94 years, and found that articular discs show age-dependent degeneration: progressively reduced cellularity, loss of elastic fibres, mucoid degeneration, exposure of collagen fibres, fibrillation, ulceration, abnormal thinning and ultimate perforation. No perforations appeared in the first two decades, 7.6% in the third, 18.1% in the fourth, 40% in the fifth, 42.8% in the sixth and 53.1% in those over 60. Comparable degenerative changes frequently occur in the 'discal' surfaces of ulna and lunate bone.

Movements. Movements at the radio-ulnar joint complex pronate and supinate the hand. In *pronation* the radius carrying the hand, turns anteromedially obliquely across the ulna, its proximal end remaining lateral, its distal becoming medial. During this action the interosseous membrane is *spiralized*. In *supination* the radius returns to a position lateral and parallel to the ulna (and the interosseous membrane is *despiralized*). The hand can be turned thus through 140°–150° and, with the elbow extended, this can be increased to nearly 360° by humeral rotation and scapular movements. Power is greater in supination, affecting the design of nuts, bolts and screws, which are tightened by supination in right-handed persons. Moreover, supination is an *anti-gravity* movement (with a pendant upper arm, and semiflexed forearm); in seizing objects for examination or manipulation, pronation is merely a preliminary and is *aided* by gravity.

The axis for pronation and supination is often represented as a line through the centre of the radial head (proximal) and the ulnar attachment of the articular disc (distal). More correctly this is the axis of movement *radius relative to ulna* and it *does not remain stationary*. The radial head rotates in the annular ligament and ulnar radial notch, its distal lower end and articular disc swing on the ulnar head. During rotation of the radial head in this ring its proximal surface spins on the humeral capitulum. The distal end of the ulna *is not stationary* during this; it moves a variable amount along a curved course, posterolaterally in pronation, anteromedially in supination. This entails that the axis, as defined above, is displaced laterally in pronation, medially in supination. Hence the axis for *supination and pronation of the whole forearm and hand* passes *between* the bones at both the proximal and distal radio-ulnar joints, when ulnar movement is marked, but through the centres of the radial head and ulnar styloid when it is minimal. The axis may be prolonged through any digit, depending on medial or lateral displacement of the distal end of the ulna (Ray et al 1951). Note that this displacement is not conjunct rotation; it can be varied at will. For example, the index finger and thumb, in a precision grip (p. 632), can describe arcs of varying radius according to functional demands. Greatest radius of arc involves minimal ulnar deviation, whereas rotation of opposed digits around a virtually fixed point (often necessary in manipulation of tools and instruments) involves marked and even maximal ulnar displacement. Ulnar movements are possible because of the incongruence of the trochlea and trochlear notch, therefore occurring *without* humeral rotation, whether the elbow is flexed, semiflexed or extended. Since this incongruence persists in all cubital positions, the 'close-packed position' of the humero-ulnar articulation at terminal elbow extension depends on ligaments rather than articular geometry.



Accessory movements include backward and forward translation of the radial head on the ulnar radial notch (p. 413) and the ulnar head likewise on the radial ulnar notch.

Muscles Producing the Movements

Pronation: pronator quadratus (p. 621), aided in rapid movement and against resistance by pronator teres (Basmajian & Travill 1961). Gravity also assists.

Supination: supinator, in slow unresisted movement and extension, assisted by biceps in fast movements in flexion, especially when resisted.

Electromyographic studies have not confirmed activity in brachioradialis during pronation and supination.

4.49 Interosseous membrane and oblique cord of the forearm: anterior aspect. Membrane and cord are syndesmoses.

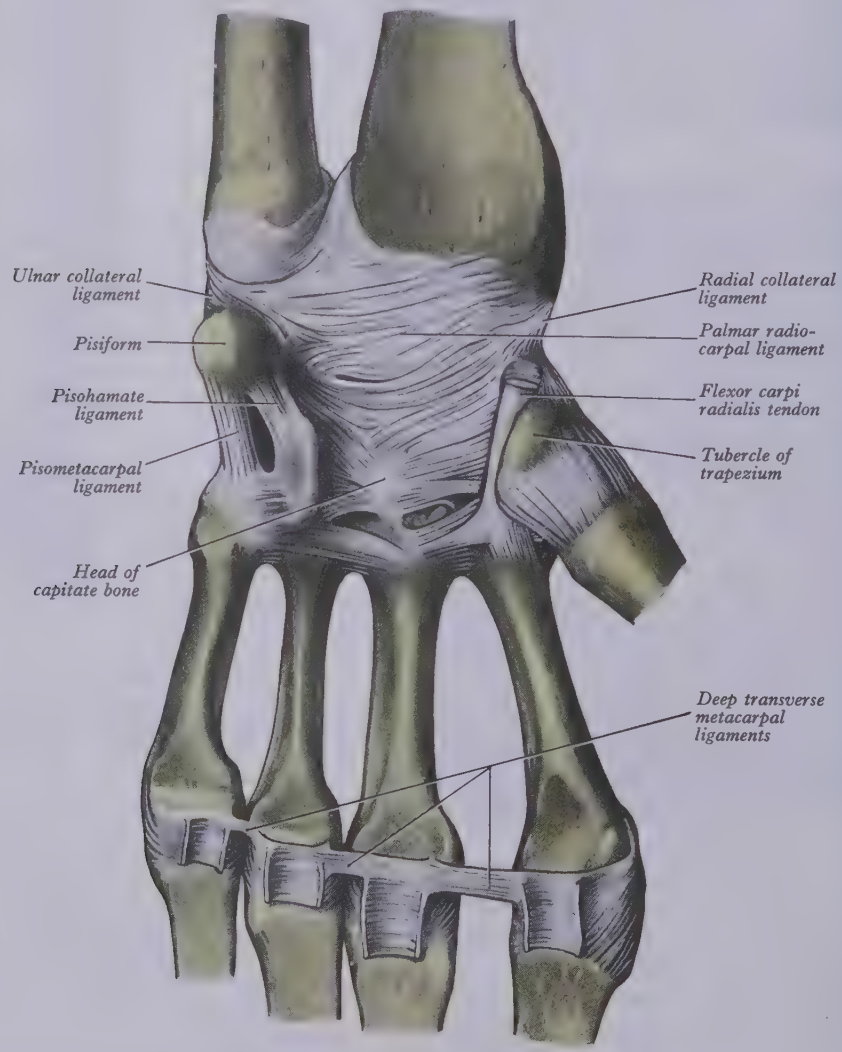
Applied Anatomy. At the elbow joint backward dislocation with ulnar abduction are commonest, the former often complicated by fracture of the coronoid process. Owing to the strength of collateral ligaments, the medial epicondyle is frequently torn off in lateral dislocations.

In acute synovitis the joint cavity becomes distended, bulging most around the olecranon, due to capsular laxity here. There is often some swelling above the radial head or the whole elbow may become fusiform.

Dislocation of the radial head alone is not uncommon, most frequently in youth from falls on the hand with forearm extended

and supinated, the head being displaced forwards, with rupture of the annular ligament. Occasionally a peculiar injury, supposedly a subluxation, occurs in children. The radial head appears to be displaced distally in the annular ligament; its upper border is folded over the head between it and the capitulum; the small size of the head in children predisposes to this. The forearm becomes fixed in semiflexion, midway between supination and pronation.

The Radiocarpal or Wrist Joint



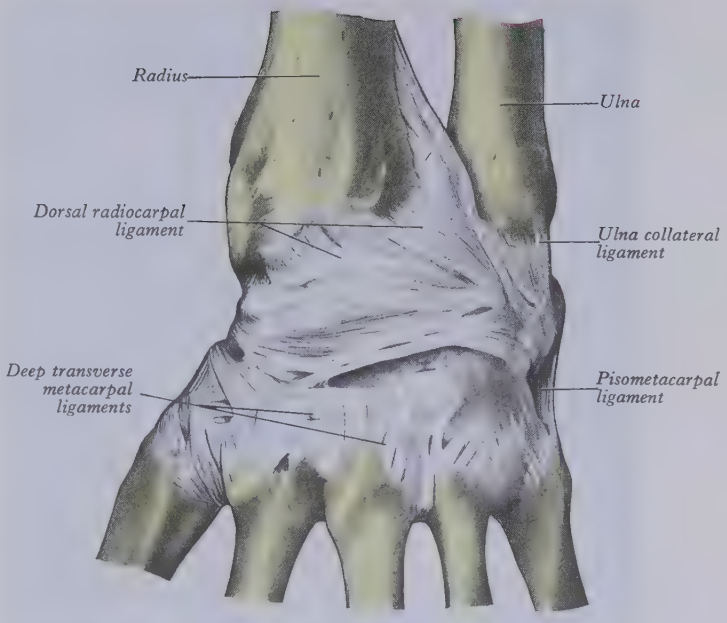
The radiocarpal joint (4.50,51,52), bi-axial and ellipsoid (vide infra), is formed by articulation of the distal end of the radius and the triangular articular disc with the scaphoid, lunate and triquetral bones. The radial articular surface and distal discal surface form an almost elliptical, concave surface with a transverse long axis; but the radial surface is bisected by a low ridge into two concavities. A similar ridge usually appears between the medial radial concavity and the concave distal discal surface. Proximal articular surfaces of scaphoid, lunate and triquetral bones and their interosseous ligaments form a smooth convex surface, received into the proximal concavity. Surface projection of the joint is a line, convex upwards, joining radial and ulnar styloid processes (4.52–54).

The articular capsule is lined by *synovial membrane* which is usually separate from that of the inferior radio-ulnar and intercarpal joints; but a protruding *prestyloid recess*, ventral to the articular disc, is present and ascends close to the styloid process. The recess is bounded distally by a *fibrocartilaginous meniscus*, projecting from the ulnar collateral ligament between the tip of the ulnar styloid process and the triquetral (4.52); both are clothed with hyaline articular cartilage. The meniscus may ossify (Lewis et al 1970). The capsule is strengthened by palmar radiocarpal and ulnocarpal, dorsal radiocarpal and radial and ulnar collateral ligaments.

The palmar radiocarpal ligament (4.50), a broad membranous band, is attached to the anterior margin of the distal end of the radius and its styloid process, its fibres passing distomedially to the anterior surfaces of scaphoid, lunate and triquetral bones, some reaching the capitate. It is partly intracapsular.

The palmar ulnocarpal ligament is a rounded fasciculus from the base of the ulnar styloid process and anterior margin of the articular disc to the lunate and triquetral bones. Lewis et al (1970) and Mayfield et al (1976) regard both palmar carpal ligaments as intracapsular; the latter also divide the radiocarpal ligament into three and the ulnocarpal ligament into two parts, each named by its attachments e.g. radiocapitate, ulnolunate, etc. It is not clear whether the ligaments are totally intracapsular, i.e. separate from the overlying articular capsule. (See also pp. 470 and 511.) The palmar carpal ligaments are perforated by vessels and are related anteriorly to tendons of flexores digitorum profundus and pollicis longus.

The dorsal radiocarpal ligament (4.51), thinner than the palmar, is attached to the posterior border of the distal end of the radius, its fibres descending distomedially to the dorsal surfaces of scaphoid, lunate and triquetral bones and continuing into the dorsal intercarpal ligaments. It is related posteriorly to the carpal and digital extensor tendons, their synovial sheaths and the posterior



510 4.50 Ligaments of the left wrist and metacarpus: palmar aspect.

interosseous nerve; anteriorly it is blended with the disc of the distal radio-ulnar articulation.

The ulnar collateral carpal ligament (4.50,51) is attached to the apex of the ulnar styloid process; it divides into two fasciculi, one attached to the medial side of the triquetral, the other to the pisiform bone. Attached to the ligament's deep (lateral) aspect is a small fibrocartilaginous *meniscus* which is the distal boundary of the synovial *prestyloid recess* (4.52, p. 510).

The radial collateral carpal ligament (4.50,51) extends from the tip of the radial styloid process to the radial side of the scaphoid bone; some fibres are prolonged to the trapezium. It is related to the radial artery, curving round laterally between the ligament and tendons of abductor pollicis longus and extensor pollicis brevis. Both collateral ligaments are relatively weak. *Arteries* supplying the joint are the anterior interosseous, anterior and posterior carpal branches of radial and ulnar, palmar and dorsal metacarpals and recurrent rami of the deep palmar arch. *Nerves* are from the anterior and posterior interosseous.

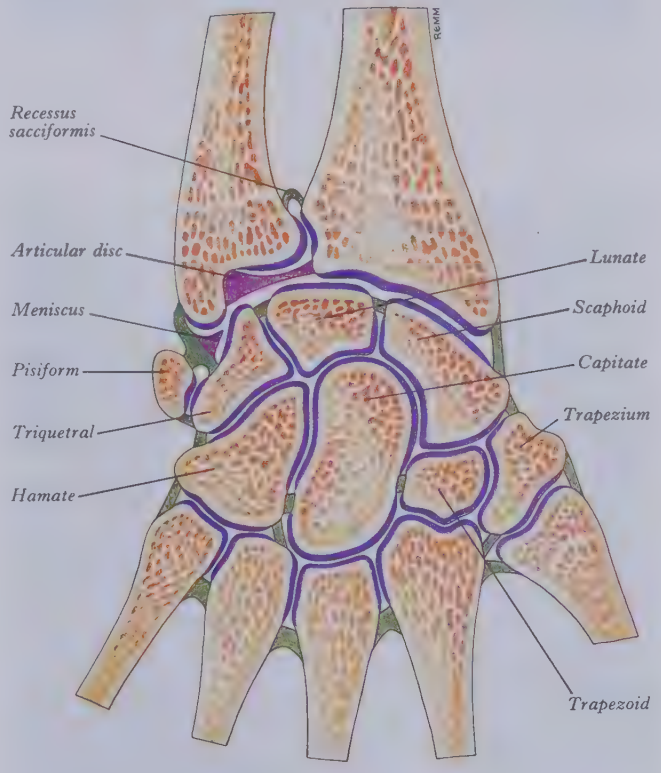
Movements accompany those of the intercarpal and midcarpal joints, described together on p. 512. The close-packed position is full extension.

4.51 Ligaments of the left wrist: dorsal aspect.

Intercarpal Joints

These interconnect carpal bones and may be summarized as (1) joints between the proximal carpal bones, (2) joints between the distal row, (3) a complex joint between the rows, the midcarpal joint. Carpal bones are connected by an extensive array of ligaments, not all specifically named. In addition to those described, the flexor retinaculum (p. 625) is an accessory intercarpal ligament. Articular surfaces are either sellar, ellipsoid or spheroidal.

JOINTS OF THE PROXIMAL CARPAL ROW



(*a*) The scaphoid, lunate and triquetral bones are connected by dorsal, palmar and interosseous ligaments.

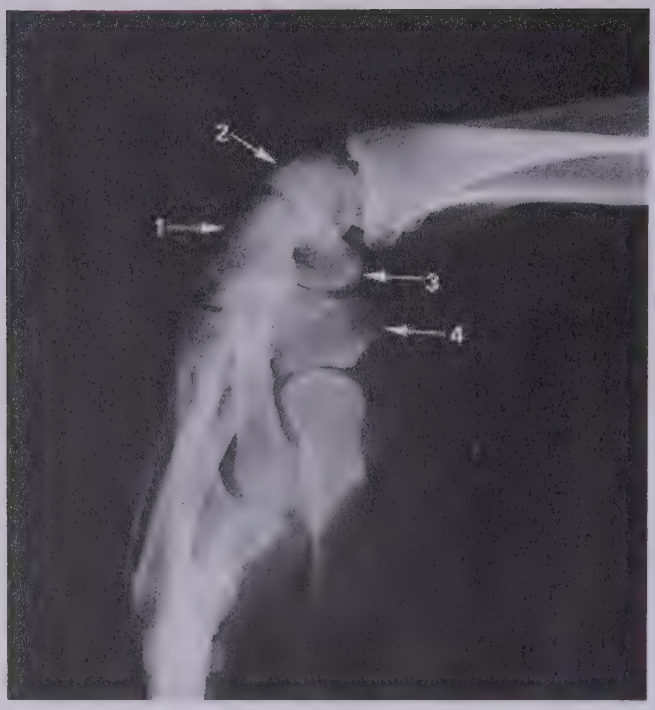
The dorsal and palmar ligaments are transverse, connecting scaphoid to lunate and lunate to triquetral. The palmar ligaments are weaker. Mayfield et al (1976) described a distinct ligament (in 28 dissections) between palmar aspects of capitate and triquetrum which crosses the hamate bone.

The interosseous ligaments (4.52), two narrow bundles, one connecting lunate and scaphoid, the other lunate and triquetral, are attached near their proximal surfaces, forming part of the convex articular radiocarpal surface.

(*b*) The pisiform articulates with the palmar surface of the triquetral bone at a small, oval, almost flat, synovial *pisotriquetral joint*; ligaments are the capsular, pisohamate and pisometacarpal. The thin capsule surrounds the joint; the synovial cavity is usually separate but may communicate with the radiocarpal joint.

The pisohamate and pisometacarpal ligaments connect the pisiform to the hamate's hook and the base of the fifth metacarpal respectively (4.50). Both are continuations of the tendon of flexor carpi ulnaris and are misnamed.

4.52 Coronal section through the distal ends of the radius and ulna, the carpus and the proximal ends of the metacarpals, showing the general form of the articular surfaces (blue), synovial cavities, interosseous ligaments (green) and fibrocartilages (purple). Partly after Lewis et al (1970).



JOINTS OF THE DISTAL CARPAL ROW

Bones of the distal carpal row are connected by dorsal, palmar and interosseous ligaments.

The dorsal and palmar ligaments extend transversely between trapezium and trapezoid, trapezoid and capitate, capitate and hamate bones. **The interosseous ligaments** are usually thicker than in the proximal row; three unite the four bones, that between capitate and hamate being strongest; one or both of the other two are often absent.

THE MIDCARPAL JOINT

This joint, between scaphoid, lunate and triquetral bones (proximally) and trapezium, trapezoid, capitate and hamate (distally) is a compound articulation divided descriptively into medial and lateral parts. Throughout most of the *medial compartment* the convexity of the capitate's head and hamate articulate with a reciprocal concavity formed by scaphoid, lunate and much of the triquetral bones; however, most medially the curvatures are reversed, thus forming a compound sellar joint. In the *lateral compartment* the trapezium and trapezoid articulate with the scaphoid, forming a second compound articulation, often said to be plane but which is also sellar. The ligaments are dorsal, palmar and collateral.

4.53A Radiograph of the hand and wrist in full flexion: lateral aspect. The arrows point to: (1) the capitate bone; (2) the lunate bone; (3) the tubercle of the scaphoid bone; (4) the tubercle of the trapezium. Compare with 4.53B and note the relative positions of the capitate and lunate, and the lunate and radius.

4.53B Radiograph of the hand and wrist: lateral aspect. The long axes of the third metacarpal bone, the capitate and the lunate are, approximately, in line with the long axis of the radius. The arrows point to the same structures as in 4.53A. Note the relative positions of the capitate and lunate, and the lunate and radius.

The dorsal and palmar ligaments are short, irregular bundles between the bones of the first and second carpal rows. Palmar fascicles radiate from the head of the capitate to surrounding bones as the *radiate carpal ligament*.

The collateral ligaments, radial and ulnar, are very short. The radial, stronger and more distinct, connects the scaphoid and trapezium, the ulnar connects triquetral and hamate; they are continuous with corresponding collateral ligaments of the wrist joint. A slender interosseous band sometimes connects capitate and scaphoid bones but does not completely divide the midcarpal synovial cavity.

The carpal synovial membrane is most extensive (4.52), lining a most irregular articular cavity, its proximal part between distal surfaces of the scaphoid, lunate and triquetral bones and the proximal surfaces of the second carpal row. It has proximal prolongations between scaphoid and lunate, lunate and triquetral and three distal prolongations between the four bones of the second row. The prolongation between trapezium and trapezoid or between trapezoid and capitate is, due to absence of an interosseous ligament, often continuous with corresponding carpometacarpal joints, variably from the second to fifth or often second and third only. If the latter, the joint between the hamate and fourth and fifth metacarpal bones has a separate synovial membrane; interposed (4.52) is the carpometacarpal interosseous ligament (p. 514). Synovial cavities of carpometacarpal joints are prolonged slightly between the metacarpal bases. The synovial joint between pisiform and triquetral is usually isolated.

4.53C Radiograph of the hand and wrist in full extension: lateral aspect. The arrows point to the same structures as in 4.53A. Compare with 4.53B and note the alterations in the relative positions of the capitate and lunate bones, and the lunate bone and the radius.

RADIOCARPAL AND INTERCARPAL MOVEMENTS

The movements of radiocarpal and intercarpal joints are considered together as a common mechanism acted on by the same muscles. Active movements are flexion (*c.* 85°), extension (*c.* 85°), adduction (ulnar deviation), abduction (radial deviation) and circumduction.

In *carpal flexion* radiocarpal and midcarpal joints are involved, the range being greater at the latter; in *extension* the reverse occurs, with more movement at the radiocarpal (4.53). Hence the proximal surfaces extend further posteriorly on the lunate and scaphoid bones. These movements are limited chiefly by antagonistic muscles; therefore the range of flexion is perceptibly diminished when fingers are flexed, due to increased tension in the extensors. Only when the joints are forced to the limits of flexion or extension are dorsal or palmar ligaments fully stretched (but vide infra).

Adduction of the hand (*c.* 45°) is considerably greater than abduction (*c.* 15°), perhaps due to the more proximal site of the

ulnar styloid process. Most adduction occurs at the radiocarpal joint; the lunate bone, articulating with both radius and articular disc when the hand is in midposition (4.52), in adduction passes off the disc to articulate solely with the radius (4.54A). Much of the proximal articular surface of the scaphoid becomes subcapsular beneath the radial collateral ligament and forms a smooth, convex, palpable prominence in the floor of the anatomical 'snuff box'.

Abduction occurs almost entirely at the midcarpal joint; radiographs of abducted hands show that the capitate rotates round an anteroposterior axis so that its head passes medially and the hamate conforms to this; the distance between lunate and the apex of hamate is increased (4.54B). The scaphoid rotates around a transverse axis; its proximal articular surface has retreated from the capsule and is now in sole articulation with the radius. Movements are limited by antagonistic muscles and, at extremes, by the collateral carpal ligaments.

Circumduction of the hand is not rotatory but successive flexion, adduction, extension and abduction or the reverse.

Abduction–adduction movements are of special functional value. The hand is commonly used with the carpus slightly extended and the forearm in midposition. Skilled abduction–adduction movements manipulate a large variety of precision tools, from fine needles to hammers.

Accessory movements are largely radiocarpal and more easily observed in flexion than extension. The carpus can be moved bodily backwards and forwards on the radius and articular disc and *rotated axially to a considerable extent*. Some side-to-side movement is also possible.

ADDITIONAL ANALYSIS OF RADIOCARPAL AND CARPAL MOVEMENTS

A 'link' joint has been suggested as the mechanical equivalent of the radiocarpal and medial midcarpal complex, in simple form illustrated by a bicycle chain. This is stable only when under tension and 'on centre' with links in line; unless strengthened by a 'stop' device it buckles under longitudinal compression, especially when 'off centre'. But some advantages are inherent: since the range of movement at each unit is less than the total, articular surfaces can be flatter than in a single joint of the same total range and are better adapted to pressure. Further, overlying tissues are less disturbed by squeezing at the extremes of movement.

Other views contrast sharply with the foregoing (MacConaill 1941). In most manual positions carpal bones are loose-packed and relatively mobile; they become a rigid block only in full extension, i.e. the close-packed position for radiocarpal and most carpal joints; close-packing is achieved in *two* stages (vide infra). The carpus is envisaged in four functional units: (1) trapezium, (2) scaphoid, (3) hamate, capitate and trapezoid, and (4) triquetrum and lunate. From full flexion to full extension the stages considered to occur are: firstly the distal row (3) moves on the proximal (2 and 4) until hand and forearm are in line, hamate, capitate, trapezoid and scaphoid coming into mutual close-pack to form a rigid mass (i.e. 2 + 3). Secondly this mass moves upon the triquetrum and lunate, which move at the radiocarpal joint until full extension is reached, with close-packing of the radiocarpal and most carpal joints (i.e. except articulations of pisiform and trapezium). In this position, adopted only for special effort, very large forces can be transmitted through the articular structures. A similar position is often adopted to resist falls on the outstretched hand, and commonly results in damage, e.g. a 'supination' (Colles') fracture of radius, fracture of scaphoid or dislocation of lunate. Mayfield et al (1976), studying the behaviour of carpal ligaments in experimental carpal fractures, have corroborated this dorsal 'locking' of the carpus and made further analysis of the roles of carpal ligaments in progressive intercarpal slides ending in close-packing. During initial stages of the movement, the scaphoid acts with the proximal carpal row but in later stages with the distal row. The trapezioscaphoid joint is not considered involved in general close-packing of the carpus, perhaps due to the thumb's functional independence when the remainder of the carpus becomes a rigid mass.

4.54A Radiograph of the hand in full adduction. The arrows point to the scaphoid bone on the lateral side and to the pisiform bone on the medial side. Note that the shadow of the pisiform bone overlaps the shadow of the tip of the styloid process of the ulna. Compare with 4.54B and observe that the movements occur at both the radiocarpal and intercarpal joints.

4.54B Radiograph of the same hand in full abduction. The arrows point to the hamate and pisiform bones. Compare with 4.54A and note that: (1) the scaphoid and lunate bones have passed medially so that the latter articulates to a large extent with the articular disc of the inferior radioulnar joint; (2) the pisiform is now widely separated from the styloid process of the ulna; (3) the scaphoid, having rotated round a transverse axis, is much foreshortened; (4) the apex of the hamate bone has been thrust away from the lunate by the rotation of the capitate around an anteroposterior axis; (5) a gap has opened up between the distal portions of the hamate and triquetral bones; and (6) the long axes of the capitate and lunate bones are now almost in the same straight line.

Further analysis by Kauer (1974) continues the concept of articular links but emphasizes *rotations* of lunate and scaphoid relative to radius and disc; during flexion–extension both rotate relative to each other and to the capitate. Proximal curvatures of lunate and scaphoid are different, dictating some independence of movement, although this is limited, their interdependence being determined by the biomechanical properties of their interosseous ligament.

Muscles Producing Carpal Movements

Flexion: flexores carpi radialis and ulnaris and palmaris longus, assisted by flexores digitorum superficialis and profundus, flexor pollicis longus and abductor pollicis longus.

Extension: extensores carpi radiales longus, brevis and ulnaris, assisted by extensores digitorum, digiti minimi, indicis and pollicis longus.

Adduction: flexor and extensor carpi ulnaris in unison.

Abduction: flexor carpi radialis, extensores carpi radiales longus and brevis in unison, with abductor pollicis longus and extensor pollicis brevis.

Carpometacarpal Joints

THE CARPOMETACARPAL JOINT OF THE POLLEX (THUMB)

This *sellar* joint, between the first metacarpal base and the trapezium, enjoys wide mobility due to its extensive articular surfaces and their topology. It has a fibrous capsule, thick but loose, extending from the circumference of the metacarpal base to the rough rim of the distal trapezial articular facet; it is thickest laterally and dorsally. The synovial membrane is separate (**4**.52). The first metacarpal and trapezium are connected by lateral, anterior and posterior ligaments and the capsule.

The broad *lateral ligament* runs from the lateral trapezial surface to the radial side of the metacarpal base. The *palmar* and *dorsal ligaments* are oblique bands converging to the ulnar side of the metacarpal base from the palmar and dorsal trapezial surfaces respectively.

Relations. The joint's *palmar surface* is covered by the thenar muscles, its *dorsal surface* by long and short extensors. *Medial* is the first dorsal interosseous muscle and radial artery, the latter passing through the first interosseous space, and the tendon of flexor pollicis longus; *lateral* is the tendon of abductor pollicis longus and that of extensor pollicis brevis.

Movements. *Active* movements are flexion–extension, abduction–adduction, rotation, and circumduction. In the resting position of the first metacarpal bone (p. 634) flexion and extension are parallel to the palmar plane, abduction and adduction at right angles to this. Except at initiation, flexion is accompanied by medial rotation; conversely, medial rotation involves flexion. Linkage of movements is largely due to the articular sellar shape imposing some conjunct rotation and to obliquity of the dorsal ligament, which when taut anchors the ulnar side of the metacarpal base while its radial side continues to move. Contraction of flexor pollicis brevis, assisted by opponens pollicis, hence produces medial rotation with flexion (Napier 1955); combined with abduction this brings the pollicial pulp into contact with those of slightly flexed fingers, a movement termed *opposition*. (The flexed fingers have varying degrees of *lateral metacarpophalangeal rotation*, minimal in the index but maximal in minimus.) Conversely, full extension of the pollicial metacarpal entails slight lateral rotation (Kuczynski 1974), attributable also to the sellar form of joint and to action of the *palmar* ligament, similar to the dorsal ligament in flexion (vide supra).

These rotations are conjunct, inevitably accompanying flexion–extension, with spiralization and tautening of the joint capsule and balanced conarticular compression at extremes of these movements. Close-packing is said to occur in powerful opposition, when greatest forces are transmitted to the joint. (For analyses consult Haines 1944, Kapandji 1963, 1970, Kuczynski 1974, MacConaill & Basmajian 1977.)

Accessory movements are axial rotation in the position of rest, and distraction.

Muscles Producing the Movements

Flexion: flexor pollicis brevis and opponens pollicis, aided by flexor pollicis longus when the other joints of the thumb are flexed. Flexion entails medial rotation.

Extension: abductor pollicis longus and extensores pollicis brevis and longus. In full extension extensor pollicis longus, owing to its oblique pull and the disposition of the palmar ligament, rotates the thumb laterally and draws it dorsally, i.e. slightly adducts it.

Abduction: abductores pollicis brevis and longus. When abduction is maximal the digit and metacarpal are not in line, the pollex being abducted at both metacarpophalangeal and carpometacarpal joints.

Adduction: adductor pollicis alone.

Opposition: opponens pollicis and flexor brevis pollicis simultaneously flex and medially rotate the abducted pollex. Interpulpal pressure, or that generated by digital grasping, is increased by adductor pollicis and flexor pollicis longus.

Circumduction: the above muscle groups acting consecutively, extensors, abductors, flexors and adductors in this or reverse order.

THE SECOND TO FIFTH CARPOMETACARPAL JOINTS

Joints between the carpus and second to fifth metacarpal bones, although widely classed as plane, have curved articular surfaces often of complex sellar shape (pp. 477–480). The bones are united by articular capsules, dorsal, palmar and interosseous ligaments.

The dorsal ligaments are strongest, connecting the dorsal surfaces of the carpal and metacarpal bones. The second metacarpal has two, from trapezium and trapezoid; the third also has two, from trapezoid and capitate; the fourth two, from capitate and hamate; the fifth a single band from the hamate continuous with a similar palmar ligament, forming an incomplete capsule.

The palmar ligaments are similar, except for the third metacarpal, which has three: a lateral from the trapezium, superficial to the tendon sheath of flexor carpi radialis, an intermediate from the capitate and a medial from the hamate bone.

The interosseous ligaments are two short, thick, fibrous bands and limited to one part of the carpometacarpal articulation; they connect contiguous distal margins of capitate and hamate with adjacent surfaces of the third and fourth metacarpal bones and proximally they may be united.

The synovial membranes are often continuous with those of the intercarpal joints. Occasionally, the joint between the hamate and fourth and fifth metacarpal bones has a separate synovial cavity, bounded laterally by the medial interosseous ligament and its extensions to the palmar and dorsal parts of the capsule (**4**.52).

Intermetacarpal Joints

The second to fifth metacarpal bases articulate reciprocally by small cartilage-covered facets connected by dorsal, palmar and interosseous ligaments.

The dorsal and palmar ligaments pass transversely from bone to bone, **interosseous ligaments** connecting contiguous surfaces just distal to their articular facets. **The synovial membranes** are continuous with those of the carpometacarpal articulations.

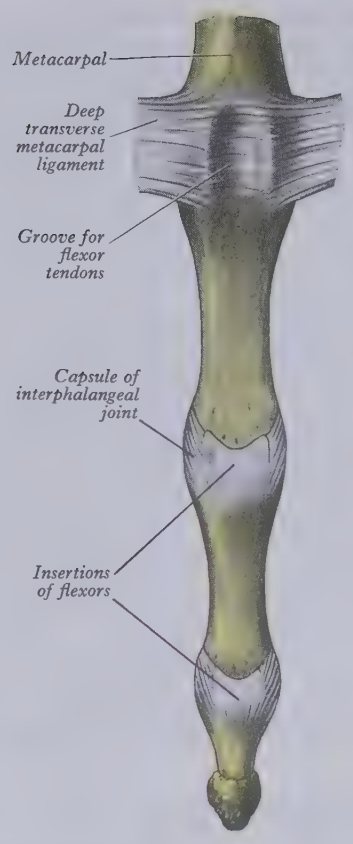
Movements at carpometacarpal and intermetacarpal articulations are limited to slight gliding, sufficient, however, to permit some flexion-extension and adjunct rotation, ranges varying in different joints. They are *partly* accessory movements of the first type (p. 484), occurring when the palm is 'cupped', as in grasping an object. Active movements also occur and are familiar, e.g. to the pianist or violinist. The fifth metacarpal is most movable, then the fourth, the second and third being least mobile. These variations are easily demonstrated by opposing each digit to the thumb over the palmar centre. About two-thirds of the movements are pollicial, as described above, but during opposition to minimus,

the latter is flexed, abducted and laterally rotated, accounting for the remaining third. These actions occur at both the carpometacarpal and metocarpophalangeal joints. (For a more extensive description of digital, including pollicial movement see below.) The close-packed position probably coincides with carpal extension, as in gripping. Further accessory movements are spiral twisting of the whole metacarpus on the carpus.

Metacarpophalangeal Joints

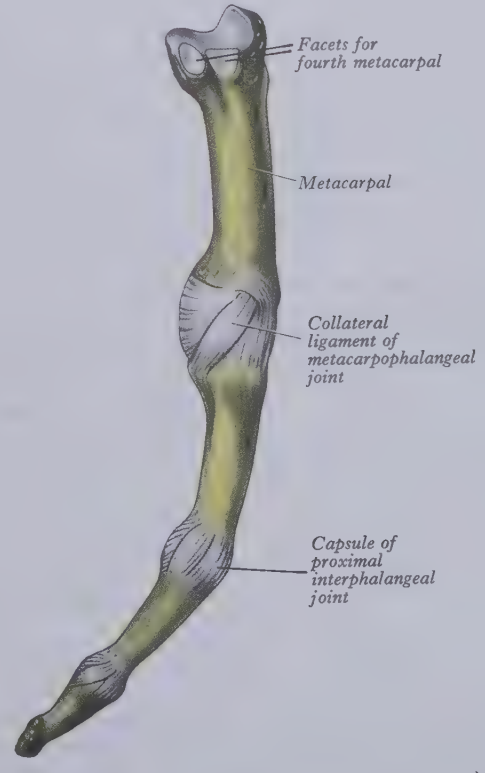
These (4.55A,B) are usually considered ellipsoid, but metacarpal heads, adapted to shallow concavities on the phalangeal bases, are not regularly convex but partially divided on their palmar aspects and thus almost bicondylar (pp. 418, 420). Each joint has a palmar and two collateral ligaments.

The palmar ligaments are unusual, being thick, dense and fibrocartilaginous, sited between the collateral ligaments and connected to them. They are attached loosely to metacarpal bones but firmly to the phalangeal bases. Their palmar aspects are blended with deep transverse palmar ligaments and are grooved for the flexor tendons, whose fibrous sheaths connect with the sides of the grooves. Their deep surfaces increase articular areas for the metacarpal heads.



The deep transverse metacarpal ligaments are three short, wide, flat bands connecting the palmar ligaments of the second to fifth metacarpophalangeal joints (4.55A) and related anteriorly to the lumbricals and digital vessels and nerves, posteriorly to interossei. Bands from the digital slips of the central palmar aponeurosis join their palmar surfaces (p. 627). On both sides of the third and fourth metacarpophalangeal joints (but only the ulnar side of the second and radial side of the fifth) transverse bands of the dorsal digital expansions (p. 632) join the deep transverse metacarpal ligaments; *ventral* to this band are the lumbricals and phalangeal attachments of dorsal interossei and *dorsal* to it are the remaining attachments of dorsal interossei and palmar interossei (p. 622 and 5.70,71).

The collateral ligaments, strong, round cords, flank the joints, each attached to the posterior tubercle and adjacent pit on the side of its metacarpal head and each passing distoventrally to the side of the ventral aspect of its phalangeal base (4.55B).



On dorsal surfaces of these joints the fibrous capsules are thin and often separated from extensor tendons by bursae (5.70). In a proportion of instances, however, part of the long extensor tendon is intercalated into the dorsal capsule and some authorities then regard the tendon as forming the capsule on this aspect. Their sensory nerve supply has been detailed by Sathian & Devanandan (1983), who found abundant Paciniform corpuscles but few Ruffini endings and no Golgi type receptors in association with these joints.

Movements are flexion, extension, adduction, abduction, circumduction, and limited rotation, the last of which cannot occur in isolation but may accompany flexion–extension; this, however, can be initiated voluntarily in the free hand (e.g. each finger flexing and rotating to place its tip near the palmar centre); the *range* of rotation is frequently increased due to the resistance of a grasped object. Extension ranges a few degrees, flexion is almost 90°; both are limited chiefly by antagonistic muscles but flexion is commonly terminated by resistance of a grasped object. Abduction and adduction are also relatively small and in flexion negligible. The pollicial metacarpophalangeal joint has a flexion–extension range of about 60° (almost entirely flexion); other movements are adduction–abduction (maximal range 25°) which invariably accompanies the corresponding carpometacarpal movements and increases their combined range; also some slight conjunct rotation, but greater adjunct rotation, accompanying flexion–extension. Of the other metacarpophalangeal joints the second is most mobile in adduction–abduction (*c.*30°), followed by fifth, fourth and third. (For further analyses of these movements see p. 632 et seq.)

Accessory movements are further rotation (marked in the thumb), anteroposterior and lateral translation of a phalanx or metacarpal, and distraction.

4.55A Metacarpophalangeal and digital joints of the middle finger: palmar aspect.

4.55B Metacarpophalangeal and digital joints of the right third finger: medial aspect.

Muscles Producing the Movements

Flexion: flexores digitorum superficialis and profundus, assisted by lumbricals and interossei (Long et al 1961) and, in the minimus, by flexor digiti minimi brevis; in the pollex, by flexores pollicis longus and brevis and the first palmar interosseous. Slight lateral rotation accompanies digital flexion of digits 3–5. Flexion of the index may be accompanied by minimal lateral or no rotation; frequently a small degree of *medial* rotation can be observed.

Extension: in the third and fourth digits extensor digitorum, assisted respectively in second and fifth by extensor indicis and extensor digiti minimi; in the thumb, by extensores pollicis longus and brevis.

Adduction: in extended fingers, palmar interossei; during flexion long flexors are predominant. In the pollex the limited metacarpophalangeal adduction possible is slightly attributable to adductor pollicis and first palmar interosseous.

Abduction: in extended fingers, dorsal interossei assisted by long extensors except in the middle finger; in minimus the abductor digiti minimi. In the thumb, abductor pollicis brevis produces the slight abduction possible, most often one factor contributing to opposition. When fingers are flexed, active abduction is impossible; but, if the long digital flexors are inactive, passive abduction is free. Inability to abduct actively in this position may be due to shortening of the dorsal interossei and abductor digiti minimi by flexion, but the altered line of pull of the interossei relative to the axis of movement is probably the determining factor; while in digital extension the axis of lateral movements is anteroposterior, in flexion it is proximodistal, the line of pull of the interossei being then nearly *parallel* to the axis.

Interphalangeal Joints

These are uni-axial hinge joints (**4**.55A,B), each with a fibrous capsule, palmar and two collateral ligaments, arranged as in the metacarpophalangeal joints (p. 514). Long extensor tendons take the place of the dorsal capsular ligaments.

Movements (active) at interphalangeal joints are flexion and extension, greater in range at proximal joints. Flexion is considerable, extension limited by tension of digital flexors and terminated by tension in palmar ligaments and conarticular compression. Full extension is the close-packed position, assumed whenever fingers are used as props to transmit body weight or powerful thrust. (In contrast alternatively the fully clenched fist may be used.) Flexion and extension are accompanied by slight conjunct rotation; during flexion this turns the digital pulps slightly laterally, i.e. to face the opposed thumb. An opposite rotation occurs during extension (vide supra.)

Accessory movements are limited rotation, abduction, adduction and anteroposterior translation. These permit the fingers to adapt to shapes of objects gripped and provide against stresses and strains.

Muscles Producing Movements

Flexion: at proximal interphalangeal joints, flexores digitorum superficialis and profundus; at the distal, flexor digitorum profundus; at the pollicial interphalangeal joint, flexor pollicis longus.

Extension: extensores digitorum, digiti minimi and pollicis longus, in association with abductor pollicis longus and extensor pollicis brevis. Extension occurs simultaneously in both joints in digits 2–5.

Simultaneous *flexion* at metacarpophalangeal and *extension* at interphalangeal joints of a digit are essential in the fine movements of writing, drawing, threading a needle etc. Lumbricals and interossei have long been accepted as not only primary agents in flexing metacarpophalangeal joints but also in extending interphalangeal joints via their attachments to the dorsal digital expansions (p. 630). Also, when lumbricals and interossei flex metacarpophalangeal joints, it has been claimed that balance between the tension of digital flexors and extensors alters in favour of extensors and that this alone is responsible for the extension of interphalangeal joints (Braithwaite et al 1948). However, lumbricals and interossei alone can both extend these joints (Sunderland 1945b, see also p. 632).

Flexure Lines of Wrist and Hand

Flexure lines commonly crease the skin across flexor surfaces of wrist and hand (**6**.105). Though not all directly over their functionally related subjacent skeletal joints they result from adhesion of skin to subjacent deep fascia and are sites of folding of skin during movement. Such flexures have often hence been termed 'skin joints'. They are useful landmarks. Less often mentioned, but quite prominent, although less regular, there are crease-line complexes, mainly transverse but with varying curvatures, which are centred over the *dorsal (extensor)* aspects of the radiocarpal, carpal, metacarpophalangeal and interphalangeal joints. During flexion the dorsal skin is stretched and the lines become less prominent (but can still be identified). During extension the now redundant skin becomes increasingly puckered and the lines are finally maximally prominent. (For a general review of 'skin lines' see p. 80.)

Near the junction of carpus and forearm there are usually three *ventral* transverse lines; the proximal marks the proximal limit of flexor synovial sheaths, an intermediate line overlies the wrist joint and a distal line is at the proximal border of the flexor retinaculum.

In the palm a curved *radial longitudinal line* encircles the thenar eminence, ending at the palm's lateral margin; medial and roughly parallel to it are several less constant longitudinal lines. *Proximal* and *distal transverse lines* ascend medially across the palm. The proximal begins at the distal end of the radial longitudinal line and runs obliquely to the middle of the hypothenar eminence across the shafts of metacarpal bones; the distal begins at or near the cleft between the index and medius and traverses the palm with a proximal convexity over the second to fourth metacarpal heads, near the proximal ends of fibrous flexor sheaths.

The second to fifth digits show proximal, middle and distal sets of transverse lines. The *proximal*, often double, are at the digital roots, about 2 cm *distal* to the metacarpophalangeal joints; the *middle* are typically double, proximal members being *directly over* the proximal interphalangeal joints; the *distal* lines, usually single, are *proximal* to the distal interphalangeal joints, their levels sometimes marked by a fainter, more distal line. The free pollicial base is partly encircled by a line starting on the radial side and crossing distally over the metacarpophalangeal joint to end between pollex and index level with the base of the proximal pollicial phalanx. A second, shorter crease is about 1 cm distal to this. At the interphalangeal joint of the thumb are two lines comparable to middle digital lines in other digits.

JOINTS OF THE LOWER LIMB

The Sacro-iliac Joint

This synovial articulation between sacral and iliac auricular surfaces (**4**.59), although often termed plane, is nearly flat only in infants; in adults surfaces are irregular, often markedly, and sometimes sinuous. Their curvatures and irregularities, greater in males, are reciprocal; they restrict movements and contribute to the joint's considerable strength in transmitting weight from the vertebral column to the lower limbs. According to Putschar (1931) and Schunke (1938) the sacral surface is covered by hyaline cartilage and the iliac by fibrocartilage, an unusual arrangement (but not subsequently confirmed). Fibrous adhesions and gradual

obliteration occur in both sexes, earlier in males, after the menopause in females. A radiological study of 94 healthy individuals (Cohen et al 1967) showed such changes in 6% before 50 years, in 24% thereafter. In old age the joint may be completely fibrosed and occasionally even ossified. The *articular capsule* is attached close to both articular margins. Ligaments are ventral, interosseous and dorsal sacro-iliac.

The ventral sacro-iliac ligament (4.56) is an anteroinferior capsular thickening, particularly well-developed near the arcuate line and posterior inferior iliac spine, where it connects the third sacral segment to the lateral side of the pre-auricular sulcus. It is thin elsewhere.

The interosseous sacro-iliac ligament (not officially recognized but the largest typical *syndesmosis*, p. 468), is the massive chief bond between the bones and fills the irregular space posterosuperior to the joint (4.60); it is covered superficially by the dorsal sacro-iliac ligament. Its deeper part has superior and inferior bands passing from depressions posterior to the sacral auricular surface to those on the iliac tuberosity. These bands are covered by, and blend with, a more superficial fibrous sheet connecting the dorsosuperior margin of a rough area posterior to the sacral auricular surface to the corresponding margins of the iliac tuberosity. This sheet is often partially divided into superior and inferior parts, the former uniting the superior articular process and lateral crest on the first two sacral segments to the neighbouring ilium as a *short posterior iliac ligament* (4.57).

The dorsal sacro-iliac ligament lies over the interosseous, but intervening are the dorsal rami of sacral spinal nerves and vessels. It has several weak fasciculi connecting the intermediate and, below this, the lateral sacral crests to the posterior superior iliac spine and internal lip of the iliac crest at its dorsal end. Inferior fibres, from the third and fourth sacral segments, ascending to the posterior superior iliac spine, may form a separate *long posterior sacro-iliac ligament* (4.57); the latter is continuous laterally with part of the sacrotuberous ligament and medially with the thoracolumbar fascia's posterior lamina (Weisl 1954a).

Accessory synovial articulations between lateral sacral crest and posterior superior iliac spine and iliac tuberosity are not uncommon (Trotter 1937).

Movements. A little anteroposterior rotation occurs around a transverse axis about 5–10 cm vertically below the sacral promontory (Weisl 1955). This accompanies flexion and extension of the trunk; its range is the same in males and non-pregnant females; it is increased in pregnancy. The greatest sacral movement relative to the iliac bones is in rising from a recumbent to a standing position (4.61). The sacral promontory advances as much as 5–6 mm as body weight impinges on the sacrum; backward movement of the lower end of the sacrum is less. Movement is not simple rotation, the axis being dynamic (Weisl 1953); some translation is associated with it.

VERTEBROPELVIC LIGAMENTS

Each ilium is connected to the fifth lumbar vertebra by an *iliolumbar ligament* (p. 324, 4.56) and the sacrum to the ischium by *sacrotuberous* and *sacrospinous ligaments*. (Further attachments are detailed below.)

The sacrotuberous ligament (4.56,57) is broadly attached by its base to the posterior iliac spine, partly blended with the dorsal sacro-iliac ligaments, to the lower transverse sacral tubercles and the lateral margins of the lower sacrum and upper coccyx. Its oblique fibres descend laterally, converging to form a thick, narrow band which widens again below and is attached to the ischial tuberosity's medial margin. It then spreads along the ischial ramus as the *falciform process*, whose concave edge blends with the fascial sheath of internal pudendal vessels (p. 778) and pudendal nerve. To the sacrotuberous ligament's posterior surface are attached the lowest fibres of gluteus maximus; superficial fibres of the ligament's lower part continue into the tendon of biceps femoris. The ligament is pierced by coccygeal branches of the inferior gluteal artery, the perforating cutaneous nerve and filaments of the coccygeal plexus.

The sacrospinous ligament (4.56), thin and triangular, extends from the ischial spine to the lateral margins of sacrum and coccyx anterior to the sacrotuberous ligament with which it blends. Its anterior surface is *muscular* and constitutes the coccygeus; the ligament is often regarded as a degenerate part of the muscle. (When pelvic and gluteal topographical relations are under consideration, it must be emphasized that muscle and ligament are co-extensive and are the ventral and dorsal aspects of the *same structure*.)

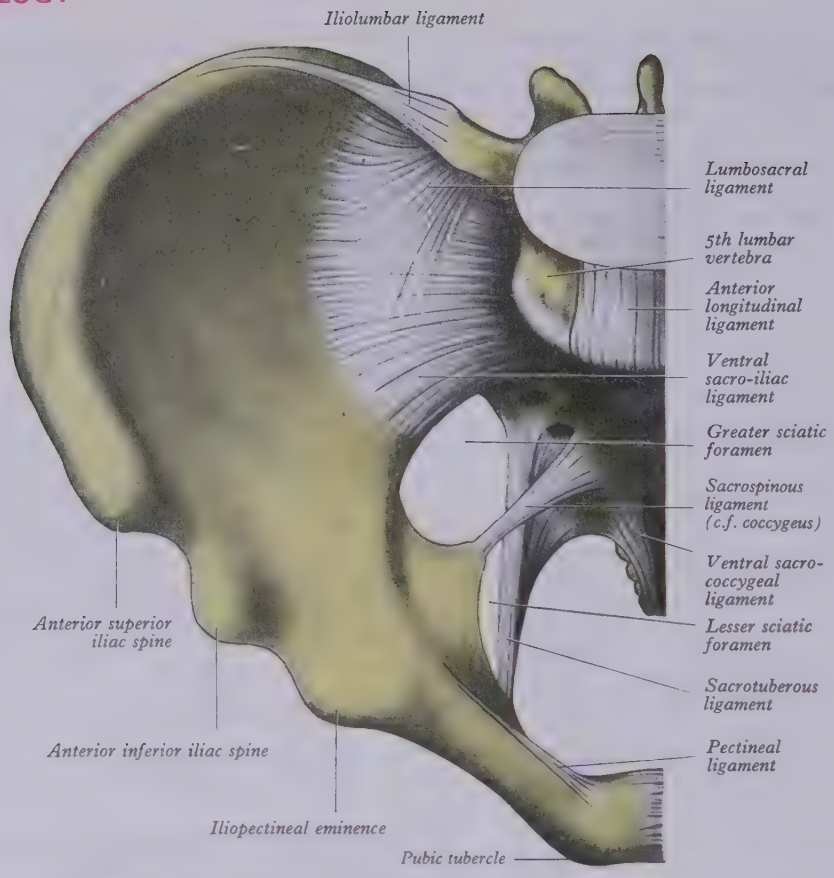
The sacrotuberous and sacrospinous ligaments oppose upward tilting of the lower part of the sacrum under downward thrust at its upper end (vide infra). They also convert the sciatic notches into foramina.

The greater sciatic foramen is bounded anterosuperiorly by the greater sciatic notch, posteriorly by the sacrotuberous and inferiorly by the sacrospinous ligament and ischial spine. It is partly filled by the emerging piriformis, above which the superior gluteal vessels and nerve leave the pelvis; below it, the inferior gluteal vessels and nerve, internal pudendal vessels and pudendal nerve, sciatic and posterior femoral cutaneous nerves and nerves to obturator internus and quadratus femoris also leave the pelvis.

The lesser sciatic foramen is bounded anteriorly by the ischial body, superiorly by its spine and sacrospinous ligament, posteriorly by the sacrotuberous ligament. It transmits the tendon of obturator internus, the muscle's nerve and the internal pudendal vessels and pudendal nerve.

The Pubic Symphysis

The pubic bones meet in the midline at a fibrocartilaginous *pubis symphysis* (4.58), connected by superior and arcuate pubic ligaments.



The superior pubic ligament connects the bones above, extending to the pubic tubercles. **The arcuate pubic ligament**, a thick arch of fibres, connects the lower borders of the symphysial pubic surfaces, bounding the pubic arch. Superiorly it blends with the interpubic disc and extends laterally attached to the inferior pubic rami; its base is separated from the ventral border of the urogenital diaphragm by an opening for the deep dorsal vein of penis or clitoris.

The interpubic disc connects the medial pubic surfaces, each covered by a thin layer of tightly adherent hyaline cartilage (surface growth cartilage in the young). The junction is not flat (p. 426) but marked by reciprocal crests and papillae. Theoretically this would resist shearing. The surfaces of hyaline cartilage are connected by fibrocartilage, varying in thickness. It often contains a cavity, probably due to absorption, rarely appearing before the tenth year and non-synovial. Better developed in females, it is usually posterosuperior but may reach the front or even occupy most of the cartilage (4.58). The disc is strengthened anteriorly by several interlacing collagenous fibrous layers, passing obliquely from bone to bone, decussating and interweaving with fibres of the external oblique aponeuroses and the medial tendons of the recti abdominis.

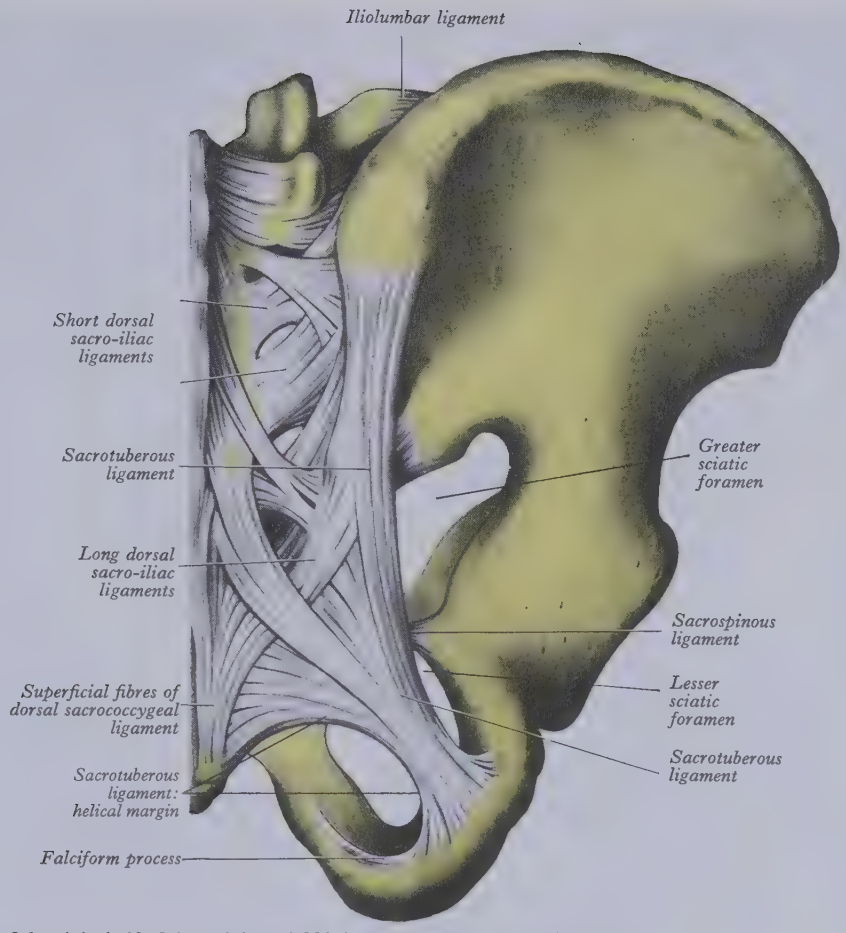
Movements have been little described. Angulation, rotation and displacement are possible but slight and are likely in activities at the sacro-iliac and hip joints. Some separation is held to occur late in gestation and during childbirth.

The Pelvic Mechanism

The skeletal pelvis undoubtedly supports and protects contained viscera, but is primarily part of the lower limbs, affording wide attachment for leg and trunk muscles. It is the major mechanism in transmitting the weight of head, trunk and upper limbs to the legs. It may be considered as two arches divided by a vertical transacetabular plane. The posterior arch, chiefly concerned in transmitting weight, consists of the upper three sacral vertebrae and strong pillars of bone from the sacro-iliac joints to the acetabular fossae (p. 428). The anterior arch, formed by the pubic bones and their superior rami, connects these lateral pillars as a tie-beam preventing separation; it also acts as a compression strut against medial femoral thrust. The sacrum, as summit of the posterior arch, is loaded at the lumbosacral joint; theoretically this force has two components, one thrusting the sacrum down

4.56 Joints and ligaments of the right half of the pelvis: ventral aspect. Anterior superior iliac spine and pubic tubercle are in the same coronal plane. Note the inclination of the 'brim' (inlet) of the lesser (true) pelvis, the boundaries of the sciatic foramina and the (partly obscured) pelvic outlet.

and back between the iliac bones, the other thrusting its upper end down and forwards. Sacral movements are regulated by osseous shape and massive ligaments. The sacrum is a tilted wedge, its base anterosuperior. The first component therefore acts against the wedge, its tendency to separate iliac bones resisted by the sacro-iliac and iliolumbar ligaments and symphysis pubis.

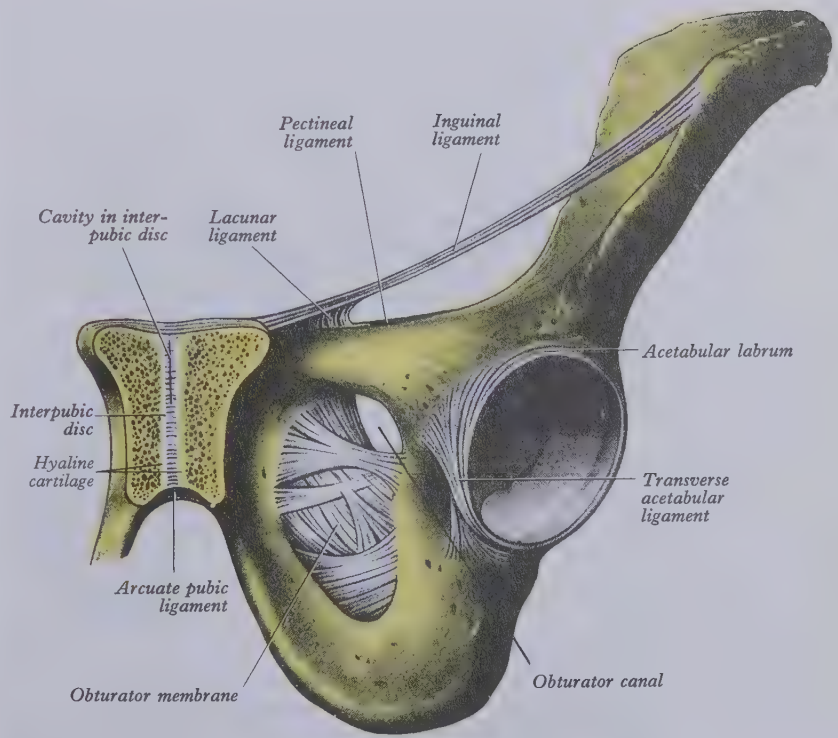


Vertical coronal sections through the sacro-iliac joints suggest division of the (synovial) articular region of the sacrum into three segments. In the *anterosuperior segment*, involving the first sacral vertebra, articular surfaces are slightly sinuous and almost parallel. In the *middle segment* (4.60) the dorsal width between articular margins is greater than the ventral, and centrally a sacral concavity fits a corresponding iliac convexity, an interlocking mechanism relieving strain on the ligaments due to body weight. In the *postero-inferior segment* the ventral sacral width is greater than the dorsal and here its sacral surfaces are slightly concave. Antero-inferior sacral dislocation by the second component (of force) is prevented therefore mainly by the middle segment, owing to its cuneiform shape and interlocking mechanism. However, some rotation occurs, in which the anterosuperior segment tilts down and the postero-inferior segment up (4.61). 'Superior' segmental movement is to a small degree limited by wedging but chiefly by tension in the massive dorsal and interosseous sacro-iliac ligaments; movement of the 'inferior' segment is also slightly checked by wedging but chiefly by tension in the sacrotuberous and sacrospinous ligaments. In all movements sacro-iliac and iliolumbar ligaments and symphysis pubis resist separation of the iliac bones.

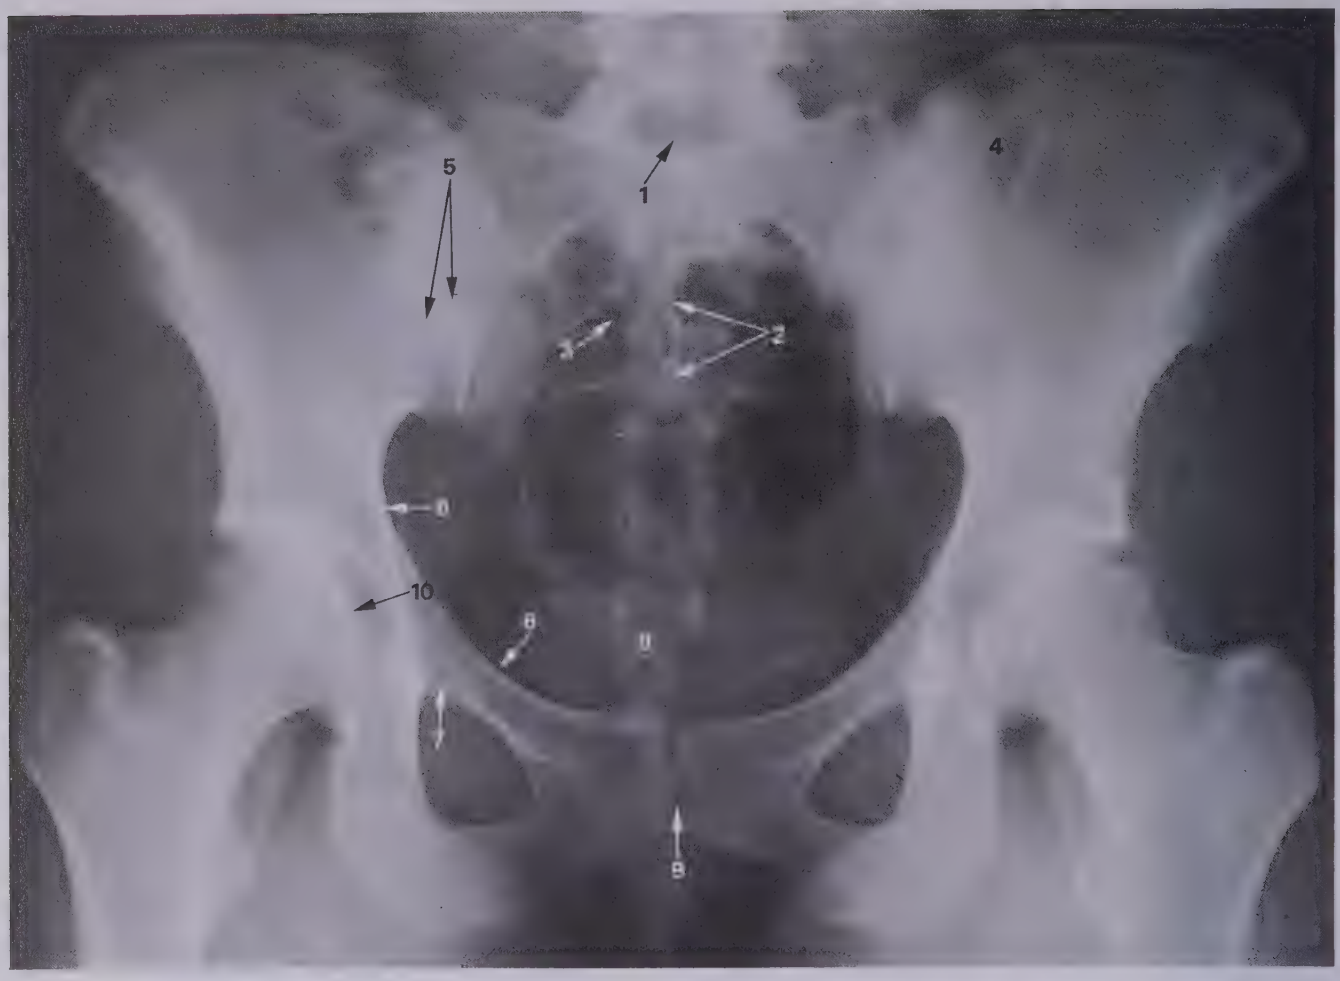
Locomotor significance of structural data has been more extensively studied on primate, including human, pelves than on any other skeletal element, except perhaps the femur. As an introduction to such metrical analysis consult Zuckerman et al (1973). Muscular, gravitational and inertial forces have been analysed in a mathematical model by Goel & Svensson (1977).

Applied Anatomy. During pregnancy pelvic joints and ligaments relax, while movements increase. Relaxation renders the sacro-iliac locking mechanism less effective, permitting greater rotation and perhaps allowing alterations in pelvic diameters at childbirth, although the effect is probably small (Young 1940). The impaired locking mechanism diverts the strain of weight-bearing to ligaments, with frequent sacro-iliac strain after pregnancy. After childbirth ligaments tighten and the locking mechanism improves; but this may occur in a position adopted during pregnancy. Such sacro-iliac 'subluxation' causes pain by unusual ligamentous tension; reduction by forcible manipulation may be attempted. The most common position in this condition of subluxation is believed to be backward rotation of the innominate bone relative to the sacrum; usually unilateral, it is on occasion bilateral.

The Coxal (Hip) Joint



This joint is multi-axial and of ball-and-socket (spheroidal, cotyloid) type. The femoral head articulates with the cup-shaped (cotyloid) acetabulum, its centre lying a little below the middle third of the inguinal ligament (4.59). (The profile of the joint's ventral margin is also *parallel to* the middle third of the inguinal ligament.) Articular surfaces are reciprocally curved but neither co-extensive nor completely congruent. Close-pack position is full extension, with slight abduction and medial rotation. As in the shoulder joint, surfaces are considered ovoid or spheroid rather than spherical but this is controversial (Hammond & Charnley 1967, Bullough & Goodfellow 1968, Greenwald & Haynes 1972). Evidence favours spheroid and slightly ovoid (p. 478) surfaces, becoming almost spherical with advancing age. The femoral head is covered by articular cartilage, except for a rough pit for the *ligament of the head* (4.62C); in front the cartilage extends laterally over a small area on the adjoining neck; it is thickest centrally. Kurrat & Oberländer (1978) measured acetabular and femoral articular cartilages in 10 human joints, finding maximal thickness



4.57 Joints and ligaments of the right half of the pelvis and fifth lumbar vertebra: posterior aspect.

in the acetabulum's anterosuperior quadrant and anterolateral on the femoral head (4.62A). Meachin & Allibone (1984) have described topographical variation in a calcified zone in this cartilage. The acetabular articular surface (4.62B) is an incomplete ring, the *lunate surface*, broadest above where pressure of the body weight falls in the erect posture, narrowest in its pubic region. It is deficient below opposite the acetabular notch and covered by articular cartilage, thickest where the surface is broadest. The acetabular fossa within it is devoid of cartilage but contains fibro-elastic fat largely covered by synovial membrane. Acetabular depth is increased by a fibrocartilaginous *acetabular labrum*. Ligaments include the fibrous capsule, labrum, ligament of the head, and iliofemoral, ischiofemoral, pubofemoral and transverse acetabular ligaments.

The fibrous capsule (4.64,65), strong and dense, is attached above to acetabular margin 5–6 mm beyond its labrum, in front to the outer labral aspect and, near the acetabular notch, to its transverse acetabular ligament and the adjacent rim of the obturator foramen. It surrounds the femoral neck and is attached *in front* to the trochanteric line; *above* to the base of the femoral neck; *behind* about 1 cm above the trochanteric crest; *below* to the femoral neck near the lesser trochanter (4.64). Anteriorly many fibres ascend along the neck as longitudinal *retinacula*, containing blood vessels for both femoral head and neck (p. 783). The capsule is thicker anterosuperiorly, where maximal stress occurs, particularly in standing; postero-inferiorly it is thin and loosely attached. It has two sets of fibres, circular and longitudinal. The circular fibres (*zona orbicularis*) are internal (4.63A,B), forming a collar round the femoral neck; though partly blended with pubofemoral and ischiofemoral ligaments, these fibres are not directly attached to bone. Externally, longitudinal fibres are most numerous in the anterosuperior region, reinforced by the *iliofemoral ligament*. The capsule is also strengthened by *pubofemoral* and *ischiofemoral ligaments*; externally it is rough, covered by muscles and separated from psoas major and iliacus by a bursa.

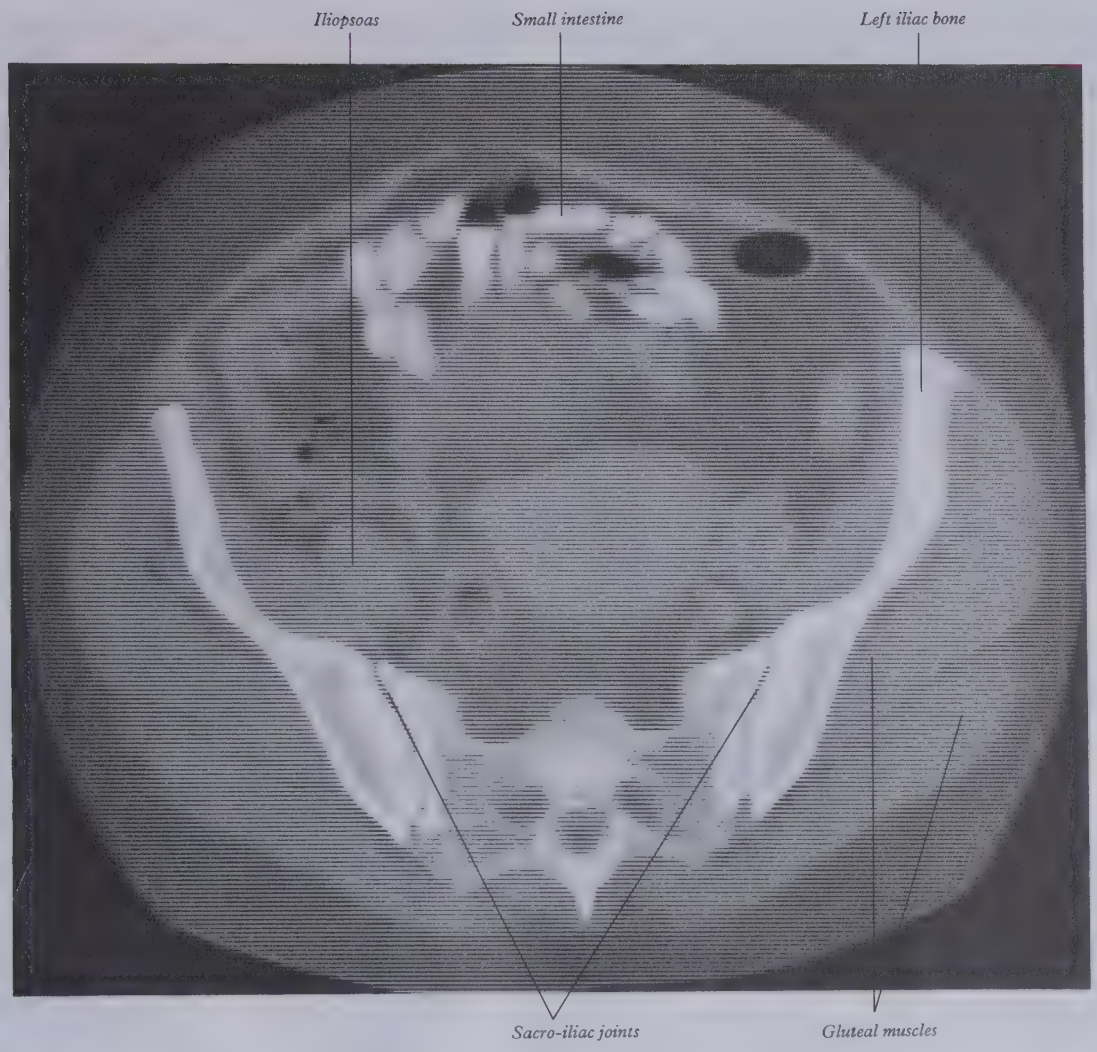
4.59A Anteroposterior radiograph of adult female pelvis. 1. Sacral promontory. 2. Sacral spinous crest. 3. Margin of anterior sacral foramen. 4. Gas in pelvic colon. 5. Sacro-iliac joint. 6. Pelvic brim. 7. Obturator groove. 8. Coccyx. 9. Symphysis pubis. 10. Fovea of femoral head.

The synovial membrane, starting from the femoral articular margin, covers the intracapsular part of the femoral neck, then passes to the capsule's internal surface to cover the acetabular labrum, ligament of the head and fat in the acetabular fossa. It is thin on the deep surface of the iliofemoral ligament where it is compressed against the femoral head and sometimes is even absent here. The joint may communicate with the subtendinous iliac (psoas) bursa (p. 635) by a circular aperture between the pubofemoral and the vertical band of the iliofemoral ligament.

The iliofemoral ligament (4.64), triangular and very strong, is anterior and intimately blended with the capsule, its apex attached low on the anterior inferior iliac spine, its base to the trochanteric line. Its medial and lateral bands are strong, its central part weaker; the medial, vertical band reaches the inferomedial (distal) end of the trochanteric line; the lateral is oblique and attached to a tubercle at the line's superolateral (proximal) end. Hence it is often named the Y-shaped ligament, its lateral band the *iliotrochanteric ligament*.

The pubofemoral ligament (4.64), also triangular, has a base attached to the iliopectineal eminence, superior pubic ramus, obturator crest and membrane; it blends distally with the capsule and deep surface of the medial iliofemoral band.

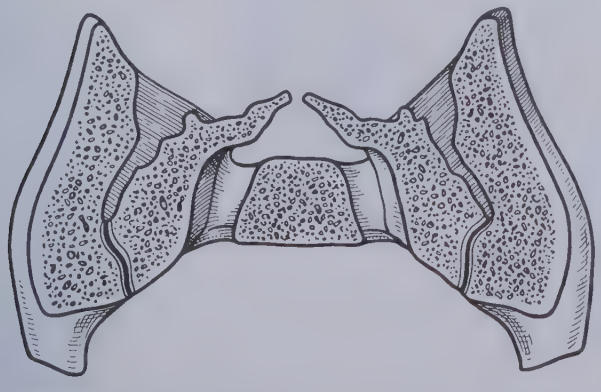


The ischiofemoral ligament (4.65) thickens the back of the capsule. From the ischium, postero-inferior to the acetabulum, it *spirals* superolaterally behind the femoral neck, some fibres blending with the zona orbicularis, others attached to the greater trochanter deep to the iliofemoral ligament.

The ligament of the femoral head (4.66) is a triangular flat band, its apex attached anterosuperiorly in the pit on the femoral head; its base is principally attached on both sides of the acetabular notch, between which it blends with the transverse ligament. (However, it receives weaker accessions from the margins of the acetabular fossa.) Ensheathed by flattened tubular synovial membrane, it varies in strength; occasionally its synovial sheath alone exists, without a core; rarely both ligament and sheath are absent. The ligament appears to tense when the thigh is semiflexed and adducted and to relax in abduction.

The acetabular labrum (4.58,62) is a fibrocartilaginous rim attached to the acetabular margin, deepening the cup. It bridges the acetabular notch as the *transverse acetabular ligament*, completing the circle. Triangular in section, it is attached by its base to the acetabular rim, the apex being its free margin. The acetabular cavity is constricted by the labral rim which embraces the femoral head.

The transverse acetabular ligament (4.58) is part of the labrum but has no cartilage cells. Its strong, flat fibres cross the notch forming a foramen through which vessels and nerves enter the joint.



Relations. The coxal capsule is surrounded by muscles (4.67). *Anteriorly*, lateral fibres of pectineus separate its most medial part from the femoral vein; lateral to this the tendon of psoas major, with iliacus lateral to it, descends across it, partly separated by a bursa. The femoral artery is anterior to the tendon; the femoral nerve deep in a groove between tendon and iliacus. More laterally the straight head of rectus femoris crosses the joint with a deep layer of the fascial iliotibial tract, which blends with the capsule under the muscle's lateral border. *Superiorly*, the reflected head of rectus femoris contacts the capsule medially, while gluteus minimus covers it laterally, closely adherent. *Inferiorly*, lateral fibres of pectineus adjoin the capsule and, more posteriorly, obturator externus spiralizes obliquely to its posterior aspect. *Posteriorly*, the lower capsule is covered by the tendon of obturator externus, separating

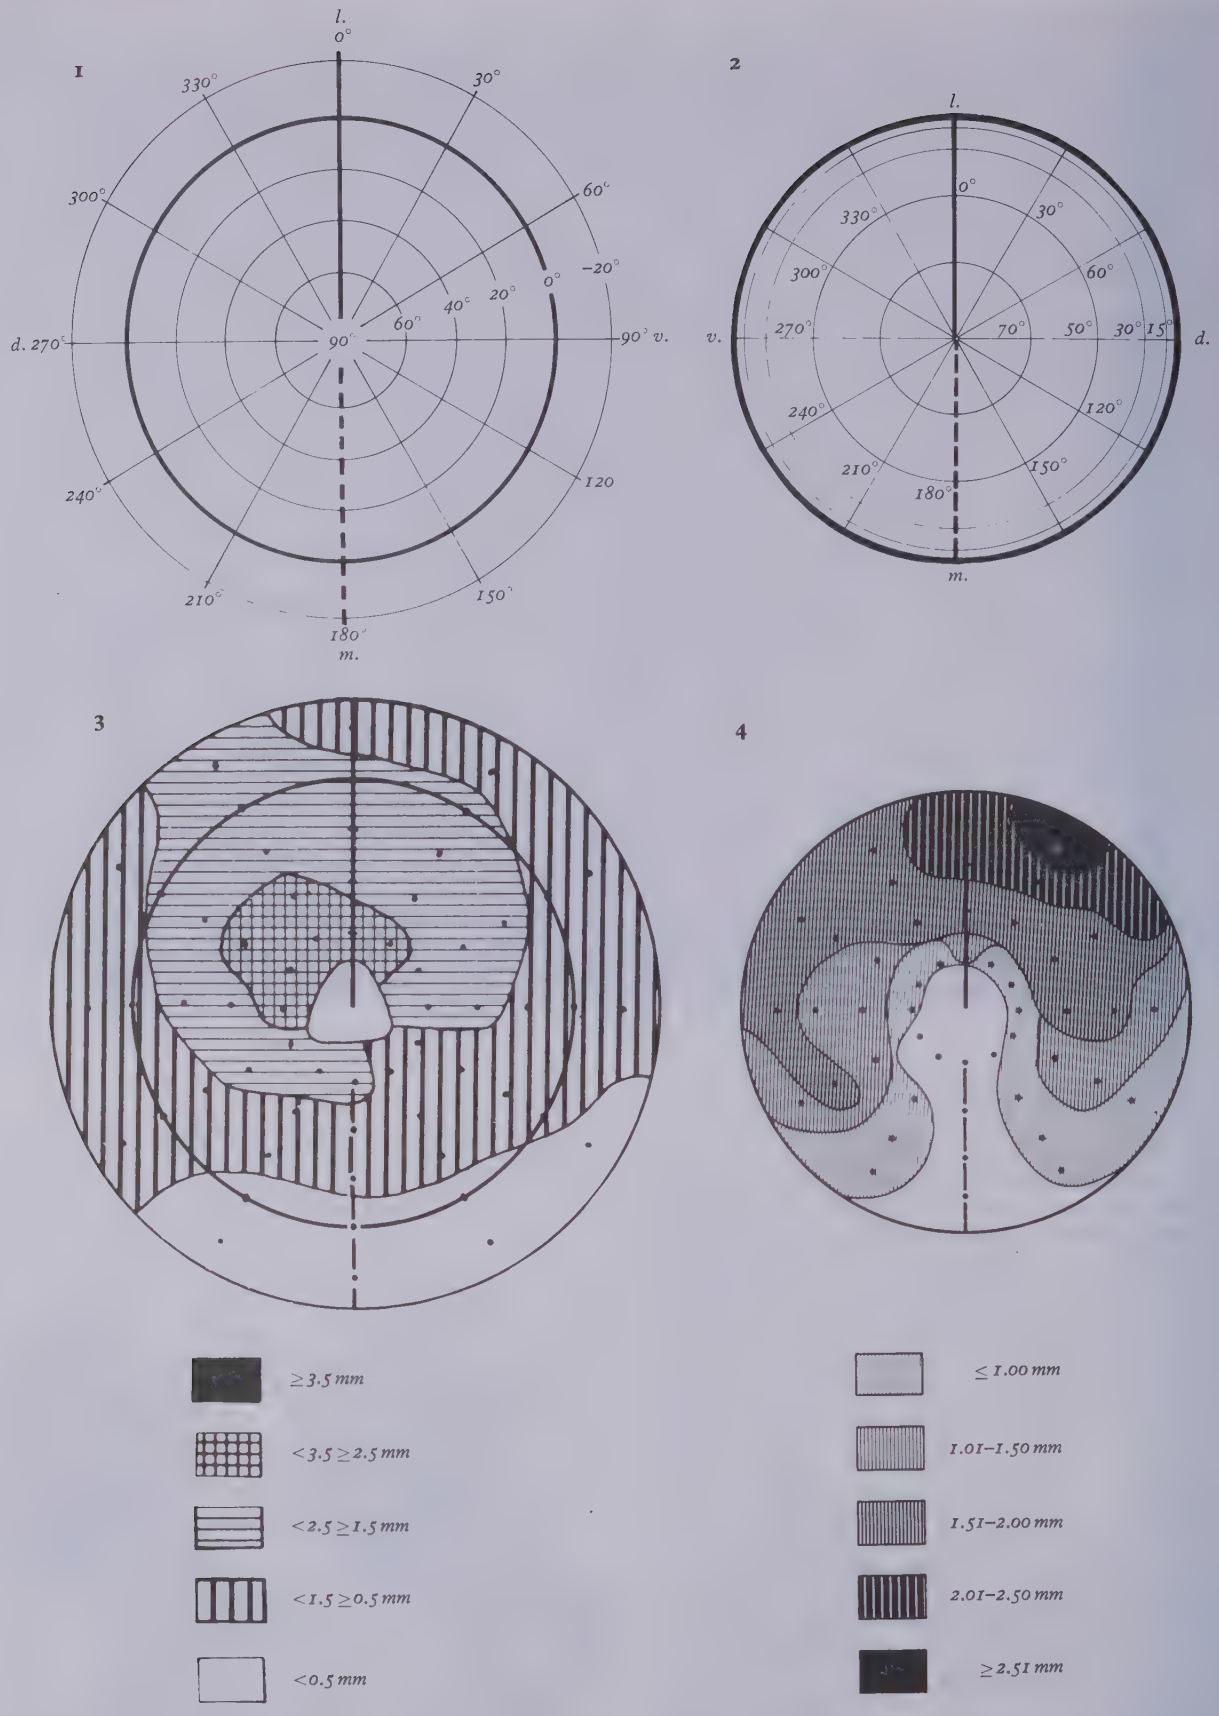
it from quadratus femoris and accompanied by an ascending branch of the medial circumflex femoral artery; above this the tendon of obturator internus and the gemelli contact the joint, separating it from the sciatic nerve; the nerve to quadratus femoris is deep to the obturator internus tendon, the nerve descending most medially on the capsule. Above this, the joint's posterior surface is crossed by piriformis.



Articular arteries are branches from the obturator, medial circumflex femoral, and superior and inferior gluteal arteries. *Nerves*

4.60 Coronal section passing through the middle segment (see text) of the sacro-iliac joints. The sacrum is in its normal position with the body in the erect attitude.

4.61 The changing relation (rotation) of the auricular surface of the sacrum and that of the ilium when changing from a recumbent to an erect posture. (Based upon work by H Weisl 1953, with permission of the author.)

4.62A Variations in the thickness of the articular cartilages of the femoral head (1 and 3) and the lunate surface of the acetabulum (2 and 4). Diagrams 1 and 2 are reference grids by which the distance and angular direction of sampling points are measured from the centres of the femoral head and of the acetabulum. Diagrams 3 and 4 show the average contours of the thickness ranges indicated in the shading codes included below. Dorsal and ventral aspects are denoted as '*d*' and '*v*'; '*l*' and '*m*' denote superolateral and inferomedial points on the circumference of the femoral articular surface. The black dots indicate the intersections of lines of 'longitude' and 'latitude' and also represent sampling points. It is immediately apparent that this method does not provide a detailed representation of the graded topology of the articular surfaces. (See p. 479 for an alternative methodology, more recently introduced.) (Provided from the paper by H J Kurrat & W Oberländer, 1978 by courtesy of Cambridge University Press.)

are from the femoral or its muscular branches, the obturator, accessory obturator, the nerve to quadratus femoris and the superior gluteal nerves (Gardner 1948a).

Movements can be categorized as flexion–extension, adduction–abduction, circumduction, medial and lateral rotation, conveniently considered as rotations around three orthogonal axes (p. 476); but when femoral movements are considered in relation to articular surfaces, length and angulation of the neck in relation to shaft must be remembered. When the thigh is flexed or extended, the femoral head 'spins' in the acetabulum on an approximately transverse axis; conversely, the acetabula rotate around similar axes in flexion and extension of the trunk on stationary femoral heads. Medial and lateral femoral rotation have a vertical axis through the femoral head's centre and lateral condyle, with the foot *stationary* on the ground. Such rotations are the inevitable conjunct rotations accompanying terminal extension or initial flexion at the knee joint (pp. 530–533). Because of the relation of this axis to the whole femur (with its angulated neck and oblique shaft), during medial rotation the medial condyle moves in an arc *backwards* on the medial tibial condyle and the greater trochanter simultaneously in a *forward* arc: converse movements occur during lateral rotation. With the foot in loose contact or free, medial and lateral adjunct rotation of the whole lower limb occurs around variable axes, all through the femoral head and any part of the foot. Conversely, with one foot stationary and the other free, the whole trunk may rotate on one femoral head—as in cross-kicking. Abduction and adduction are around an anteroposterior axis through the femoral head; but since this is not truly spherical

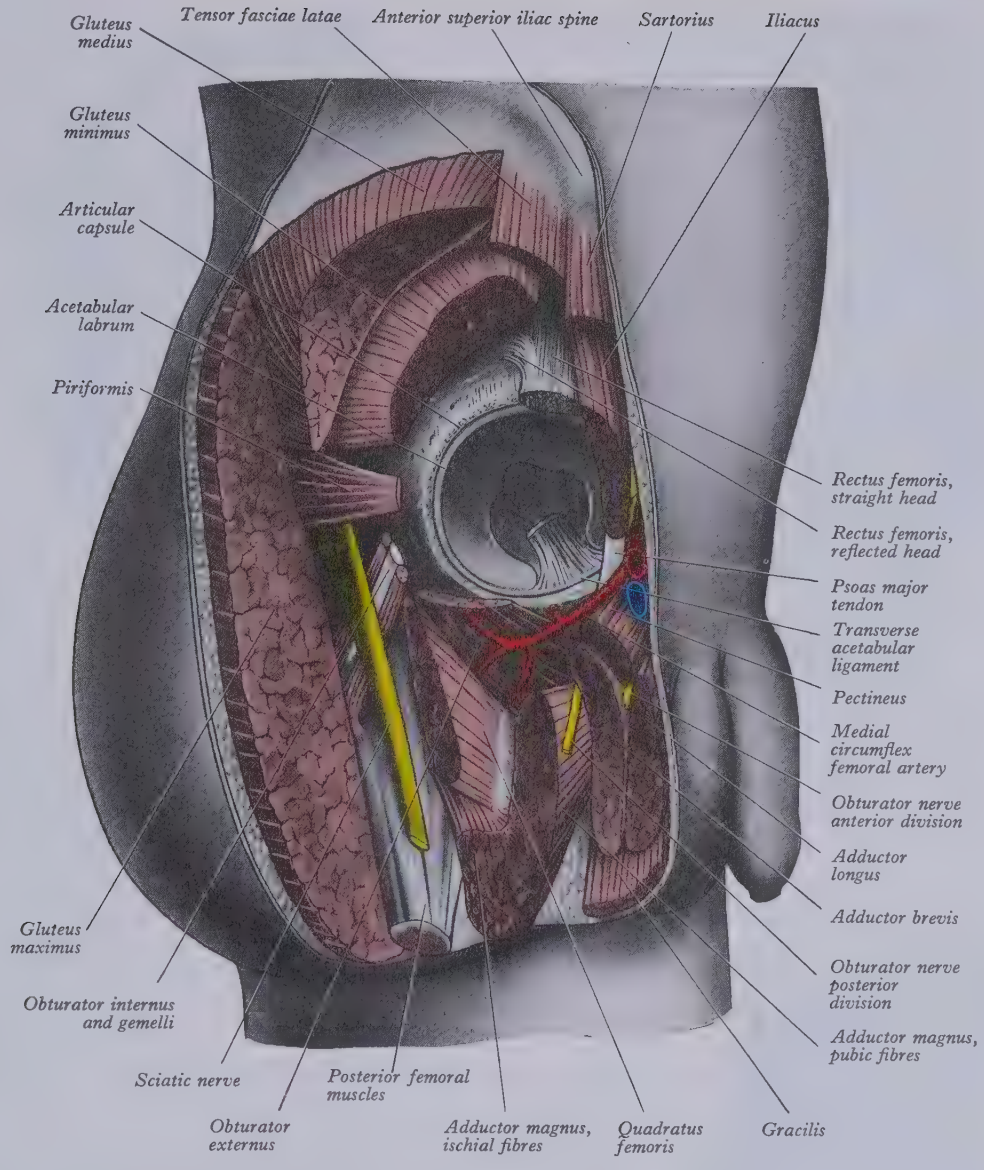
no axis is stationary (Walmsley 1928). Some kinesiologists refer to a *mechanical axis* coincident with the topographical long axis of the femoral neck, impinging on the approximate centre of its head's articular surface (p. 435), making extension and flexion of the thigh relatively pure 'spins' at the hip joint and most effective in spiralizing and tautening or straightening and relaxing the capsular ligaments (vide infra). All other movements are regarded as pure or impure swings (p. 480). While this permits analysis closer to actual articular function than a cardinal tri-axial system, related arbitrarily to the 'anatomical' position, the mechanical axis is itself (incorrectly) regarded by some as dynamic, because forms of apparent dynamic 'spin' may occur in many positions; this view stems from an imprecise definition of the varieties of axes employed in arthrokinematics. The notional mechanical axis of the kinesiologist makes an angle of about 125° with the long topographical axis of the femoral shaft, the angle varying with age and sex. The mechanical axis is not dynamic *relative to the femur*. It is stationary during pure spins; it moves relative to its con-articular surface in chordal or arcuate paths during pure or impure swings respectively.



4.66 Left hip joint, opened by the removal of the floor of the acetabulum from within the pelvis.

Simple flexion is possible to 90°–100° from the *vertical*; extension beyond the *vertical* is limited (perhaps 10°–20°). Both movements are augmented by adjustments of spinal column and pelvis, flexion of the knee and concomitant medial or lateral coxal rotation. For example, genual flexion (lessening tension in the posterior femoral muscles) increases coxal flexion to 120°; the thigh can be drawn passively to the trunk, though with some spinal flexion. Extension in walking, running, etc., is increased by forward inclination of the body, pelvic tilting and rotation and lateral coxal rotation. (For analyses consult Kapandji 1965, 1974, Joseph 1975.) Abduction and adduction can be similarly increased.

The hip joint differs much from the shoulder joint in limitation of its movements. The humeral head's articular surface much exceeds that of the glenoid cavity and movements are little restrained by the capsule. In the hip, in contrast, the femoral head is closely fitted to the acetabulum in an area of almost half a sphere, embraced more closely by its labrum, being held in place even when the capsule is divided. The iliofemoral is the strongest of all ligaments and is progressively tightened by spiralization when the femur extends to the line of the trunk. The pubofemoral and ischiofemoral ligaments also tauten and, as the joint approaches close-packing, resistance to an extending torque rapidly increases.

No accessory movements occur, except for very slight separation effected by strong traction.

4.67 Dissection to display the structures surrounding the right hip joint. The head of the femur has been disarticulated and removed.

Muscles Producing Coxal Movements

Flexion: psoas major and iliacus, assisted by pectineus, rectus femoris and sartorius. Adductors, particularly adductor longus, also assist, especially in early flexion from full extension.

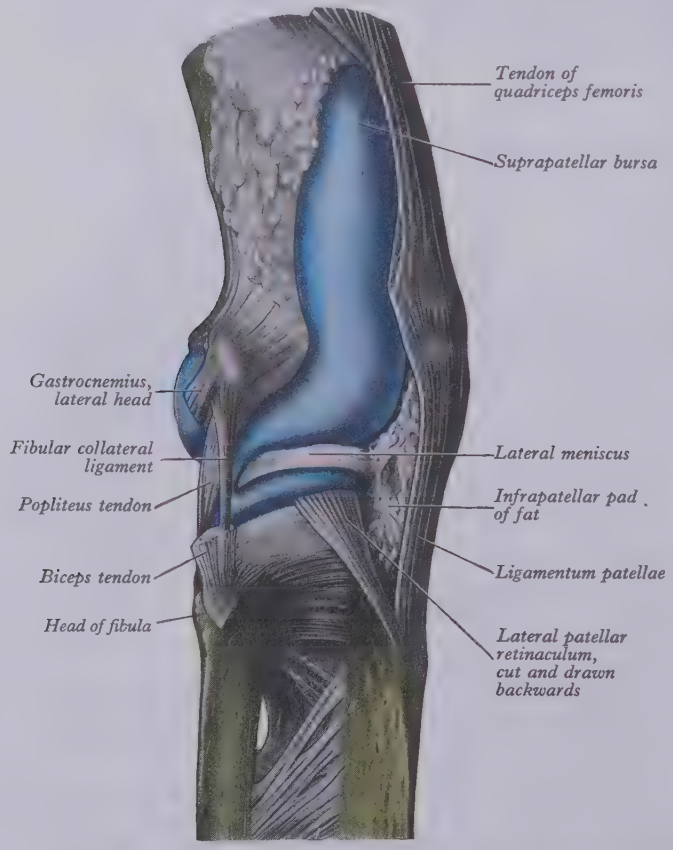
Extension: gluteus maximus and posterior femoral muscles. In full erect posture with pendant arms a vertical through the body's centre of gravity is behind a line joining the centres of the femoral heads; therefore the body tends to incline backwards but is counterbalanced by ligamentous tension and congruence and compression of articular surfaces with the hip joints in the close-packed position. Under increased loading of the trunk or leaning backwards, these resistive but passive factors are assisted by active contraction of the joint's flexors. In swaying forwards at the ankles, or when the arms are stretched forward, and also in forward bending at the hip, the line of body weight moves in front of the transverse axis and the posture adopted, or the rate of change of posture, is largely controlled by the posterior femoral muscles ('hamstrings') which, although powerful *flexors* of the knee, are equally strong *extensors* of the hip. Gluteus maximus only becomes active when the thigh is extended against resistance, as in rising from a bending position or climbing.

Abduction: glutei medius and minimus (p. 642), assisted by tensor fasciae latae and sartorius. Abduction is limited by adductor tension, the pubofemoral ligament and medial band of the iliofemoral ligament. These muscles are consistently involved in walking or running (p. 658), contracting periodically at precise phases of the walking or running cycle.

Adduction: adductores longus, brevis and magnus, assisted by pectineus and gracilis. Adduction is limited by contact with the opposite limb but its range is wider with the thigh flexed when it is limited by the abductor muscles, the lateral band of the iliofemoral ligament and ligament of the femoral head.

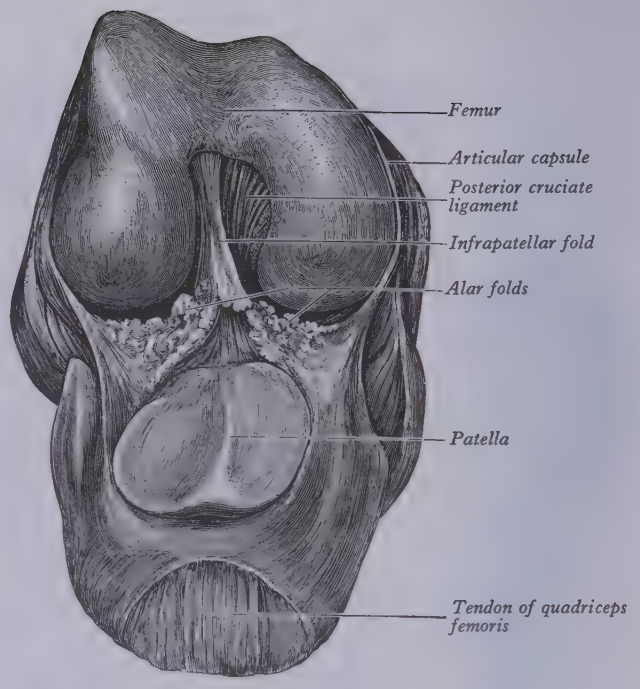
Medial rotation: tensor fasciae latae and anterior fibres of glutei minimus and medius. It is relatively weak and is limited by the lateral rotators, ischiofemoral ligament and posterior part of the capsule. Electromyographic data suggest that adductors usually assist in *medial* rather than lateral rotation but this is, of course, dependent on the primary position.

Lateral rotation: obturator muscles, gemelli and quadratus femoris, assisted by piriformis, gluteus maximus and sartorius. It is a powerful action and limited by tension in the medial rotators and the lateral band of the iliofemoral ligament.



Applied Anatomy. The iliofemoral ligament is rarely torn during dislocation, an advantage in reduction because it can act as the fulcrum to a lever, its long arm the femoral shaft, the short being the femoral neck. Congenital dislocation is more common at the hip than elsewhere. Displacement is usually to the gluteal surface

of the ilium, the acetabular rim being deficient above. In manipulation of the sacro-iliac joints the surgeon takes advantage of the tautness of the iliofemoral and ischiofemoral ligaments in coxal extension. So strong are they that forcible coxal hyperextension with forward pressure on the iliac crest produces sacro-iliac movement.



The Genual (Knee) Joint

The knee (4.4), largest of human joints, is *compound* (4.69–78) and sometimes derived from a primitive double condylar articulation, although contrary evidence exists (Haines 1942a). Despite its single cavity in man, it is convenient to describe it as two condylar joints between femur and tibia and a sellar joint between patella and femur. The former are partly divided by menisci between corresponding articular surfaces. (Strictly, the joint is therefore also classified as *complex*.) The level of the joint is at the (palpable) proximal margins of the tibial condyles (4.77).

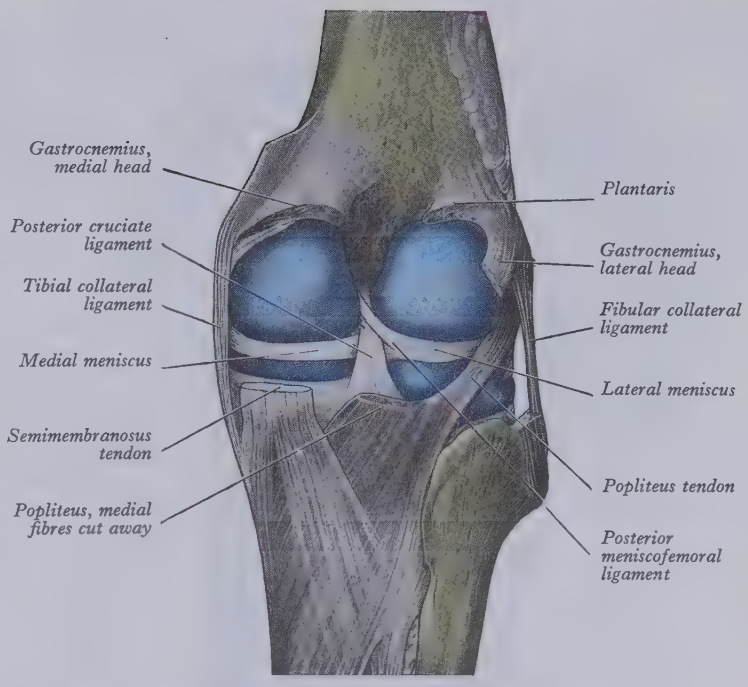
The articular surfaces (pp. 437, 439, 441) are most incongruent. Femoral condyles, bearing articular cartilage, are almost wholly convex; in lateral profile both are spiral with a curvature increasing posteriorly, the lateral condyle more rapidly. The tibial surfaces are also cartilage-covered areas, separated by the intercondylar region; each is gently hollow centrally and flattened peripherally where a meniscus rests. The lateral tibial articular surface is almost circular and smaller, the medial oval with a longer anteroposterior axis. Both tibial surfaces slope up near the intercondylar area on to its eminences; posteriorly the lateral is prolonged on the back of its condyle, in relation to the popliteal tendon; anteriorly, near the anterior cornu of the lateral meniscus, it descends onto the anterior sloping condylar surface (vide infra). Femorotibial congruence is improved by the menisci, shaped to increase the concavity of tibial surfaces, the combined lateral tibiomeniscal surface being deeper. The lateral femoral condyle has in front a faint groove, resting on the peripheral edge

4.68 Dissection of the right knee joint: lateral aspect. The joint cavity has been injected and the synovial membrane is coloured blue.

4.69 Right knee joint in flexion: anterior exposure.

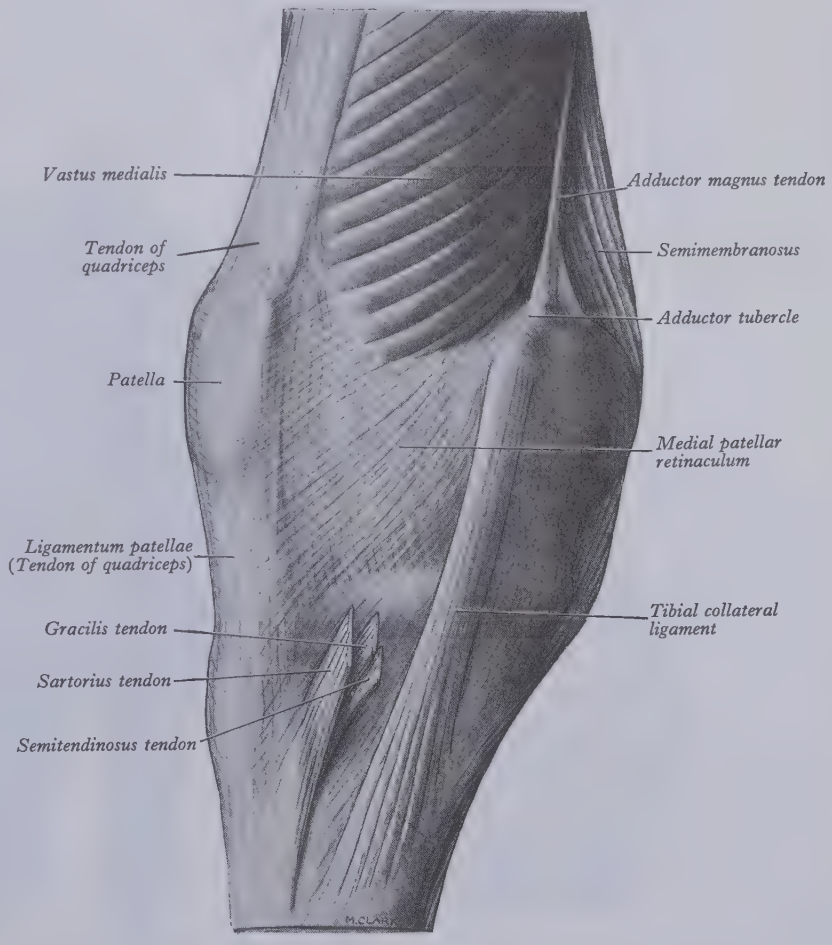
of the lateral meniscus in full extension. A similar groove appears on the medial condyle but does not reach its lateral border, where a narrow strip contacts the medial patellar articular surface in full flexion. These grooves demarcate the femoral patellar and condylar surfaces, the latter articulating only with tibia and menisci. The distal outlines (4.69) of femoral surfaces conform to tibiomeniscal articular surfaces. The lateral femoral surface is almost circular, the medial is larger, somewhat oval but curved with a lateral concavity. These differences correlate with movements of the joint (vide infra). The surfaces approach congruence in full extension, the close-packed position, as confirmed by casting techniques and radiological studies of excised human joints. (Vide infra for detailed discussion of close-packing and consult Kettlekamp et al 1972 for relevant bibliography.)

The patella's articular surface is adapted to the femoral surface (p. 439), which extends on the anterior surfaces of both condyles like an inverted U. An oblique groove, descending a little laterally, divides the femoral patellar surface into a larger lateral and a medial area; the lateral is wider, passes more steeply on to the prominent anterior boss of the lateral condyle and ascends higher on its anterior surface. Since the whole area is concave transversely and parasagittally convex, it is an asymmetrical sellar surface (p. 478). A rounded, almost vertical ridge, dividing the articular surface of the patella also into larger lateral and medial areas, fits the corresponding femoral groove; but the two areas are not fully congruent with those of the femur. The patellar surface may be subdivided by two faint, horizontal ridges which, with the vertical ridge, map out three pairs of facets. But in many patellae there is only *one* horizontal ridge, better marked laterally, and the upper lateral facet is more deeply hollowed. Medially, a second vertical ridge separates a narrow semilunar strip from the medial border which contacts the lateral anterior end of the medial femoral condyle in full flexion, when the highest lateral patellar facet contacts the anterior part of the lateral condyle. As the knee extends, the middle patellar facets contact the lower half of the femoral surface; in full extension only the lowest patellar facets are in contact with the femur (4.79). Seedham & Tsubuku (1977) have applied a special technique for study of contact areas between visco-elastic bodies to the patella. They emphasize temporal factors in compressive contacts.



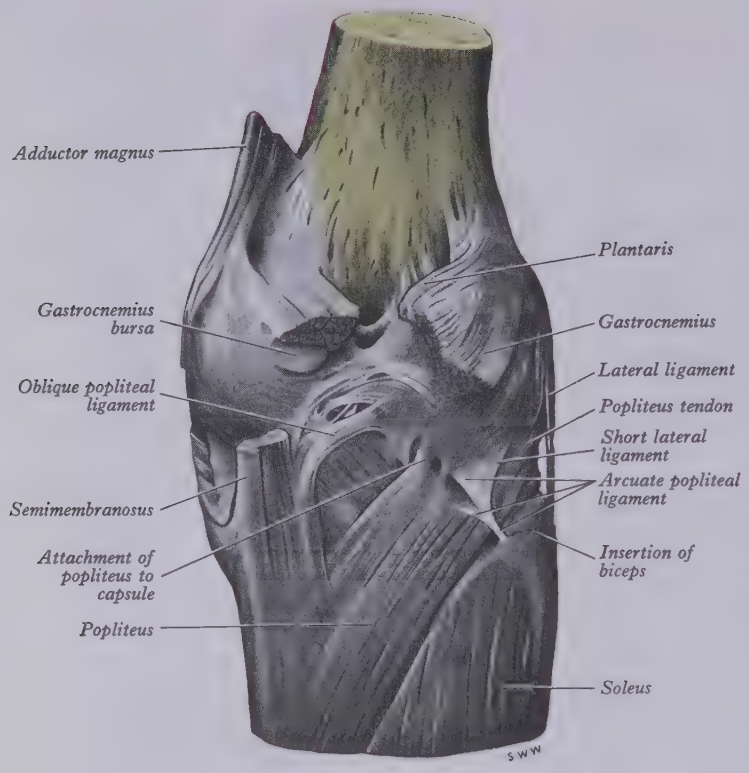
Ligaments of the joint are its fibrous capsule, ligamentum (tendo) patellae, tibial and fibular collateral, oblique and arcuate popliteal, anterior and posterior cruciate and transverse genual ligaments.

The fibrous capsule is complex, partly deficient and partly augmented by expansions from adjacent tendons. Its *posterior, vertical fibres* are attached proximally to the posterior margins of the femoral condyles and intercondylar fossa and distally to the posterior margins of the tibial condyles and intercondylar area; proximally on each side it is blended with attachments of gastrocnemius and centrally strengthened by the oblique popliteal ligament. *Medial capsular fibres* are attached to femoral and tibial condyles just beyond their articular margins; here the capsule blends with the tibial collateral ligament. Between the medial epicondyle and the convex border of the medial meniscus is a capsular thickening, a deep component of the tibial collateral ligament (Last 1948). *Lateral capsular fibres*, attached to the femur above popliteus, descend over its tendon to the tibial condyle and fibular head. The fibular collateral ligament is separated from the capsule by fat and the inferior lateral genicular vessels and nerve. *Anteriorly* the capsule does not pass proximal to the patella or over the patellar area; elsewhere it blends with expansions from the vasti medialis and lateralis; these are attached to the patellar margins and ligamentum patellae, extending back to the corresponding collateral ligaments and distally to the tibial condyles. They form *medial* and *lateral patellar retinacula*, the lateral being augmented by the iliotibial tract. Proximal to the patella an absence of capsule allows continuity of the suprapatellar bursa (p. 640) with the joint. Posterior capsular attachment to the lateral tibial condyle is interrupted where popliteus emerges (4.72) but elsewhere, as mentioned, the oblique popliteal ligament, derived from the tendon of semimembranosus, thickens the posterior capsule. A prolongation of the iliotibial tract fills the interval between oblique popliteal and fibular collateral ligaments, partly covering the latter; its expansions also reach the lateral patellar retinaculum and patellar ligament. Medially, expansions from sartorius and semimembranosus ascend to the tibial collateral ligament. Internally the capsule is attached to the meniscal rims, connecting them to the tibia by short *coronary ligaments*.



The synovial membrane of the knee is the most extensive and complex in the body. At the proximal patellar border, it forms a large *suprapatellar bursa* between quadriceps femoris and lower femoral shaft (4.68,75). This is, in practice, an extension of the genual cavity, sustained by the *articularis genus* which is attached to it. Alongside the patella the membrane extends beneath the aponeuroses of the vasti, more extensively under the medial. Distal to the patella the synovial membrane is separated from the ligamentum patellae by the *infrapatellar pad of fat*, covering which the membrane projects into the joint as two fringes, or *alar folds*; these bear villi and then converge posteriorly to form the single *infrapatellar fold (ligamentum mucosum)* which curves posteriorly to its attachment in the femoral intercondylar fossa (4.69); this may be a vestige of the inferior boundary of an originally separate femoropatellar joint (p. 526). At the sides of the joint the synovial membrane descends from the femur, lining the capsule as far as the menisci whose surfaces have no synovial covering. Posterior to the lateral meniscus the membrane forms a *subpopliteal recess* between a groove on the meniscal surface and the tendon of popliteus (4.70); this may connect with the superior tibiofibular joint (p. 533). The relation of synovial membrane to cruciate ligaments is described on p. 528.

The ligamentum patella (4.71) is the central band of the tendon of quadriceps femoris, continued distally from patella to tibial tuberosity. It is strong, flat, about 8 cm in length, attached proximally to the apex, adjoining margins and to rough areas on the anterior surface and on the depression on the distal posterior patellar surface, and distally to the superior smooth area of the tibial tuberosity. Its superficial fibres are continuous over the patella with the tendon of quadriceps femoris, medial and lateral parts of which descend, flanking the patella, to the sides of the tibial tuberosity, merging into the fibrous capsule as *medial* and *lateral patellar retinacula*. The ligamentum patellae is separated from synovial membrane by a large infrapatellar fat pad and from the tibia by a bursa (4.75).



The oblique popliteal ligament (4.75) expands from the tendon of semimembranosus, blends partly with the capsule and ascends laterally to the lateral part of the intercondylar line and lateral femoral condyle. Its fasciculi are separated by apertures for

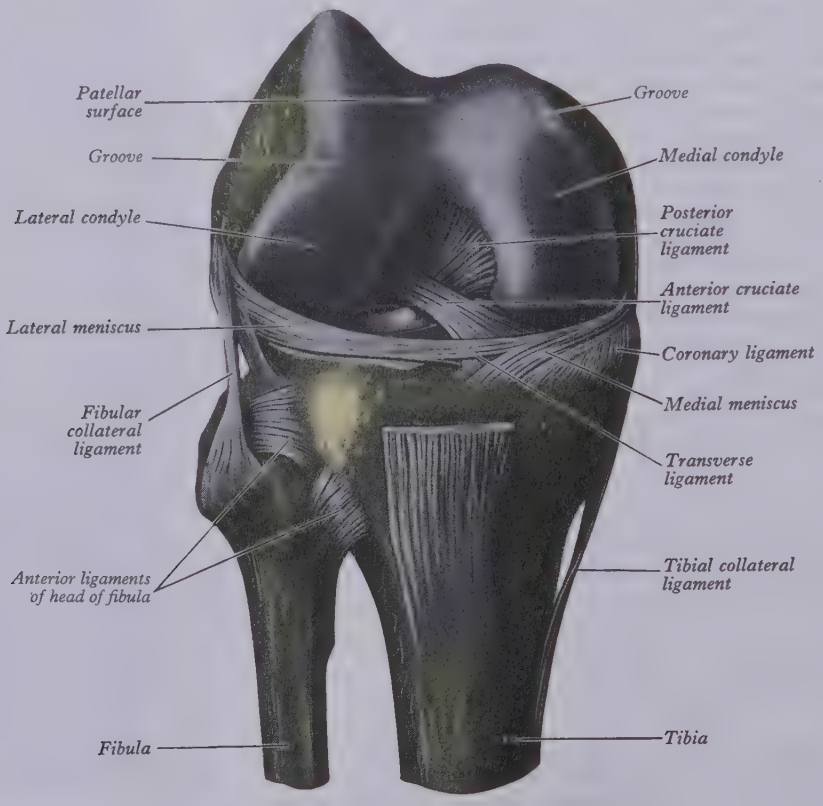
4.70 Posterior dissection of the right knee joint. The fibrous capsule has been removed, exposing the unopened synovial membrane which is coloured blue. The cavity of the joint had been partially distended by injection.

4.71 Right knee joint: anteromedial aspect.

4.72 Right knee joint: posterior aspect.

vessels and nerves; it is in the floor of the popliteal fossa with the popliteal artery in contact.

The arcuate popliteal ligament (4.72), a Y-shaped mass of capsular fibres, has a stem attached to the head of the fibula; its posterior limb arches medially over the emerging tendon of popliteus to the posterior border of the tibial intercondylar area; the anterior limb, sometimes absent, extends to the lateral femoral epicondyle, is connected with the lateral head of gastrocnemius and is often termed the *short lateral genual ligament*.



The tibial collateral ligament (4.71,76), a broad flat band nearer the back of the joint, extends from the medial femoral epicondyle, immediately distal to the adductor tubercle, to the medial meniscus, tibial condyle and adjacent shaft. Its *anterior part* is flat, about 10 cm long, and may be separated from the capsule and medial meniscus by one or more bursae (Brantigan & Voshell 1943). It slopes anteriorly as it descends to the medial margin and posterior medial surface of the tibial shaft where it is crossed by tendons of sartorius, gracilis and semitendinosus, with a bursa interposed. It lies over the medial inferior genicular vessels and nerve and anterior part of the tendon of semimembranosus, and may have tenuous connections with the latter. Its *posterior part* fans out to blend with the back of the capsule; it is short and descends posteriorly to the medial tibial condyle proximal to the groove for semimembranosus.

The fibular collateral ligament (4.73), a strong cord, is attached to the lateral femoral epicondyle, proximal to the popliteal groove, and extends to the fibular head in front of its apex. It is largely overlapped by the tendon of biceps femoris, which embraces and partly blends with it; deep to the ligament are the tendon of popliteus and the inferior lateral genicular vessels and nerve. The ligament is *not* attached to the lateral meniscus.

The cruciate ligaments are very strong and sited a little posterior to the articular centre. They are termed *cruciate* because they cross and *anterior* and *posterior* from their *tibial* attachments. Their disposition suggests identification with collateral ligaments of originally separate medial and lateral femorotibial joints (pp. 526, 527).

The anterior cruciate ligament (4.74) is attached medially to the tibial *anterior* intercondylar area and partly blended with the anterior cornu of the lateral meniscus; it ascends *posterolaterally*, twisting on itself and fanning out to attach to the posteromedial aspect of the *lateral* femoral condyle (Last 1951). It is anterolateral to the posterior cruciate.

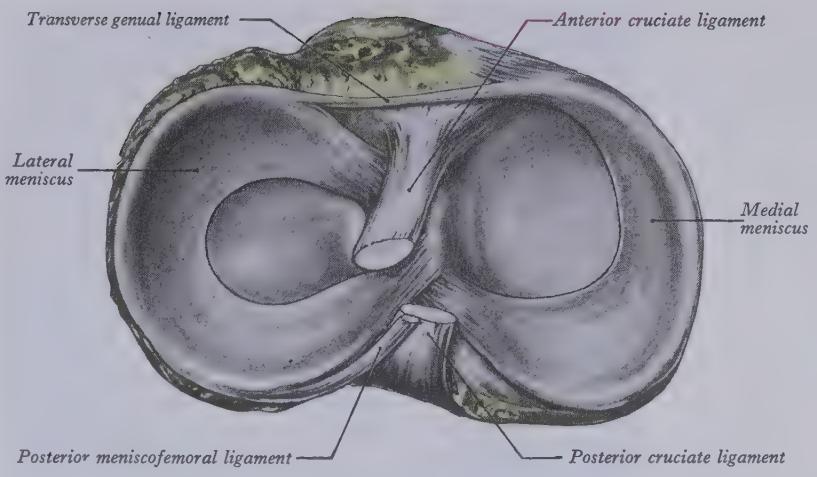
The posterior cruciate ligament (4.73,74) is stronger, less

 4.73 Right knee joint in full flexion: dissection from anterior aspect.

oblique, with some shorter fibres and it is attached to the *posterior* intercondylar area and posterior cornu of the lateral meniscus; it ascends *anteromedially*, broadening out to its attachment on the lateral surface of the *medial* femoral condyle.

Observations on 24 fresh joints (Girgis et al 1975) suggested that each ligament has a main posterolateral and a smaller anteromedial band, which behave differently in movement (vide infra). Spiralization is apparent and more pronounced in certain positions. Average dimensions were: anterior cruciate length 38 mm, width 11 mm; posterior cruciate length 38 mm, width 13 mm. Odensten et al (1985) in a functional and surgical study gave a mean length of 31.3 mm in 33 adult cadavers (Swedish).

It should be noted that these ligaments have substantial cross-sectional areas and attachments that are not only in orthogonal planes but also displaced dorsoventrally; all these factors introduce difficulties during mensuration, particularly determinations of 'length'.

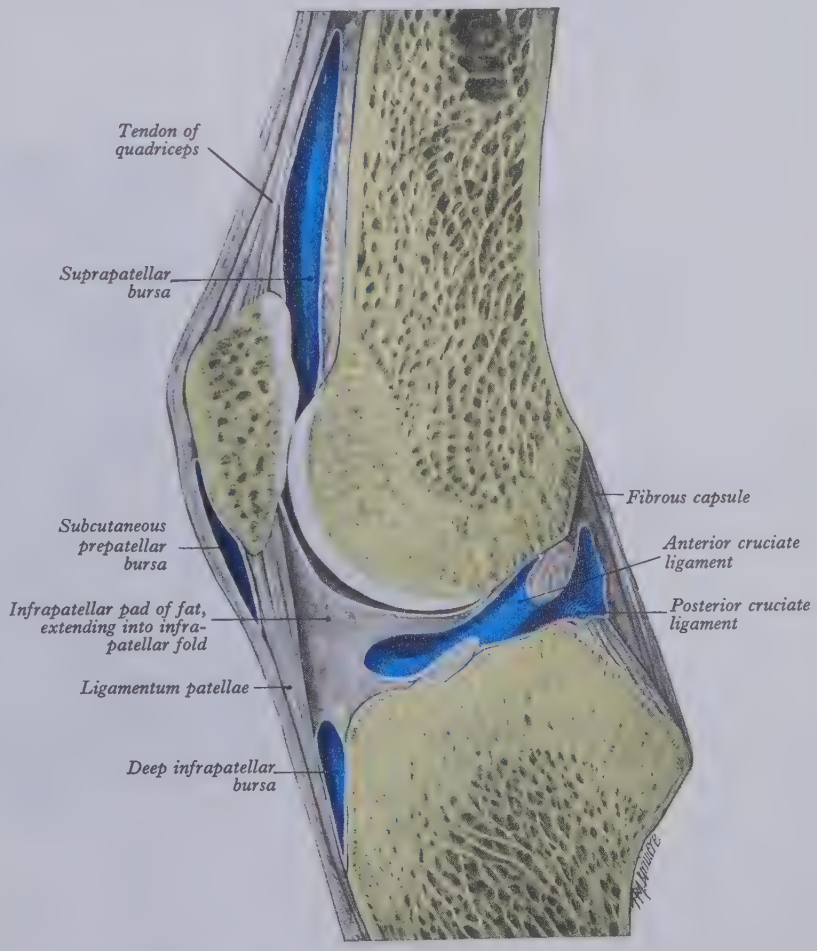


Synovial membrane almost surrounds the ligaments but is reflected posteriorly from the posterior cruciate to adjoining parts of the capsule. Thus the intercondylar part of the posterior region of the *fibrous capsule* has no synovial covering. A synovial bursal recess intrudes between the ligaments from their lateral aspect (4.75) and may reach the medial wall of the femoral intercondylar fossa.

The menisci (semilunar cartilages) (4.74) are crescentic laminae deepening the articulation of the tibia which receives the femur. Their peripheral attached borders are thick and convex; their free borders are thin and concave. Their peripheral zone is vascularized by capillary loops from the fibrous capsule and synovial membrane, their inner regions avascular (Davies & Edwards 1948). Their proximal surfaces are smooth and concave, in contact with articular cartilage on femoral condyles, their distal surfaces smooth and flat, resting on tibial articular cartilage. Each covers about two-thirds of its tibial articular surface. Gh»dially et al (1983) have detailed meniscal ultrastructure.

The medial meniscus, almost a *semicircle* and broader behind (4.74), is attached at its *anterior end* (cornu) to the anterior tibial intercondylar area in front of the anterior cruciate ligament, its posterior fibres continuous with the transverse genual ligament. This anterior cornu is in the floor of a depression medial to the upper part of the ligamentum patellae. The *posterior cornu* is fixed to the posterior tibial intercondylar area, between attachments of the lateral meniscus and posterior cruciate ligament. Its peripheral border is attached to the fibrous capsule and the deep surface of the tibial collateral ligament (4.78).

The lateral meniscus, about four-fifths of a *ring* (4.74), covers a larger area than the medial. Its breadth is uniform, except for the short tapering cornua; it is grooved posterolaterally by the popliteal tendon, separating it from the fibular collateral ligament. Its *anterior cornu* is attached in front of the tibial intercondylar eminence, posterolateral to the anterior cruciate ligament, with which it partly blends. Its *posterior cornu* is attached behind this eminence, in front of the posterior cornu of the medial meniscus. Its anterior attachment is twisted, its free margin facing posterosuperiorly, the anterior cornu resting on the anterior slope of the lateral intercondylar tubercle. Near its posterior attachment it commonly sends a *posterior meniscofemoral ligament* (4.74) superomedially behind the posterior cruciate ligament to the medial femoral condyle. An *anterior meniscofemoral ligament* may also connect the posterior cornu to the medial femoral condyle anterior to the posterior cruciate ligament. The meniscofemoral ligaments are often the sole attachments of the posterior cornu of the lateral meniscus. More medially, however, part of the popliteal tendon is attached to the lateral meniscus and mobility of its posterior cornu may thus be controlled by the meniscofemoral ligaments and popliteus (Last 1948). A *meniscofibular ligament* has been described in about 80% of knee joints (Živanović 1973).

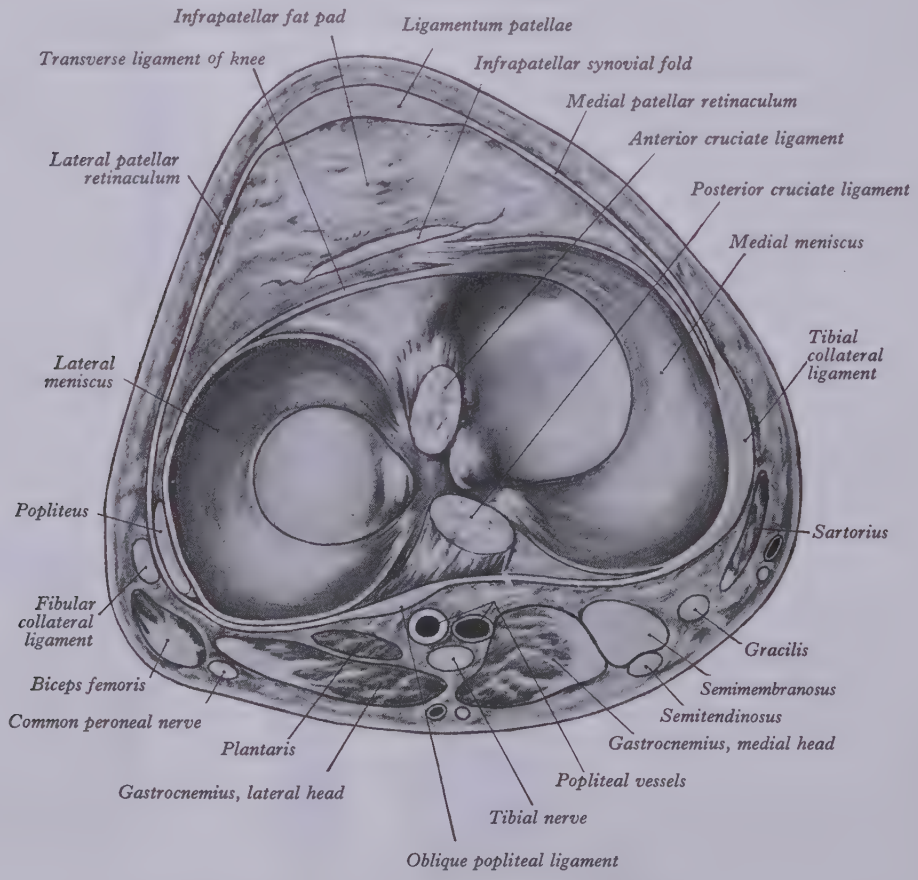


That menisci meet a functional need is shown by their reformation after full excision, regeneration being from peripheral vascular tissue. Prior to such reformation the knee joint shows no instability; but if it is subjected to continued violent exercise, subsequent history indicates that articular cartilage suffers permanent damage, perhaps due to inefficient lubrication.

4.74 Superior aspect of the left tibia, showing the menisci and the tibial attachments of the cruciate ligaments.

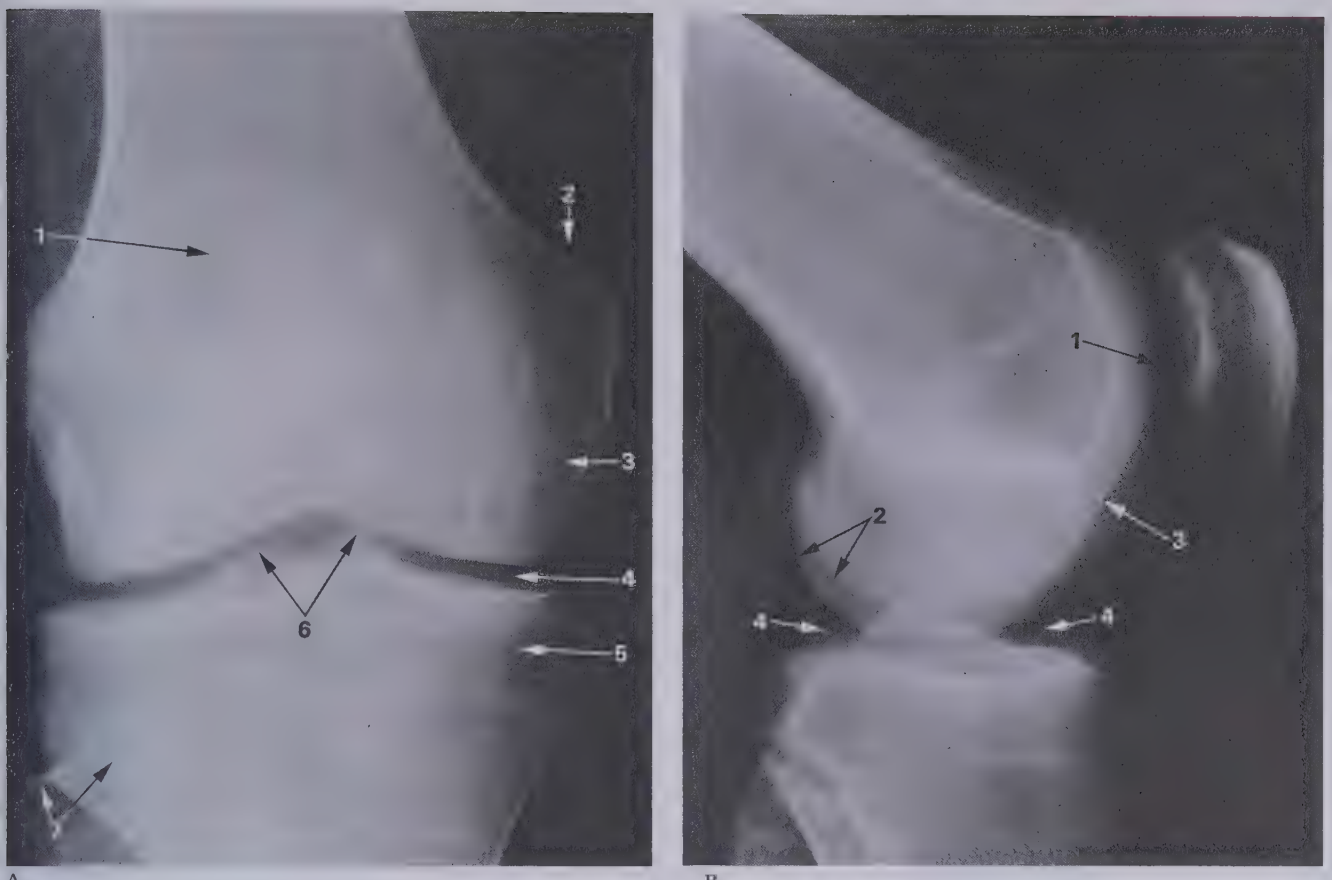
The transverse genual ligament (4.74) connects the anterior convex margin of the lateral to the anterior cornu of medial meniscus; it varies in thickness and may be absent. According to Živanović (1974) this *menisco-meniscal* ligament varies much and is absent from about 40% of joints. A posterior menisco-meniscal ligament was observed in 20% of 300 knee joints; the same observer described other inconstant ligaments.

Bursae associated with the knee are numerous. **Anteriorly** are: (1) a large *subcutaneous prepatellar bursa* between the lower



4.75 Sagittal section through the left knee joint: lateral aspect. The synovial membrane is shown in colour. See also 4.4.

patella and skin; (2) a small *deep infrapatellar bursa* between the tibia and ligamentum patellae; (3) a *subcutaneous infrapatellar bursa* between the distal part of the tibial tuberosity and skin; and (4) a large *suprapatellar bursa* between the femur and quadriceps femoris (4.75), developing separately although (4) is later continuous with the joint and better regarded as part of it. **Laterally** there are: (1) a bursa between the *lateral head of gastrocnemius* and joint capsule (sometimes continuous with the joint); (2) one between the *fibular collateral ligament* and *tendon of biceps femoris*; (3) one also between the *fibular collateral ligament* and *tendon of popliteus* (sometimes an expansion from 4); (4) one between the *tendon of popliteus* and *lateral femoral condyle*, usually an extension from the joint. **Medially** are bursae: (1) between the *medial head of gastrocnemius* and fibrous capsule, with a prolongation between the medial tendon of gastrocnemius and the tendon of semimembranosus, often communicating with the joint; (2) superficial to the *tibial collateral ligament*, between this and *tendons of sartorius, gracilis and semitendinosus*; (3) *deep* to the *tibial collateral ligament* in variable numbers and positions between this ligament and the femur, capsule, medial meniscus, tibia or tendon of semimembranosus; (4) between the *tendon of semimembranosus* and the *medial tibial condyle* and also the medial head of gastrocnemius, named the *semimembranosus bursa* which may communicate with (1); (5) occasionally between the tendons of semimembranosus and semitendinosus. Posteriorly, bursal extensions vary.



Relations. *Anterior* are the tendon of quadriceps femoris enclosing and attached to nonarticular surfaces of the patella, the tendon's continuation, the ligamentum patellae, and tendinous expansions from vasti medialis and lateralis extending over *anteromedial* and *anterolateral* aspects of the capsule respectively, as patellar retinacula. *Posteromedial* is sartorius, with the tendon of gracilis along its posterior border, both descending across the joint. *Posterolaterally* biceps tendon, with the common peroneal nerve medial to it, is in contact with capsule, separating it from popliteus (4.76). *Posteriorly* the popliteal artery and associated lymph nodes are on the oblique popliteal ligament, with the popliteal vein posteromedial or medial and tibial nerve posterior to both. The nerve and vessels are overlapped by both heads of gastrocnemius and laterally by plantaris. Around the vessels gastrocnemius contacts the capsule and medial to its medial head semimembranosus is between capsule and semitendinosus.

Arteries supplying the joint are the descending genicular branches of the femoral, superior, middle and inferior genicular branches of the popliteal, anterior and posterior recurrent branches of anterior tibial, the circumflex fibular artery and the descending branch of lateral circumflex femoral. (For genicular anastomoses see p. 786.) Scapinelli (1968) and Wladmirow (1968) showed a penetrative ligamentous supply, even the cruciate ligaments receiving small vessels. *Nerves* are from the obturator, femoral, tibial and common peroneal nerves (Gardner 1948a, Freeman & Wyke 1967).

Movements are customarily described as flexion, extension, medial and lateral rotation. Flexion and extension differ from true hinging: firstly, the spiral profiles of femoral condyles shift the axis up and forwards during extension, back and downwards during flexion; secondly, with the foot fixed, the last 30° of extension involves conjunct medial femoral rotation and early flexion entails corresponding lateral rotation. These conjunct rotations are due to the geometry of articular surfaces and the disposition of ligaments. Conversely, with the foot free to move, extension involves lateral rotation of tibia and flexion a medial rotation. In full flexion posterior parts of tibial surfaces contact posterior parts of femoral articular surfaces. During extension tibia and menisci glide forwards on the femoral condyles, the area of contact increasing and also moving forwards, carrying menisci with it. As movement progresses flatter parts of the femoral condyles contact the tibia and menisci are opened out, their anterior ends moving forwards, the posterior moving little. In flexion the reverse occurs so that menisci, moving with tibia, adapt to the curves of the femoral condyles where contact occurs.

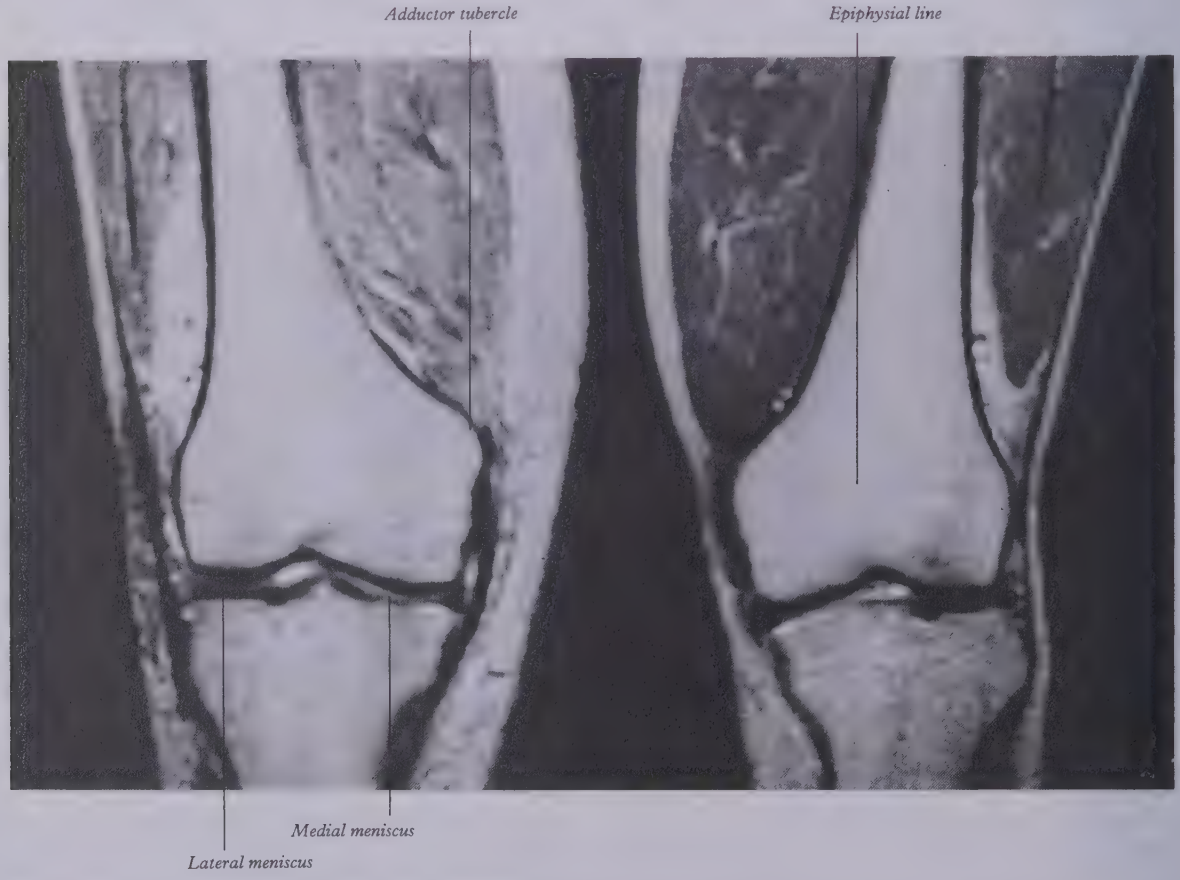
Rotations have a smaller range than flexion and extension, and involve translation of menisci *with* femoral condyles on the tibia. These rotations are *conjunct*, integral with flexion and extension but can be *adjunct* and independent, best demonstrated with the knee semiflexed.

Range of extension is about 5–10° beyond a vertical femorotibial axis, flexion about 120° with the hip extended, or 140° when it is flexed, and 160° when a passive element such as sitting on the heels aids it. *Passive* rotation is about 60–70° but *conjunct* rotation only about 20°.

Conjunct medial rotation of femur on tibia in later stages of extension is part of a 'locking' mechanism, an asset when fully extended knees are subjected to strain. Full extension is the position of close-packing, with maximal congruence, compression and contact area, maximal spiralization and tautening of ligaments. The roles of articular surfaces, musculature and ligaments in generating conjunct rotations have been much disputed (Barnett 1952, Kapandji 1974, Girgis et al 1975, Rajendran 1985) but the following points can be made. The *lateral* combined meniscotibial 'receiving surface' is smaller, more circular, more deeply concave. The lateral femoral articular surface is also smaller, rounder and flattens more rapidly. Consequently, the lateral femoral condyle approaches full congruence with the opposed surface about 30° before full extension (well before the medial condyle). Simple extension cannot continue but medial rotation of the femur occurs on a vertical axis through its head and lateral condyle, the medial femoral condyle moving backwards in an arc; while rotation of the lateral femoral condyle and meniscus brings the latter's anterior cornu on to the anterior slope of the lateral tibial condyle. Full congruence of lateral condyle is thus delayed by this deformation of its 'receiving surface' and extension continues. Rotation and extension follow simultaneously and smoothly until final close-packing of both condyles coincides. At the beginning of flexion from full extension (with foot fixed) lateral femoral rotation occurs, 'unlocking' the joint. While joint surfaces and many ligaments are again similarly involved, electromyographic evidence shows that contraction of popliteus is important, pulling down and backwards on the lateral femoral condyle, *lateral* to the axis of femoral rotation. Through its attachment to the lateral meniscus, it also retracts its posterior cornu during lateral rotation and continuing flexion, obviating traumatic compression (Last 1950).

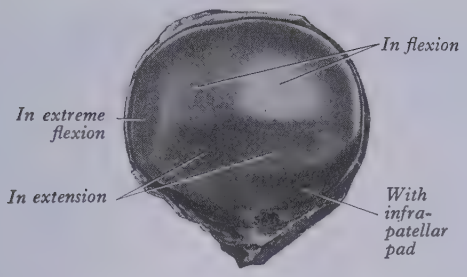
During extension femoral rotation is observable about 30° before full extension; it first progresses slowly, but more rapidly in the last 5°, when there is a progressive increase in passive mechanisms resisting further extension, i.e. spiralizing and tautening of ligaments, increasing congruence and compression of articular surfaces and gradually increasing tension in all extra-articular tissues crossing the joint's posterior aspect (Smith 1956). Any actual position of extension adopted is a balance between forces (torque) extending the joint and passive mechanisms resisting this. The range *near* to close-packing is functionally important. In symmetrical standing, the line of body weight is anterior to the transverse axes of the knee joints but the *passive* mechanisms noted above preserve posture with minimal muscular effort (Joseph 1960). Active contraction of extensors and a close-packed position only occur in asymmetrical postures, in leaning forward, heavy loading or when powerful thrust is needed.

In extension parts of both cruciate ligaments, tibial and fibular collateral ligaments, the posterior capsular region, oblique posterior ligament, skin and fasciae are all taut; passive and sometimes active tension exists in the hamstrings and gastrocnemius, and the anterior parts of menisci are compressed between femoral and tibial condyles. (Kaplan 1958 and Evans 1977 have suggested



4.78A Radiograph taken after injection of air into the knee joint, showing the shadow thrown by the medial meniscus. The upper arrow points to the medial ligament and the lower to the medial meniscus. (Aerogram by A A Butler, RAF.)

the iliotibial tract as a strong tibial collateral ligament, see p. 528.) During extension the ligamentum patellae is tightened by quadriceps femoris but is relaxed in the erect attitude. When the knee flexes the fibular collateral and *posterior* part of the tibial collateral ligament relax but the cruciate ligaments and *anterior* part of the tibial collateral remain taut; posterior parts of the menisci are compressed between femoral and tibial condyles. Flexion is checked by the quadriceps extensor, anterior parts of the capsule, posterior cruciate ligament, and compression of soft tissues behind the knee. In extreme *passive* flexion, contact of calf with thigh may be the limiting factor; parts of both cruciate ligaments also tense. In addition to conjunct rotation with terminal extension or initial flexion, relaxed collateral ligaments allow independent medial and lateral rotation (adjunct rotation) when the joint is flexed. One cruciate ligament at least is taut in all positions; it acts as a direct bond between tibia and femur, limiting the former's translation back or forwards. In extension collateral ligaments assist the cruciate ligaments in this role. Forward gliding of tibia on femur is prevented by the anterior cruciate, backward gliding of tibia on femur by the posterior cruciate ligament.



During femoral extension on a fixed tibia, femoral articular surfaces simultaneously roll forward, slide back and spin medially. However, tibial extension on a relatively fixed femur involves simultaneous forward tibial roll, slide and lateral spin. This analysis is illustrated in **4**.16A,B. For geometrical analysis consult Low & Lewis (1977).

Menisci probably assist lubrication, facilitate combined sliding, rolling and spinning, and may cushion extremes of flexion and extension (p. 529). Seedham et al (1974,1979) have demonstrated their role in cushioning compression forces.

Accessory movements. Wider rotation can be obtained by passive movements when the knee is semiflexed; the tibia can also, to a limited extent, be translated back and forwards on the femur. Abduction and adduction are prevented in full extension by

4.78B Magnetic resonance imaging scan of the knee joints of an adult male, showing the menisci. (Supplied by Philips Medical Systems; photographed by Sarah Smith.)

4.79 Posterior surface of the right patella, showing areas of contact with the femur and infrapatellar fat pad in different positions of the knee joint as indicated.

collateral and cruciate ligaments. With the knee slightly flexed limited adduction and abduction are possible, passive and active. Slight separation of femur and tibia results from strong traction.

Muscles Producing Movements

Flexion: biceps femoris, semitendinosus and semimembranosus, assisted by gracilis, sartorius and popliteus. With the foot stationary, gastrocnemius and plantaris also assist.

Extension: quadriceps femoris, assisted by tensor fasciae latae.

Medial rotation of flexed leg: popliteus, semimembranosus and semitendinosus, assisted by sartorius and gracilis.

Lateral rotation of flexed leg: biceps femoris.

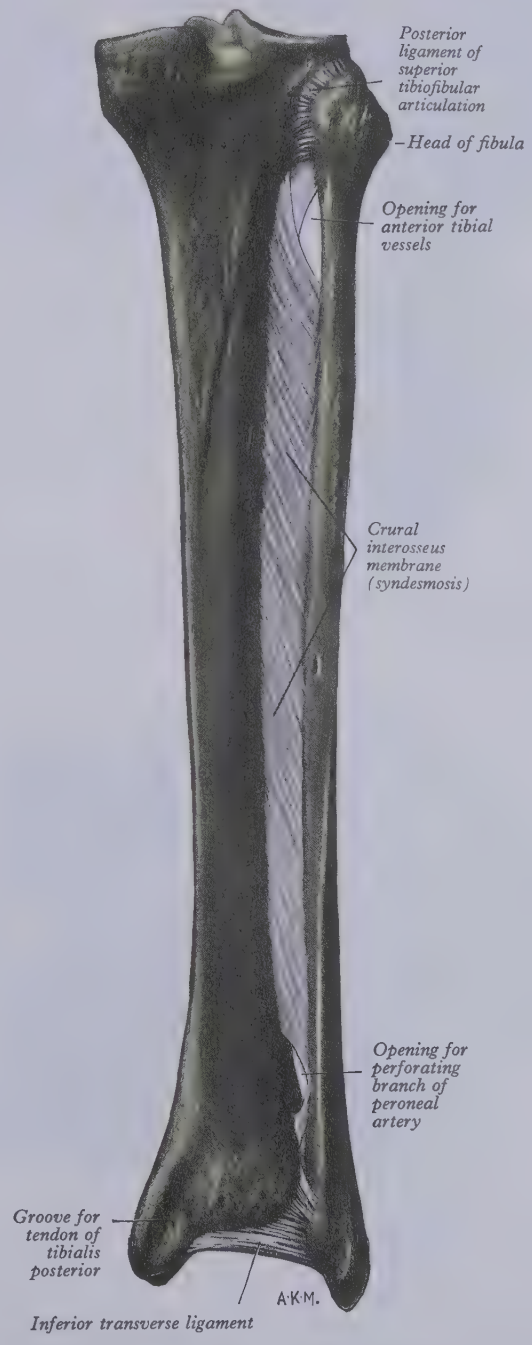
Applied Anatomy. The knee appears to be an insecure joint. Between the two longest bones, it is subject to much leverage; articular surfaces are poorly congruent and range of motion is great. Nevertheless, the powerful ligaments and strong muscles concerned make it one of the strongest joints. Many muscles have direct attachments to the fibrous capsule. Traumatic dislocation is rare. Injuries of a meniscus are, however, common, resulting from twisting strains applied to the knee when slightly or fully flexed. Damage may be a complete tear across the full width, a partial split extending from the free border or a longitudinal tear within the cartilage; occasionally its periphery is detached from the capsule. The torn or detached part may be displaced centrally and jam between surfaces of femur and tibia, arresting all movement. Menisci are largely avascular; a tear cannot heal unless close to the capsule (p. 529). The medial meniscus is more commonly injured, probably because it is more securely attached to the medial capsule and ligaments and less adaptable to sudden change of position. During rotation of a flexed or partially flexed knee the medial cartilage moves more than the lateral. On the other hand, medial fibres of popliteus may draw the posterior part of the lateral meniscus back onto the groove behind the lateral tibial condyle, preventing trapping between articular surfaces.

Injuries to cruciate ligaments are also common, ranging from sprain to rupture. The anterior is more commonly affected. Damage to the tibial collateral ligament is less common, since excessive strain is likely only in full extension.

Osteoligamentous preparations have aided analysis of excessive movements due to ligamentous injuries. In a flexed knee the fibular collateral and posterior part of the tibial collateral ligaments relax. If either cruciate ligament is cut, tibial gliding is increased. Rotation is increased if either cruciate or tibial collateral ligaments are cut. Division of both collateral ligaments allows excessive lateral rotation but medial rotation is unchanged. Abduction and adduction are excessive if both cruciate ligaments are cut.

Acute traumatic synovitis is frequent in the knee. When its cavity is distended with fluid, the swelling shows above and alongside the patella, 5 cm or more above the femur's patellar surface, and extends a little more under vastus medialis than under the lateralis; the synovial membrane descends just below the tibial plateau.

Genual bursae are sometimes distended. Subcutaneous prepatellar or infrapatellar bursae are frequently caused by excessive kneeling. The semimembranosus bursa is occasionally enlarged, forming a fluctuant swelling at the back of the knee. During extension it is tense but in flexion soft, if it communicates with the joint.

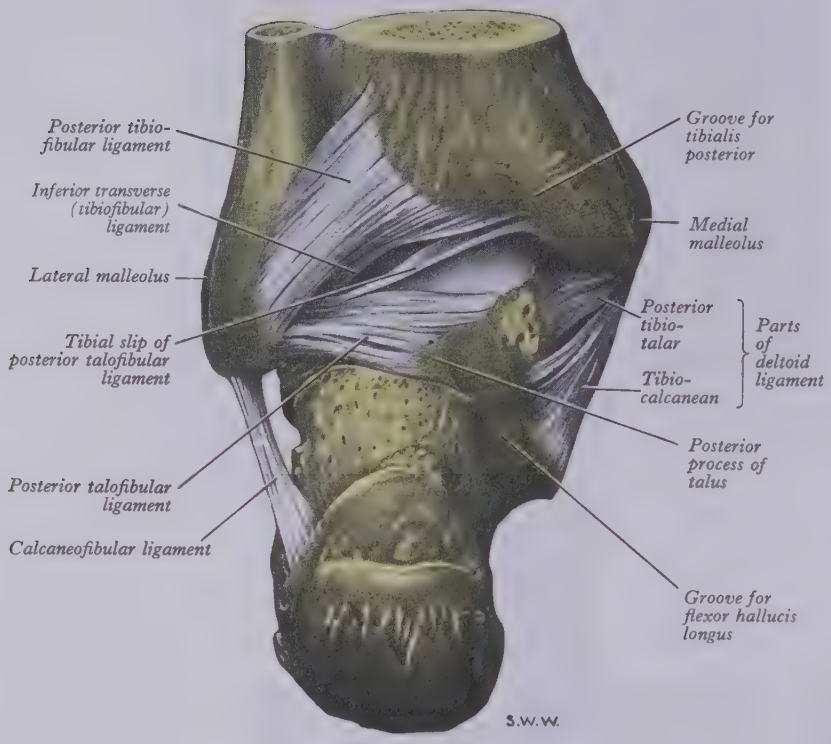


Tibiofibular Articulations

Tibia and fibula are connected at both ends by a proximal synovial and distal fibrous joint. Their shafts are also tied by the crural interosseous membrane. The distal fibrous joint and interosseous membrane are syndesmoses.

THE PROXIMAL TIBIOFIBULAR JOINT

This (4.80) is an almost plane joint between the lateral tibial condyle and fibular head. The *articular surfaces* vary in size, form and inclination. The fibular facet is usually elliptical or circular, almost flat or slightly grooved. Surfaces are hyaline cartilage, with anterior and posterior ligaments.



The fibrous capsule is attached to the margins of rims of facets on tibia and fibula and anteriorly and posteriorly thickened. In about 10% the synovial membrane is continuous with that of

4.80 Crural interosseous membrane: posterior aspect. Note contrasting directions of collagen fibre bundles around both vascular apertures.

the knee joint via the subpopliteal recess (p. 527). **The anterior ligament** has two or three flat bands, passing obliquely up from the fibular head to the front of the lateral tibial condyle. **The posterior ligament**, a thick band, ascends obliquely between posterior aspects of the fibular head and the lateral tibial condyle, covered by the popliteal tendon. These ligaments are not entirely separate from the capsule.

Arteries are from anterior and posterior tibial recurrent rami of the anterior tibial, *nerves* from the common peroneal nerve and from the nerve to the popliteus.

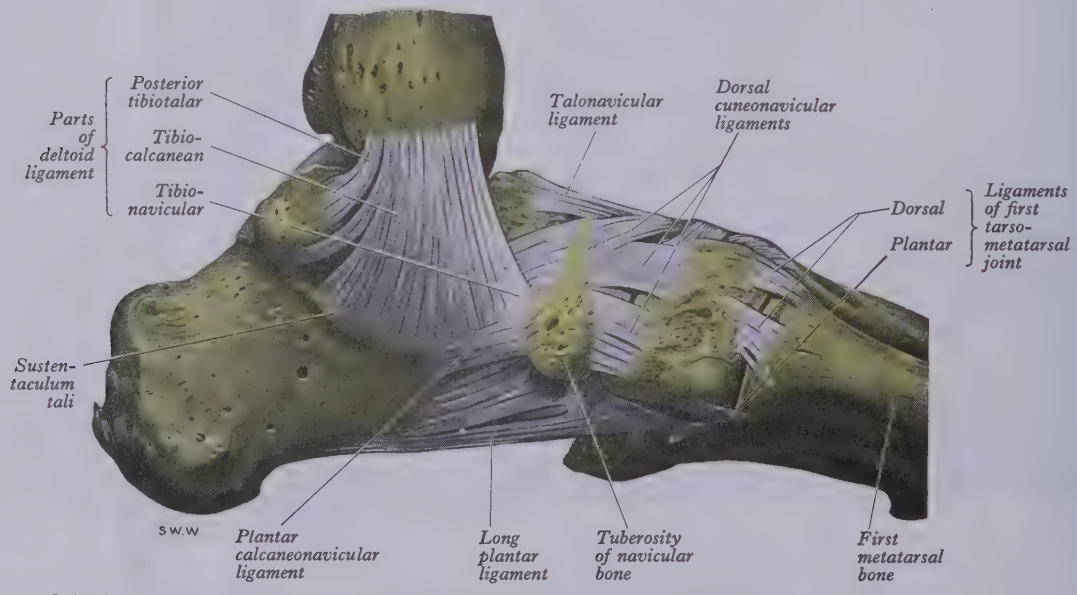
4.81 Left talocrural joint: posterior aspect. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, with permission from the Council.)

THE CRURAL INTEROSSEOUS MEMBRANE

This (4.80) connects the interosseous borders of tibia and fibula, separating the anterior and posterior muscles in the leg, some being attached to it. The anterior tibial artery passes forwards through a large oval opening near the membrane's proximal end; distally the perforating branch of the peroneal artery pierces it. Its fibres, largely oblique, mainly descend laterally but a few descend medially including a bundle at the proximal border of the proximal opening. The membrane is distally continuous with the interosseous ligament of the distal tibiofibular joint. Anterior to it are tibialis anterior, extensors digitorum longus and hallucis longus, peroneus tertius, the anterior tibial vessels and deep peroneal nerve; posterior to it, tibialis posterior and flexor hallucis longus.

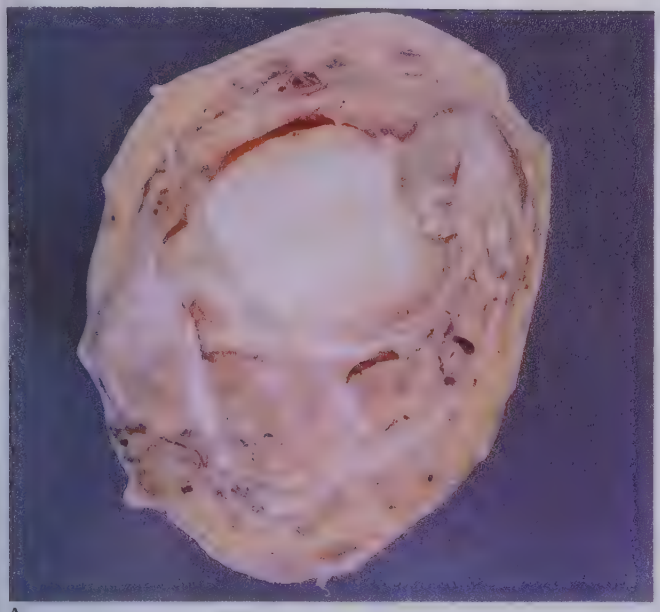
THE DISTAL TIBIOFIBULAR JOINT

This is between the rough, medial *convex* surface on the fibula's distal end and the rough *concave* surface of the tibia's fibular notch, which are separated distally for about 4 mm by a synovial prolongation from the talocrural joint and may be covered by articular cartilage in the lowest millimetre. The joint is usually considered a syndesmosis (p. 468).



The anterior tibiofibular ligament (4.87), a flat band, descends laterally between adjacent margins of tibia and fibula, anterior to the syndesmosis.

The posterior tibiofibular ligament (4.81) is stronger and disposed similarly on the posterior aspect of the syndesmosis. Its distal, deep part is the *inferior transverse ligament*, a thick band of yellow fibres crossing from the proximal end of the lateral malleolar fossa to the posterior border of the tibial articular surface almost to the medial malleolus. The ligament projects distal to the bones, in contact with the talus. Its colour reflects its content of yellow elastic fibres.



The interosseous ligament, continuous with the crural interosseous membrane, contains many short bands between rough adjacent tibial and fibular surfaces and is the strongest bond between the bones.

Movements

The tibiofibular joints permit only slight movement. Due to the varying slope of the talar lateral malleolar surface, the fibula rotates laterally a little during dorsiflexion at the ankle (Barnett & Napier 1952), the bones being also slightly separated. Although slight bending or torsion of the fibular shaft might permit

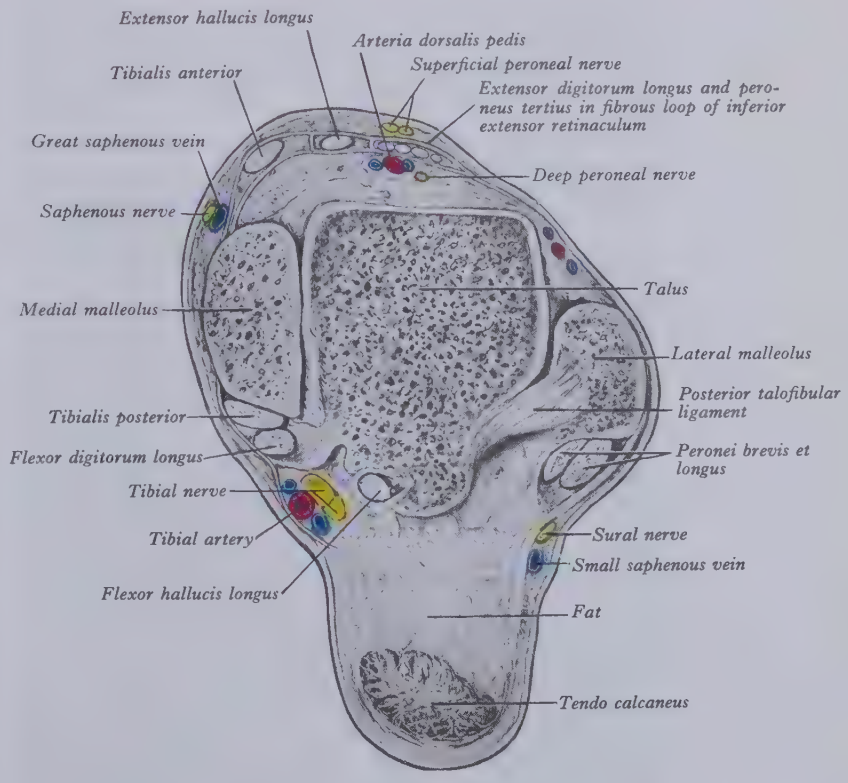
movements at the distal tibiofibular joint, the proximal probably also helps (p. 536).

Arteries are from the peroneal perforating branch and medial malleolar rami of anterior and posterior tibial arteries. *Nerves* are from the deep peroneal, tibial and saphenous nerves.

The Talocrural Joint



The talocrural (ankle) joint is approximately uni-axial. The tibia's lower end and its medial malleolus, with the fibular lateral malleolus and inferior transverse tibiofibular ligament, form a deep recess for the body of the talus. Its line is judged by the anterior margin of the tibia's distal end, which is palpable when the overlying tendons are relaxed. Although it appears a simple hinge, usually styled 'uni-axial', its axis of rotation is dynamic, shifting during dorsi- and plantar flexion (Sammarco 1977).

Articular surfaces are covered by hyaline cartilage. The talar trochlear surface, convex parasagittally, transversely gently concave, is wider in front; the distal tibial articular surface is reciprocally curved. The talar articular surface for the medial malleolus is a proximal area on the medial talar surface, being fairly flat, comma-shaped and anteriorly deeper. The larger lateral talar articular surface is triangular and vertically concave, that on the lateral malleolus is reciprocally curved. Posteriorly the edge between trochlear and fibular articular surfaces of the talus is bevelled to a narrow, flat triangular area articulating with the inferior transverse tibiofibular ligament (4.85,86). All these talar surfaces are continuous. The bones are connected by a fibrous capsule, medial (deltoid), anterior and posterior talofibular and calcaneofibular ligaments.

The fibrous capsule around the joint is thin in front and behind, attached proximally to the borders of tibial and malleolar articular surfaces and distally to the talus near the margins of its trochlear surface, except in front where it reaches the dorsum of the talar neck. It is strengthened by strong collateral ligaments. Its posterior part is mainly of transverse fibres. It blends with the inferior transverse ligament and is thickened laterally where it reaches the fibular malleolar fossa.

Synovial membrane lining the capsule ascends as a short vertical recess between tibia and fibula (4.88).

The medial ligament (deltoid collateral 4.82,88) is a strong, triangular band, attached to the apex and to the anterior and posterior borders of the medial malleolus. Of its *superficial fibres* the anterior (*tibionavicular*) pass forwards to the navicular tuberosity and behind this blend with the medial margin of the plantar calcaneonavicular ligament; intermediate (*tibiocalcaneal*) fibres descend almost vertically to the whole length of the sustentaculum tali; posterior fibres (*posterior tibiotalar*) pass

4.84 Transverse section through the lower part of the right talocrural joint: superior aspect.

posterolaterally to the medial side of talus and its medial tubercle. The *deep fibres* (*anterior tibiotalar*) pass from the tip of medial malleolus to the non-articular part of the medial talar surface. The ligament is crossed by tendons of tibialis posterior and flexor digitorum longus.

The anterior talofibular ligament (4.87) extends anteromedially from the anterior margin of the fibular malleolus to the talus, attached in front of its lateral articular facet and to the lateral aspect of its neck. **The posterior talofibular ligament** (4.81) runs almost horizontally from the distal part of the lateral malleolar fossa to the lateral tubercle of the posterior talar process. A 'tibial slip' of fibres connects it to the medial malleolus. **The calcaneofibular ligament** (4.87), a long cord, runs from a depression anterior to the apex of fibular malleolus to a tubercle on the lateral calcaneal surface and is crossed by tendons of peroneus longus and brevis. The three ligaments above constitute the **lateral ligament** of the talocrural joint.

Relations. *Anteriorly*, from the medial side, tibialis anterior, extensor hallucis longus, anterior tibial vessels, deep peroneal nerve, extensor digitorum longus and peroneus tertius; posteriorly from the medial side, tibialis posterior, flexor digitorum longus, posterior tibial vessels, tibial nerve, flexor hallucis longus; in the groove behind the fibular malleolus, tendons of peroneus longus and brevis (4.83).

Arteries are from malleolar rami of anterior tibial and peroneal arteries. *Nerves* are from deep peroneal and tibial nerves.

Movements. When the body is upright and the foot at right angles to the leg, *active movements* of the joint are dorsiflexion (*c.*10°) and plantar flexion (*c.* 20°), the former decreasing the anterior angle between leg and foot, the latter increasing it. Dorsiflexion is the position of 'close-pack', with maximal congruence and ligamentous tension; from this position all major thrusting movements are exerted, in walking, running and jumping. The malleoli embrace the talus; even in relaxation no appreciable lateral movement can occur without stretch of the inferior tibiofibular syndesmosis and slight bending of the fibula. The superior talar surface is broader in front, and in dorsiflexion the malleolar gap is increased by slight lateral rotation of the fibula by 'give' at the inferior tibiofibular syndesmosis and gliding at the superior tibiofibular joint. The medial (deltoid) ligament is very strong and is even able to resist forces which tear the bone to which it is attached. Its middle part, with the calcaneofibular ligament, binds leg firmly to foot, resisting displacement in all directions. The posterior talofibular ligament assists the calcaneofibular in resisting posterior displacement, deepening the joint for the talus. The anterior talofibular ligament limits anterior displacement. Plantar flexion is limited by the opposing muscles, anterior fibres of the medial (deltoid) and by the anterior talofibular ligaments. Dorsiflexion is limited by the calcaneal tendon and contraction of triceps surae, posterior fibres of medial (deltoid) and calcaneofibular ligaments (4.87). Dorsi- and plantar flexion are increased by intertarsal movements, adding about 10° to the former, 20° to the latter.

Accessory movements. Slight amounts of side-to-side gliding, rotation, abduction and adduction are permitted, when the foot is plantarflexed.

Muscles Producing the Movements

(see also pp. 645–651, 656–657)

Dorsiflexion: tibialis anterior, assisted by extensores digitorum longus and hallucis longus, and peroneus tertius.

Plantar flexion: gastrocnemius and soleus, assisted by plantaris, tibialis posterior, flexores hallucis longus and digitorum longus.

In symmetrical standing the line of body weight is anterior to the ankle joints, which are not even near their close-packed position. Stability requires continuous action by the solei,

increasing (often with gastrocnemii involved) with leaning forward and vice versa. If backward sway takes the 'weight line' posterior to the transverse axes of the talocrural joints, plantar flexors relax and dorsiflexors contract.

Applied Anatomy. Owing to its depth the talocrural joint is rarely dislocated without malleolar fracture. So-called sprains of the talocrural joint are almost always actually abduction sprains of *subtalar joints*, although some medial (deltoid) fibres may also be torn. True sprains are usually due to forcible plantar flexion, resulting in capsular tears in front (most commonly of the anterior talofibular ligament) and bruising by impaction of structures behind the joint. In ankylosis the optimal position is slight plantar flexion.

Intertarsal Joints

THE SUBTALAR (TALOCALCANEAL) JOINT

There are anterior and posterior articulations between calcaneus and talus, forming a functional unit often termed the 'subtalar joint'; this term is used here only for the posterior, the anterior being treated as part of the talocalcaneonavicular joint (vide infra).

The subtalar joint proper involves the concave posterior calcaneal facet on the posterior part of the inferior surface of the talus and the convex posterior facet on the superior surface of the calcaneus. The joint is modified multi-axial and its permitted movements are considered together with those at other tarsal joints. The bones are connected by a fibrous capsule, lateral, medial, interosseous talocalcaneal and cervical ligaments.

The fibrous capsule (4.89) envelops the joint, its fibres being short and attached to its articular margins; it is split into slips, between which it is thin; its synovial membrane is separate from other tarsal joints.

The lateral talocalcaneal ligament, a short flat fasciculus, descends obliquely back from the lateral talar process to the lateral calcaneal surface and is attached anterosuperior to the calcaneofibular ligament.

The medial talocalcaneal ligament connects the medial talar tubercle to the back of the sustentaculum tali and adjacent medial surface of the calcaneus. Its fibres blend with the medial (deltoid) ligament, the most posterior fibres lining the groove for flexor hallucis longus between the talus and calcaneus.

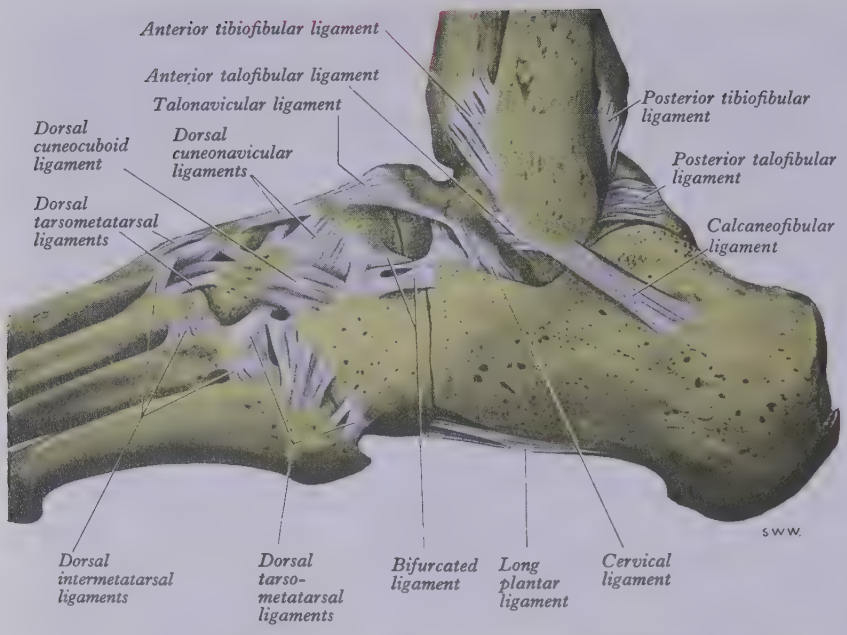
The interosseous talocalcaneal ligament (4.88,89) is a broad, flat, bilaminar transverse band in the sinus tarsi, descending obliquely and laterally from sulcus tali to sulcus calcanei. Its medial fibres are taut in eversion. The ligament's posterior lamina is associated with the talocalcanean joint, its anterior lamina with the talocalcaneonavicular joint (vide infra).

The cervical ligament is just lateral to the sinus tarsi and attached to the superior calcaneal surface, medial to the attachment of extensor digitorum brevis, whence it ascends medially to an inferolateral tubercle on the talar neck (Barclay-Smith 1896, Smith 1958). It is considered taut in inversion.

Movements between talus and calcaneus accompany those at the talocalcaneonavicular joint and will be so described.

THE TALOCALCANEONAVICULAR JOINT

This compound articulation is multi-axial; the ovoid talar head is continuous with the triple-faceted anterior area of its inferior surface (p. 450) and the whole fits the concavity formed by the posterior surface of the navicular, the middle and anterior talar facets of the calcaneus and the superior fibrocartilaginous surface of the plantar calcaneonavicular ligament. The reverse of the subtalar (talocalcaneal) joint, the proximal talocalcaneonavicular surface is convex. The joint's position is judged by the talar head, to be seen and palpated about 3 cm anterior to the lower end of the tibia, with the foot passively inverted. The bones are connected by a fibrous capsule and three ligaments—talonavicular, plantar calcaneonavicular and calcaneonavicular part of the bifurcated ligaments.



4.86 The same foot as in 4.85 with heel raised from the ground, as near the end of the 'stance phase' in walking. Note the forward angulation of the leg bones, plantar flexion at the talocrural joint and the position of the metatarsals and phalanges. 1. Talocrural joint. 2. Subtalar joint. 3. Os trigonum. 4. Sinus tarsi. 5. Calcaneocuboid joint. 6. Sesamoid in peroneus longus tendon. 7. Cuboid. 8. Tuberosity on base of fifth metatarsal. 9. Cuneiforms. 10. Navicular. 11. Talonavicular joint. 12. Head of talus.

The fibrous capsule is poorly developed, except posteriorly, where it is thick and is the anterior part of the interosseous ligament filling the sinus tarsi.

The talonavicular ligament (4.82,87), a broad, thin band, connects the dorsal surfaces of the neck of the talus and the navicular; it is covered by extensor tendons. The *plantar calcaneonavicular ligament* (p. 539) and the *calcaneonavicular part of the bifurcated ligament* (4.87) are the joint's plantar and lateral ligaments respectively.

Movements. Gliding and rotation occur at the talocalcaneal and talocalcaneonavicular joints, by which the calcaneus and navicular, carrying the (*free, non-weight-bearing*) foot, rotate medially on the talus, thus elevating the medial and depressing the lateral border of the foot, bringing its plantar aspect medial. This is *inversion*, occurring mainly at the subtalar joint and the complex articulation between the talar head, with its plantar extensions, and the sustentaculum tali, calcaneus, plantar calcaneonavicular ligament and posterior navicular surface. Joint surfaces are reciprocally curved but in opposite directions in the two joints, and movements at them have been likened to those between radius and ulna at the superior and inferior radio-ulnar joints. The axis joins their approximate centres of curvature, ascending anteromedially from the back of the calcaneus, crossing the sinus tarsi obliquely to reach the superomedial aspect of the talar neck (Shepard 1951). Axial obliquity explains, in part, the adduction and slight plantar flexion of the foot (but to a greater degree the forefoot) in inversion. Movement of calcaneus around talus,

4.87 Ligaments of the left talocrural and tarsal joints: lateral aspect. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, by permission of the Council.)

however, also involves movement at the *transverse tarsal articulation* (talonavicular and calcaneocuboid joints); forefoot range is thereby increased. These joints are almost in one transverse plane; during inversion the navicular rotates on the talar head, while the cuboid glides down and rotates at the sellar calcaneocuboid joint. Range of inversion is further increased in plantar flexion; the narrow part of the talar trochlear surface now occupies the tibiofibular mortice and slight talar movement increases adduction with inversion. The opposite movement, more limited in range, is *eversion*.

Inversion is chiefly checked by peroneal muscles and the lateral part of the interosseous talocalcaneal ligament (p. 537). The other tarsal interosseous ligaments and the calcaneofibular are less powerful factors. Eversion is arrested by tibiales anterior and the posterior and medial (deltoid) ligament.

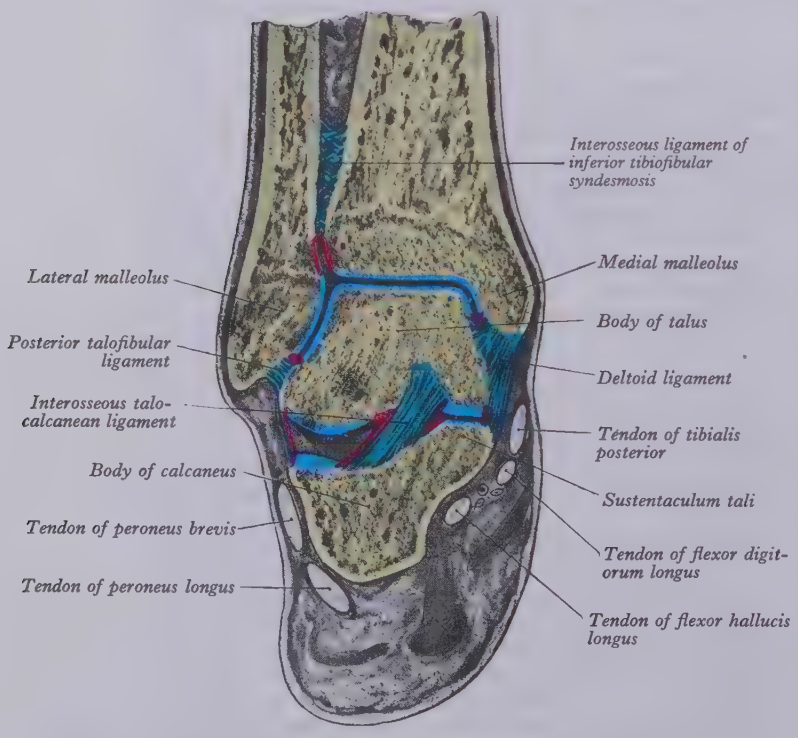
The complex actions of inversion and eversion described above refer to changes in the whole foot (with minor movements of the talus), *when it is off the ground*. The fully inverted foot is also plantar flexed; conversely, eversion is linked with dorsiflexion. *When the foot is transmitting weight or thrust* these movements are modified to maintain plantigrade contact. The distal tarsus and metatarsus are *pronated* or *supinated* relative to calcaneus and talus, pronation involving a downward rotation of the medial border and hallux; supination being the reverse, both bring the lateral border into plantigrade contact. Further, when there is *angulation* of tibia and fibula in the coronal plane, either laterally but particularly medially, these bones and their distal mortice carry the talus with them in their movements. The talus tilts (rotates) around the oblique transarticular intercentroid axis (described above) at first, relative to the rest of the subtalar foot and moving at the talocalcaneal and talocalcaneonavicular joints. When close-packing occurs between talus and calcaneus, further angulation is accompanied by tilting of the functional unit of the combined *talus and calcaneus*, the latter involving the calcaneocuboid joint. Unfortunately, the terms inversion and eversion are often confused with pronation and supination, the latter being *components* of the former, like the slight adduction and abduction which may accompany inversion and eversion. Supination and pronation can be dissociated from inversion and eversion in adaptation of the forefoot in plantigrade stance or progression (pp. 542–544, 656–659).

Terminology of pedal movements is somewhat confused amongst orthopaedists, kinesiologists and others. The above account represents widely accepted usage (MacConaill 1950, Kapandji 1970, MacConaill & Basmajian 1977, Keller 1977). According to Kapandji (1970), inversion is a combination of adduction and supination, eversion involving abduction and pronation.

Muscles Producing the Movements

Inversion: tibiales anterior and posterior.
Eversion: peroneus longus and brevis.

THE CALCANEOCUBOID JOINT



Articular surfaces of the calcaneocuboid joint, which is 2 cm proximal to the tubercle, on the fifth metatarsal base, are sellar. Its ligaments are: the fibrous capsule, calcaneocuboid part of the bifurcated ligament, long plantar and plantar calcaneocuboid ligaments.

The fibrous capsule is thickened dorsally as the *dorsal calcaneocuboid ligament*. The synovial membrane is distinct from other tarsal articulations (4.92).

The bifurcated ligament (4.87), a strong Y-shaped band, is attached by its stem proximally to the anterior part of the upper calcaneal surface; distally it divides into calcaneocuboid and calcaneonavicular parts. The *(medial) calcaneocuboid ligament* extends to the dorsomedial aspect of the cuboid bone, forming a main bond between the two rows of tarsal bones; the *(lateral) calcaneonavicular ligament* is attached to the dorsolateral aspect of the navicular bone.

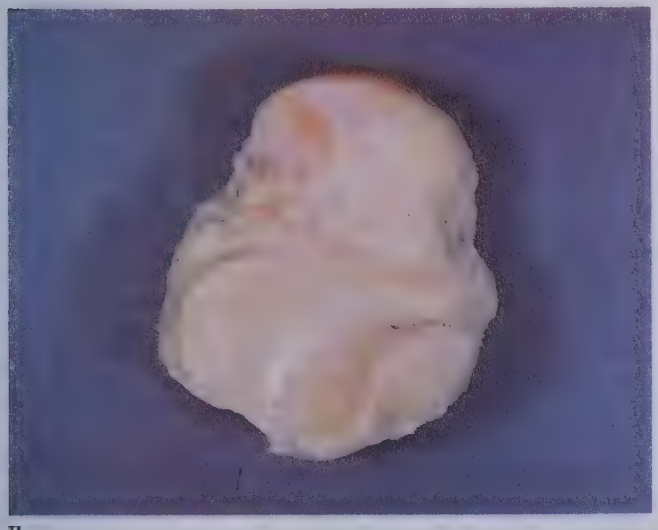
The long plantar ligament (4.90), the longest ligament in the tarsus, extends from the plantar surface of the calcaneus (anterior to its tuberosity's processes) and from its anterior tubercle, to the ridge and tuberosity on the cuboid's plantar surface, to which deep fibres are attached, more superficial fibres continuing to the bases of the second to fourth and sometimes fifth metatarsal bones. This ligament, with the groove on the cuboid's plantar surface, makes a tunnel for the tendon of peroneus longus. It is a most powerful factor limiting depression of the lateral longitudinal arch (p. 543).

The plantar calcaneocuboid ligament (*short plantar ligament*) is nearer to bone than the preceding, from which it is separated by areolar tissue. It is a short, wide band of great strength, stretching from the anterior calcaneal tubercle and the depression anterior to it to the adjoining part of the plantar surface of the cuboid; it also sustains the lateral longitudinal arch.

4.88 Coronal section through the left talocrural and talocalcaneal joints.

Movements. Movements between the calcaneus and cuboid are gliding with conjunct rotation upon each other during inversion and eversion of the whole foot and during pronative or supinative changes between fore- and hindfoot (pp. 542–544).

LIGAMENTS CONNECTING CALCANEUS AND NAVICULAR BONE



Though calcaneus and navicular do not articulate directly, they are connected by (lateral) calcaneonavicular and plantar calcaneonavicular ligaments. **The (lateral) calcaneonavicular ligament** has been described above as the medial band of the bifurcated ligament.

The plantar calcaneonavicular (spring) ligament (4.82,89,91), a broad, thick band, connects the anterior margin of the sustentaculum tali to the navicular's plantar surface. It ties the calcaneus to the navicular below the head of the talus as part of its articular cavity; it sustains the foot's medial longitudinal arch (p. 543). The ligament's *dorsal surface* has a triangular fibrocartilaginous facet on which part of the talar head rests (4.89). Its *plantar surface* is supported medially by the tendon of tibialis posterior and laterally by tendons of flexores hallucis longus and digitorum longus; its *medial border* is blended with anterior superficial fibres of the lateral (deltoid) ligament. There is no real evidence that the 'spring' ligament is particularly resilient.

THE CUNEONAVICULAR JOINT

The navicular articulates distally with the cuneiform bones at a compound joint often described as plane although the distal navicular surface is transversely convex and divided into three facets by low ridges, adapted to the proximal, slightly curved cuneiform surfaces. Its capsule is continuous with those of intercuneiform and cuneocuboid joints, as is its synovial cavity, and it is connected also to the second and third cuneometatarsal joints and inter-metatarsal joints between the second to fourth metatarsal bones (p. 540).

Dorsal and plantar ligaments connect the navicular to each cuneiform bone; of the three dorsal ligaments, one is attached to each cuneiform. The fasciculus from navicular to medial cuneiform is continued as the joint's capsule around its medial aspect, and then blends medially with the plantar ligament. Plantar

C

4.89B,C. A dissection in which the talus has been removed from the subjacent osseous and ligamentous tarsal elements. Compare the reciprocal articular curvatures of the inferior surface of the talus (B) and those of the superior aspects of their conarticular tarsal elements (C). Note the ovoid surfaces of the (posterior) talocalcaneal articulation (the *subtalar* joint of some authorities). Anteriorly, the complex convexity of the talar head is received into the '*acetabulum pedis*' which is formed by the calcaneus, navicular, the plantar calcaneonavicular ligament and part of the deltoid ligament. The detailed ligamentous architecture between these articulations is described in the text, and illustrated diagramatically (4.89A).

4.90 Ligaments of the plantar surface of the left foot. Some of the fibres of the long plantar ligament which arise in front of the medial tubercle of the calcaneus have been removed. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, by permission of the Council.)

ligaments have similar attachments and receive slips from the tendon of tibialis posterior.

THE CUBOIDEONAVICULAR JOINT

This is usually a fibrous joint, its bones connected by dorsal, plantar and interosseous ligaments. **The dorsal ligament** extends distolaterally, **the plantar** nearly transversely from cuboid to navicular. **The interosseous ligament**, of strong transverse fibres, connects non-articular parts of adjacent surfaces of the two bones (4.92). This syndesmosis is often replaced by a synovial joint, almost plane, its articular capsule and synovial lining continuous with the cuneonavicular.

INTERCUNEIFORM AND CUNEOCUBOID JOINTS

These are all synovial and approximately plane or slightly curved. Their articular capsules and synovial linings are continuous with the cuneonavicular joint. The bones are connected by dorsal, plantar and interosseous ligaments.

The dorsal and plantar ligaments each have three transverse bands, between medial and intermediate cuneiform, intermediate and lateral cuneiform and between lateral cuneiform and cuboid bones. The plantar ligaments receive slips from the tendon of tibialis posterior. **The interosseous ligaments** connect nonarticular areas of adjacent surfaces and are strong agents in the maintaining transverse arch (p. 543).

Movements at cuneonavicular, cuboideonavicular, intercuneiform and cuneocuboid joints are merely slight gliding and rotation during pedal pronation or supination (p. 542), i.e. in alterations of a loaded foot in contact with the ground. For example, they increase suppleness when the forefoot is stressed, as in the initial thrust of running and jumping.

Tarsometatarsal Articulations

These are approximately plane synovial joints. The first metatarsal articulates with the medial cuneiform; the second is recessed between medial and lateral, articulating with the intermediate cuneiform; the third articulates with lateral cuneiform; the fourth with the lateral cuneiform and cuboid and the fifth with the cuboid. The joints are approximately on a line from the fifth metatarsal's tubercle to the hallucial tarsometatarsal joint, except for that between the second metatarsal and intermediate cuneiform, which is 2–3 mm proximal (4.92). The hallucial joint has its own capsule; articular capsules and cavities of the second and third are continuous with intercuneiform and cuneonavicular joints but separated from the fourth and fifth joints by an interosseous ligament between the lateral cuneiform and fourth metatarsal base. The bones are connected by dorsal and plantar tarsometatarsal and interosseous cuneometatarsal ligaments.

The dorsal ligaments are strong and flat. The first metatarsal is joined to the medial cuneiform by an articular capsule; the other tarsometatarsal capsules are blended with dorsal and plantar ligaments. The second metatarsal receives a band from each cuneiform, the third from the lateral cuneiform, fourth from lateral cuneiform and cuboid, fifth from the cuboid alone. **The plantar ligaments** are longitudinal and oblique bands, less regular than the dorsal. Those for the first and second metatarsal bones are strongest; the second and third metatarsals are joined by oblique bands to the medial cuneiform, the fourth and fifth by a few fibres to the cuboid.

The interosseous cuneometatarsal ligaments comprise: (1) the strongest from the lateral surface of the medial cuneiform to the adjacent angle of second metatarsal (4.92); (2) one connecting the lateral cuneiform to the adjacent angle of second metatarsal; this does not divide the joint between the second metatarsal and lateral cuneiform and is inconstant; (3) one connecting the lateral angle of the lateral cuneiform to the adjacent fourth metatarsal base.

Movements between tarsal and metatarsal bones are limited to gliding, very limited in range except between medial cuneiform and first metatarsal, where appreciable *passive* metatarsal flexion, extension and rotation are possible with muscles relaxed but all occurring *actively* in standing and walking to maintain plantigrade contact. Being recessed between medial and lateral cuneiform bones, the second is the least mobile metatarsal. Proximal articular profiles of cuneiform bones bring them into a close-packed state in plantar flexion, splaying them out in dorsiflexion.

Pronation and **supination** keep the feet in plantigrade apposition in a range of stances, from wide straddling to crossed legs. This is usually but inaccurately ascribed to inversion or eversion, because these involve the whole unsupported foot beyond the talus and even including the talus, if the slight adduction and abduction possible at the plantar-flexed ankle are added.

Feet planted far apart are wholly 'inverted' but relative positions of the forefoot and hindfoot must also change to maintain plantigrade contact, because each talus tilts medially with the tibiofibular extremities and its inferior mortice and talar tilt is followed by the calcaneus when limited movement between them is used up. If the rest of the foot followed this tilting (inversion), weight would be largely taken from the lateral to the medial border. To correct this and distribute weight by plantigrade contact, the *forefoot rotates* in the opposite sense, i.e. it *supinates* or *untwists*. This largely occurs at the transverse tarsal joint but others contribute, especially the hallucial cuneometatarsal. Conversely, when feet are together or even crossed, contact with the ground can only be maintained by maximal *pronation* of the forefoot relative to the calcaneus and talus (pp. 542–544).

INTERMETATARSAL JOINTS

The first metatarsal *base* is not connected to the second by ligaments; in this respect hallux resembles pollex (but differs in being distally connected). A small bursa often occurs between first and second metatarsal bases (4.92). Second to fifth metatarsal bases are connected by dorsal, plantar and interosseous ligaments. All metatarsal *heads* are connected indirectly by deep transverse

4.91 Ligaments on the plantar surface of the left foot. The long plantar ligament has been removed. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, by permission of the Council.)

metatarsal ligaments (p. 515). **Dorsal and plantar ligaments** pass transversely between adjacent *bases*. **Interosseous ligaments** are strong transverse bands connecting non-articular parts of the adjacent surfaces (4.92).

Movements between the tarsal ends of metatarsal bones are slight gliding when the forefoot is working under load (cf. intercuneiform joints, p. 540).

Synovial Arrangements of Tarsus and Metatarsus

Synovial cavities (4.92) in tarsus and metatarsus are: (1) subtalar; (2) talocalcaneonavicular; (3) calcaneocuboid; (4) a complex of cuneonavicular, intercuneiform, cuneocuboid; (5) intermediate and lateral cuneiform respectively with second and third metatarsals; (6) second to fourth intermetatarsals; (7) medial cuneiform with first metatarsal; and (8) cuboid with fourth and fifth metatarsals. A small synovial cavity sometimes occurs between the navicular and cuboid, usually communicating with that between cuboid and lateral cuneiform.

Metatarsophalangeal Articulations

These joints are ovoid or ellipsoid between rounded metatarsal heads and shallow cavities on proximal phalangeal bases. They are 2.5 cm proximal to the webs of the toes.

Articular surfaces cover the distal and plantar aspects of metatarsal heads but not the dorsal. The plantar aspect of the first metatarsal head has two longitudinal grooves separated by a ridge; each articulates with a sesamoid bone embedded in the joint's capsule, formed here by tendons of intrinsic hallucial muscles. Articular areas on the proximal phalangeal bases are concave. Ligaments are capsular, plantar, deep transverse metatarsal and collateral.

The fibrous capsules are attached to their articular margins. Thin dorsally, they may be separated from the long extensor tendons by small bursae or they may be replaced by the tendons: they are inseparable from plantar and collateral ligaments.

The plantar ligaments, thick and dense, are between and blend with the collateral ligaments; their attachment to metatarsal bones is loose but firm to phalangeal bases. Their margins blend with the deep transverse metatarsal ligaments. Their plantar surfaces are grooved for the flexor tendons, whose fibrous sheaths connect with the edges of the grooves. Their deep surfaces extend articular areas for metatarsal heads.

The deep transverse metatarsal ligaments are four short, wide, flat bands uniting plantar ligaments of adjoining metatarsophalangeal joints. Dorsal to them are the interosseous muscles, whereas lumbricals and digital vessels and nerves are plantar. They resemble the deep transverse metacarpal ligaments (p. 515) *but* connect with the plantar ligament of the hallucial metatarsophalangeal joint.

The collateral ligaments are strong cords flanking each joint, attached to the dorsal tubercles on the metatarsal heads and the corresponding sides of phalangeal bases; they slope down and forwards.

Movements are like those at the hand's corresponding joints but differ in range. Unlike that of the hand, the range of active extension (50–60°) is greater than flexion (30–40°); an adaptation to the needs of walking and a difference even more marked in the hallucial joint where flexion is a few degrees while extension may reach 90°. When the foot is on the ground metatarsophalangeal joints are already extended to at least 25°, because metatarsal bones slope up in the foot's longitudinal arches (4.93A,B). *Passive* range in these joints is 90° (extension) and 45° (flexion), according to Kapandji (1974). Adduction is linked to flexion, abduction to extension; but abduction of the fifth toe is always linked with slight flexion. As in the hand, *accessory movements* are gliding and rotation of phalanges on their long axes.

Muscles Producing the Movements

Flexion: flexor digitorum brevis, lumbricals and interossei, assisted by flexores digitorum longus and accessorius. In the fifth toe flexor digiti minimi brevis assists; in the hallux flexores hallucis longus and brevis are the only flexors.

Extension: extensores digitorum longus and brevis, extensor hallucis longus.

Adduction: adductor hallucis; in the third to fifth toes, the first, second and third plantar interossei respectively.

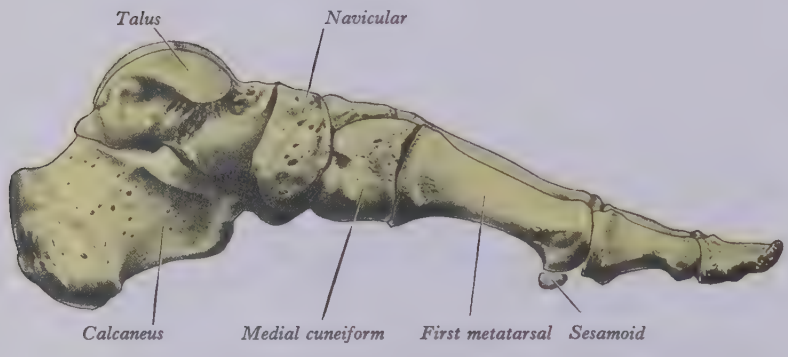
Abduction: abductor hallucis; in the second toe, first and second dorsal interossei; in the third and fourth, corresponding dorsal interossei; in the fifth, abductor digiti minimi.

Note. The line of reference for adduction and abduction is along the *second digit*, whose metatarsal is least mobile. This is hence 'abducted' by both its interossei medially or laterally.

Interphalangeal Articulations

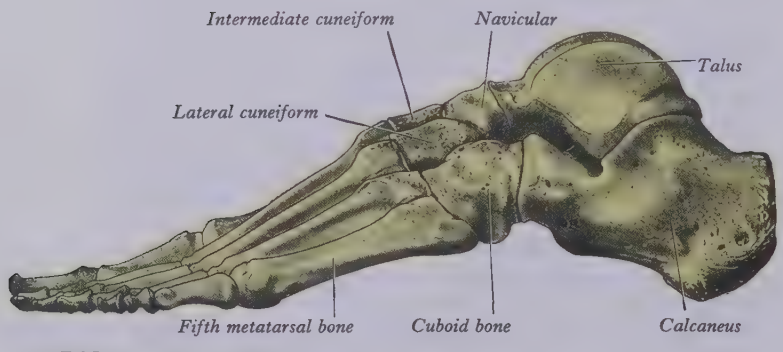
These are almost pure hinge joints in which trochlear surfaces on phalangeal heads articulate with reciprocally curved surfaces on adjacent phalangeal bases. Each has an articular capsule and two collateral ligaments, as in the metatarsophalangeal joints (vide supra). The capsule's plantar surface is a thickened fibrous plate, like the plantar metatarsophalangeal ligaments, and is often termed the *plantar ligament*.

Movements are flexion and extension, greater in amplitude between the proximal and middle phalanges than the middle and distal. Flexion is marked, but extension is limited by tension of the flexor muscles and plantar ligaments. Flexion and extension are accompanied by slight conjunct rotation. *Accessory movements* are abduction, adduction and rotation.



Muscles Producing the Movements

Flexion: flexores digitorum longus, brevis and accessorius, flexor hallucis longus.



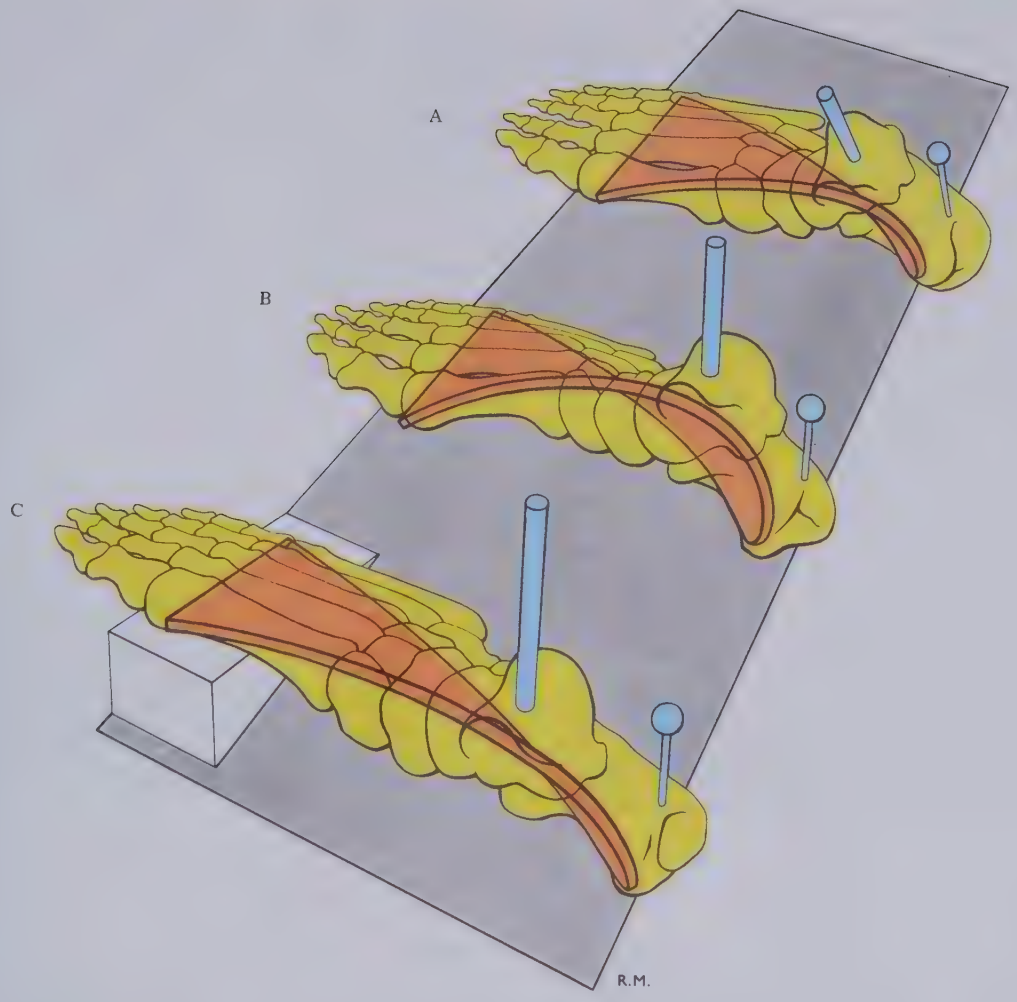
Extension: extensores digitorum longus and brevis, extensor hallucis longus.

4.92 Oblique section that descends mediolaterally through the right foot, showing the synovial cavities of the intertarsal and tarsometatarsal joints; also the medial malleolar part of the talocrural joint: Superior aspect. Note: the section passed below the joint between the medial cuneiform and the base of the second metatarsal bone; no synovial joint was present between the navicular and cuboid bones. The laminae of the interosseous talocalcaneal ligament form accessory ligaments to the fibrous capsules of the talocalcaneonavicular and subtalar (posterior talocalcaneal) joints. The (diagrammatic) apparently uniform thickness of the articular cartilages obscures the variations in thickness and curvature that obtain in life.

4.93A Skeleton of the left foot: medial aspect. Note the height and number of bones constituting the medial part of the longitudinal arch and compare with the lateral part in 4.93B.

4.93B Skeleton of the left foot: lateral aspect.

Movements of the Foot



The foot may move both *off the ground*, freely and relatively only to the leg, or while *on the ground*, bearing weight or transmitting thrust. The latter movements are more limited and partly imposed from the leg by body weight but are also the result of muscular contraction (pp. 656–659.)

Active movements occur at talocrural, talocalcaneonavicular and subtalar joints. At the talocrural joint movements are almost restricted to dorsi- and plantar flexion, but slight rotation may occur in plantar flexion; at the talocalcaneonavicular joint and subtalar joint ranges of movement are greater and here inversion and eversion largely occur.

With the foot grounded, body weight causes some supination, with flattening of the longitudinal arches; about one-third of the weight borne by the forefoot is taken by the first metatarsal's head. When a resting position becomes active, on starting to walk, the foot is *pronated* by muscular effort; the first metatarsal head (the second less so) is *depressed*, accentuating the medial longitudinal arch to its maximum height (Hicks 1953). Similar changes can be imposed on a weight-bearing foot by active lateral femoral rotation, which is transmitted through the tibia to the talus. This entails passive inversion of the foot at the subtalar joints. Medial femoral rotation has an opposite effect. When the foot is grounded and immobile, muscles which move it when freely suspended may exert effects *on the leg*, e.g. dorsiflexors can then pull the *leg forwards* at the talocrural joint.

The foot has two major functions: (1) to support the body in standing and progression; (2) to lever it forwards in walking, running and jumping. To fulfil the first the pedal platform must be able to spread stresses of standing and moving and be pliable enough for uneven and sloping surfaces. To fulfil its second function it must be transformable into a strong adjustable lever to resist inertia and powerful thrust. A segmented lever can best meet such stresses if arched in form.

In infants and young children plantar amassed, fatty, connective

4.94 The concept of the pedal skeleton as a twisted plate which may be untwisted (supination) or further twisted (pronation) during the maintenance of a plantigrade stance in various positions of the foot. (Based upon MacConaill 1945, 1950.) A. The pedal skeleton in supination, as in standing with the feet widely separated. Note the marked medial tilting of the talus and, to a lesser degree, of the calcaneus and the depression of the medial longitudinal arch. B. Relative pronation of the foot, as in standing with the feet close together. C. Supination of the foot when standing on an inclined surface; if the position of the wedge had been reversed, the pedal skeleton would, of course, approach maximal pronation.

tissue may give the foot a flat appearance; soft tissues variably modify its appearance at all ages. But the human foot, alone among primates, is normally arched in its *skeletal* basis, usually with visible concavity in the sole. The word 'arch', so applied, has perhaps become too architectural, imposing rigidity on classical descriptions of curved pedal form and differences of interpretation more linguistic than factual. The word has several meanings and doubtless 'arches of the foot' has various implications. As a start, at simplest, the term implies little more than a curved form, concave on the plantar aspect. Such an arch should not be compared with static masonry, with pediments on terra firma and an intermediate keystone structure. The pedal arch is dynamic; muscles and ligaments are functionally inseparable. Moreover, its heel is often *off* the ground. In this account, therefore, 'arch' denotes no more than curved form, just as the back is merely curved when 'arched'.

This curvature is customarily analysed into longitudinal and transverse arches, of some value in initial analysis. They vary individually in height, especially the longitudinal in its medial part, and, being dynamic, in different phases of activity. Arches are often said to be mainly dependent on osseous shapes and ligamentous ties, the associated muscles playing a secondary role (Jones 1941, Hicks 1955). But clinical experience points to muscular insufficiency as the commonest cause of flat foot, in which ligaments elongate and bones in consequence alter in shape. It is perhaps unwise to give any factor major emphasis; all function together in the living foot. Loading experiments, on amputated legs and by electromyography in the living, show that in *standing* ligaments play a major role; but as soon as movement occurs muscles predominate. Longitudinal curvature is usually described as composed of medial and lateral arches, a division partly justified by differences in osseous arrangement and function in the foot's medial and lateral regions.

The medial arch contains the calcaneus, talus, navicular, cuneiform and medial three metatarsal bones. Its summit is at the superior talar articular surface, taking full thrust from the tibia and passing it backwards to the calcaneus, forwards through the navicular and cuneiforms to the metatarsals. When the foot is grounded these forces are transmitted through the three metatarsal heads and calcaneus (especially its tuberosity). This arch is higher, more mobile and resilient than the lateral; its flattening progressively tightens plantar ligaments of all joints involved, including the plantar calcaneonavicular (p. 539) and plantar fascia. Tibialis posterior, flexor digitorum longus, flexor hallucis longus and intrinsic muscles all act on the curvature of the medial arch; they are adjustable, unlike ligaments. Nevertheless, they are often considered secondary and claimed to be usually inactive in standing but markedly active in any movement elevating the arch. This view, as regards static posture, does not accord with clinical experience in the aetiology of flat foot.

The lateral arch contains the calcaneus, cuboid and lateral two metatarsal bones; its summit is considered to be the subtalar articulation. It is hence skeletally lower than the medial. Its main joint is the calcaneocuboid part of the 'transverse tarsal joint' (p. 538), of very limited range. The lateral arch, being lower and less mobile, is adapted to transmit weight and thrust rather than to

absorb such forces. As it flattens, long plantar and plantar calcaneocuboid ligaments tighten; its special muscles are peroneus longus and the intrinsic muscles of the fifth toe. It makes contact with the ground more extensively than the medial arch. With the foot flat its anterior and posterior ends or 'pillars' (heads of the lateral two metatarsals and calcanean tuberosity) of course transmit forces; but, as it flattens, an increasing fraction of load traverses soft tissues inferior to the whole arch. In fact the whole lateral border usually touches the ground; the medial border does not but is visibly concave, usually even in standing. This explains the familiar outline of human footprints (though this varies with position of feet, apart or together (4.94), development of soft tissues and the nature of the surface). As soon as the heel rises, in any activity, the toes are extended and muscular structures (including plantar aponeurosis) tighten up in the sole, accentuating the longitudinal arches. (It is suggested by Hicks 1955 that in this phase tension diminishes in deeper plantar ligaments.)

Since the sole is transversely concave, both in skeletal form and usually external appearance, serial transverse arches, most developed inferior to the metatarsus and adjoining tarsus, are usually described. Apart from metatarsal heads and to some degree along the lateral border, transverse arches cannot transmit forces though subjacent soft tissues; medially, only metatarsals heads can do so. Hence the foot has been likened to a half-dome, its plantar concavity directed medially, a complete dome forming when feet are close together. Peroneus longus is a strong agent in maintaining transverse curvature.

The foregoing structural analysis is a necessary prelude to the study of activities in the living. Direct observation, coupled with electromyography, kinesiology and clinical data all contribute to understanding the dynamic events in the foot during natural use. Unfortunately, disagreements persist with consequent uncertainties. The following remarks are hence not to be taken as dogmatic.

In standing, with only body weight to support, intrinsic and extrinsic muscles appear to relax, plantar ligaments being relied on to tie bones into an arched form. This they can do only if longitudinal arches are allowed to sink by muscular relaxation. The medial arch is more elevated when feet are together than when they are apart; i.e. inversion with supination increases as feet are separated. This medial sag can be countered by voluntary contraction of muscles such as the anterior tibial. Pronation and supination ensure that in standing, whatever the position of the feet, a maximal weight-bearing area is grounded, from metatarsal heads along the lateral border to calcaneus. Twist imparted by pronation (partly undone in supination) prompted MacConaill (1945,1950) to liken the foot to a twisted but resilient plate (4.94); this would ensure adequate ground contact whatever the angle between foot and leg, also imparting adaptable resilience in standing and progression. Such a form would strengthen the foot in leverage, perhaps by spiralization of ligaments.

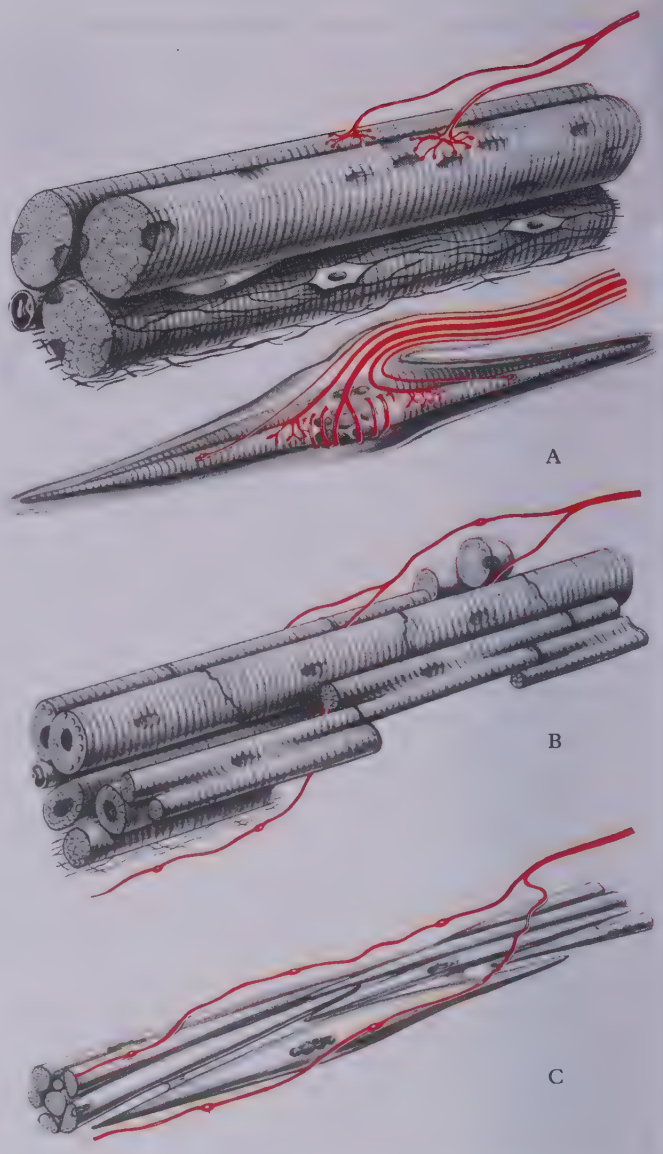
In walking, the suspended foot, arches accentuated by muscles, is swung forward until the heel meets the ground. As it plantarflexes, the lateral border, from heel to metatarsal heads, rolls into contact, the foot supinated for maximum contact. As it now rises, heel first, pronation (with elevation of the medial arch) transfers thrust largely to the 'ball' of the hallux. The dorsiflexed ankle and elevated metatarsus, being now near 'close-pack', are adapted to stresses of maximum thrust. As in repetitive actions at hip and knee joints, a cycle from a position of near close-pack coupled with maximal effort and return to a mobile range of joints, prepares re-entry into a phase of thrust. Kapandji (1970) has analysed foot movements in extenso. For a scholarly discussion of the evolution of the mammalian *pes*, in structure and function, see Lewis (1983).

GRAY'S ANATOMY

MYOLOGY

5

Introduction

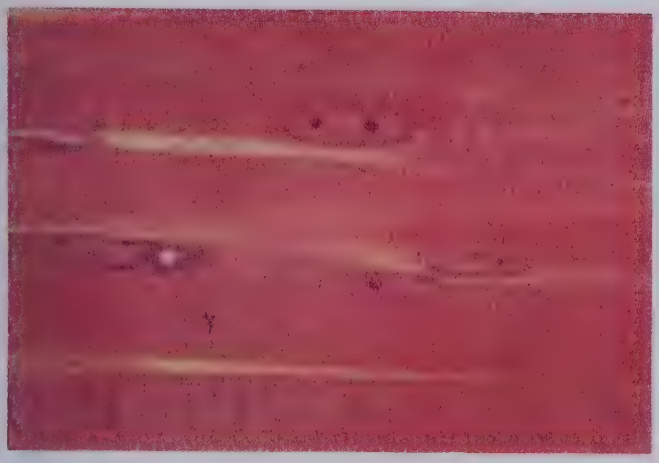


The ability to generate movement is a feature of all animals, enabling them to transport materials within their bodies and to react appropriately to external and internal stimuli. As outlined in Section 1 (p. 49), almost all cells of the body possess organelles with motile functions, prominent among which are complex interactive systems of actin and myosin filaments (see e.g. Lackie 1986). In many cells these serve to maintain shape or cause slow movements such as those seen in cellular locomotion or morphogenetic transformations in embryonic tissues. In other cells, specialized for more powerful and rapid movement, actin, myosin and other associated proteins are present in high concentrations and are deployed so as to produce efficient, linear contraction. Their plasma membranes are excitable and control the activities of the contractile apparatus they enclose. Such cells are the *myocytes* (muscle cells) which, when grouped into distinct tracts, form *muscles*. They are associated with other tissues such as those of the skeleton and, co-ordinated directly or indirectly by the nervous system, produce effector systems of great variety, capable of a wide range of highly complex actions.

Myocytes are formed in various regions of the body from myoblasts, cells of mesenchymal origin which may differentiate along one of three possible lineages to form the myocytes of *skeletal, cardiac* or *non-striated muscle* (5.1). Other contractile cells also exist as isolated individuals or small groups in various parts of the body, including *myofibroblasts* in regenerating connective tissue and *myoepitheliocytes*, cells arising from embryonic ectoderm which are associated with glands. In skeletal and cardiac muscle, the myosin and actin filaments are organized in a highly regular pattern to give myocytes a cross-striated appearance under the microscope, a cellular feature which suits them for rapid contraction.

Skeletal muscle, so named by virtue of its widespread (though not exclusive) attachment to the skeleton, is also known less appropriately as *voluntary muscle*, because in many sites it is on occasion under voluntary control, or as *striated* or *striped muscle* (an ambiguous term, of course, because cardiac muscle is also striated). Skeletal muscle is innervated by somatic motor nerves and forms the bulk of the body's muscular tissue.

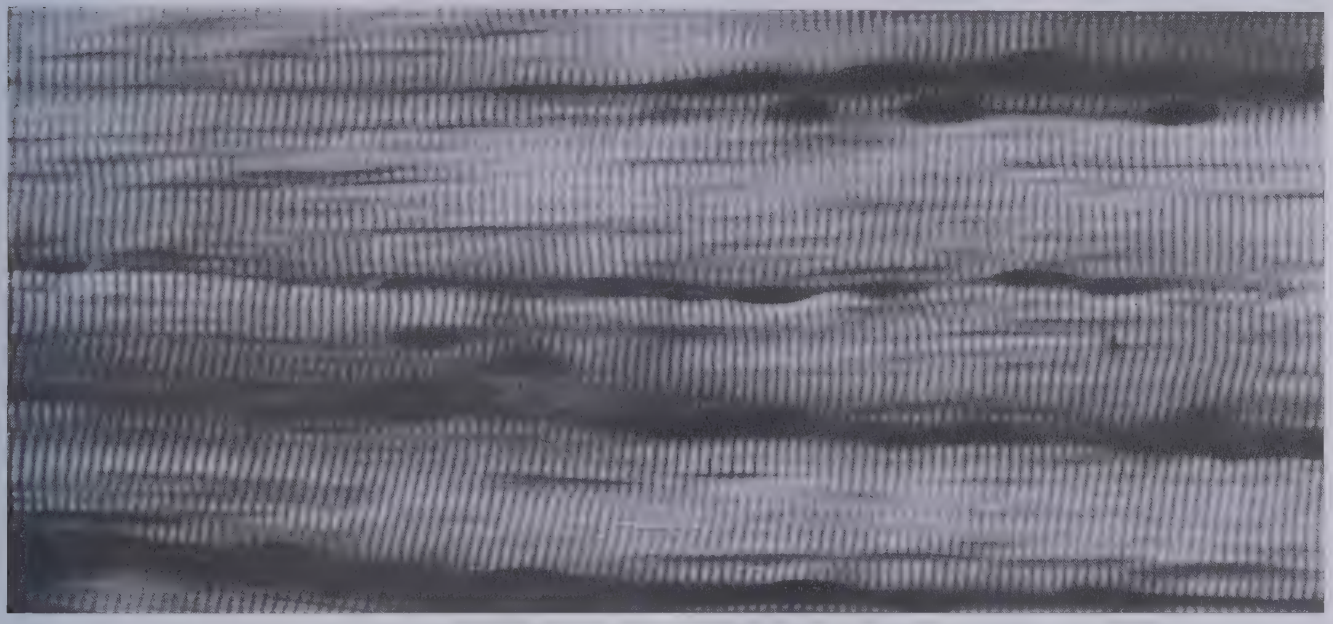
Cardiac muscle is confined to the heart and is rhythmically contractile; its rate of beating is under nervous control but many individual cells do not receive direct innervation. In **non-striated muscle**, known also as *smooth, plain* or *involuntary muscle*, the actin and myosin are less ordered and the contraction is slower though of greater extent and may be sustained for long periods. Non-striated muscle is innervated by the autonomic system and is therefore not under voluntary control. It occurs: in the walls of the viscera including most of the alimentary, respiratory and urinogenital tracts; in blood vessels; in the dermis (as arrector pili muscles); in the intrinsic muscles of the eye; and the dartos muscle of the scrotum. Elsewhere there are several sites where smooth muscle fasciculi intermingle with those of skeletal muscle, particularly that classified on embryological grounds as 'special visceral muscle' (p. 172): e.g. anal and vesical sphincters, the tarsi of the upper and lower eyelids and the orbitalis muscle, the suspensory ligament of the duodenum (but see p. 1356), the intermediate zones of the oesophagus and the many fasciculi which are admixed with the fasciae and ligaments on the pelvic aspect of the pelvic diaphragm (termed by some authors the *smooth muscle pelvic diaphragm*). The mode of contraction of non-striated muscle is in general particularly suited to the regulation of the internal environment and disturbances in its function often result in impaired homeostasis.



These three types arise in different regions of the embryo (see p. 175). Skeletal muscles are largely derived from the myotomes of paraxial mesodermal somites but some differentiate in situ, e.g. the extrinsic ocular muscles in condensations of premandibular and maxillo-mandibular mesenchyme of the pharyngeal floor (often considered to be a derivative of occipital myotomes, p. 228), limb muscles from condensed limb-bud mesenchyme of somatopleuric origin (p. 174) and the various striated 'special visceral' muscles from condensations of unsplit lateral plate mesenchyme (of mixed origin) in the branchial arches and the post-branchial region (p. 174). Cardiac muscle stems from splanchnopleuric mesenchyme of the primitive pericardium, while the non-striated muscle of the viscera also arises from splanchnopleuric cells elsewhere or from those derived from intermediate mesoderm. Vascular non-striated muscle may, however, develop in any region from uncommitted mesenchyme cells. The non-striated muscle of the iris is thought to be derived from ectodermal cells near the margin of the optic cup; similarly, myoepitheliocytes appear to be ectodermal, whereas the non-striated ciliaris oculi and arrector pili muscles are mesodermal in origin.

Skeletal muscle fibres, showing a group of three fibres with satellite cells (above), and a muscle spindle containing intrafusal muscle fibres (below). B. Cardiac muscle, with smaller myocardial myocytes, larger Purkinje cells of the conducting tissue and rounded nodal cells. C. Non-striated myocytes.

Skeletal Muscle



The cellular units of skeletal muscle (5.1–3) are the *muscle fibres*, each a long, cylindrical structure bounded by a plasma membrane (the *sarcolemma*) enclosing numerous nuclei (muscle fibres are *syncytial*, see p. 15) and a relatively large amount of cytoplasm (*sarcoplasm*). Many muscle fibres are grouped into bundles

5.2A Longitudinal section of uncontracted human skeletal muscle showing characteristic banding pattern of large A bands (stained dark purple) and I bands (light pink). The Z bands are thin and transect the I bands. Araldite section stained with methyl green PAS. (Material supplied by R O Weller.)

Magnification × 500.

(*fasciculi*) of varying size and pattern and an individual muscle may consist of many fasciculi. Connective tissue sheaths enclose the different muscle components: the delicate networks surrounding and infilling the spaces between muscle fibres are collectively termed *endomysium*; the stronger *perimysium* ensheaths individual fasciculi; and the more substantial *epimysium* bounds the whole muscle but is also continuous with the perimysial septa within and the connective tissue external to it.

Microscopically, muscle fibres are rounded or polygonal in cross section, varying from 10–100 μm in diameter in mature muscle. Each fibre is elongated and may extend for many centimetres in long muscles. Usually they traverse only part of a muscle, ending in tendinous extensions or intersections within it. In longitudinal section, muscle fibres appear as long ribbons, but their cylindrical or prismatic shape can be readily seen in teased preparations. The nuclei are flattened, moderately euchromatic with one or more nucleoli and lie peripherally in the fibre immediately beneath the sarcolemma. They are especially numerous in the region of the neuromuscular junction (p. 556). Within the sarcoplasm are numerous longitudinal cylindrical *myofibrils*, often apparently aggregated in small groups (fields of Cohnheim; see however 5.2B) when viewed in transverse section. The myofibrils are, in turn, composed of numerous *myofilaments* of actin and myosin, but these are visible only with the electron microscope. Myofibrils are crossed at regular intervals by transverse bands which have distinctive staining and optical properties; in general the bands of all myofibrils are in close register, giving the whole fibre its characteristic cross-striated appearance. The myofibrils extend for long distances within muscle fibres, which therefore also display longitudinally striations.

In longitudinal sections stained with haematoxylin, there is an alternation of light and dark-staining bands; the lighter also rotate the plane of polarized light only slightly and are known as *Isotropic (I or J bands)*, while the darker bands rotate the plane of polarized light strongly (*Anisotropic* or *A bands*, 5.3, sometimes named *Q bands*). Each I band is bisected by a thin, densely staining *Z band* (Zwischenscheibe, or inter-band, also termed Krause's membrane). The A bands are bisected by a paler *H* or *Hensen's band*. In relaxed muscle these bands are all clearly visible in appropriately stained sections and in unstained sections with

polarizing microscopy but, when muscle fibres shorten, the I and H bands narrow to extinction, while A bands are unaffected and eventually *contraction bands* appear on either side of Z bands. Other, less well defined bands have also been described in the I bands (N lines).

Although these details have been known for over a hundred years, their significance in muscle contraction was first appreciated only relatively recently when two groups of investigators came independently to the same conclusion; A F Huxley & Neidergerke (1954) chiefly from polarized light studies; and H E Huxley & Hanson (1954) from electron microscopic observations. Their results and subsequent studies by many other investigators using a variety of cytological, biophysical, biochemical and physiological methods have provided a wealth of information about the structure and function of skeletal muscle, which will now be briefly outlined. For further reviews of ultrastructure, the reader is referred to the recent comprehensive accounts by H E Huxley (1983) and Ishikawa (1983).

THE ULTRASTRUCTURE OF SKELETAL MUSCLE

With the electron microscope, the myofibrils of skeletal muscle are seen to be divided transversely into serial units, *sarcomeres*, each about 2.5 μm long in resting muscle (5.4–8). These are composed of two major filament types, myosin filaments about 12 nm thick and actin filaments 6 nm in diameter. The myosin filaments correspond to the A band of light microscopy; the actin filaments are attached at one end to a Z band and interdigitate at the other with the myosin filaments; the I bands correspond to the adjacent regions in two sarcomeres where actin filaments do not overlap myosin (5.7). H bands are the middle regions of myosin filaments into which actin filaments have not penetrated.

Adjacent myosin filaments are connected to each other in their central regions by transversely running filaments which together constitute the *M band*. Along the sides of myosin filaments are also regularly spaced projections which, during contraction, can move to form cross-bridges with the adjacent actin filaments; however, these are absent from a short zone around the M band, sometimes called the pseudo-H band. Various other faint cross-striations have also been described, including several *C bands* across the myosin filaments and at least two *N bands* crossing the exposed regions of actin filaments. The strongest of these is the N_2 band close to the Z band. These minor bands will be discussed again in more detail later (p. 551).

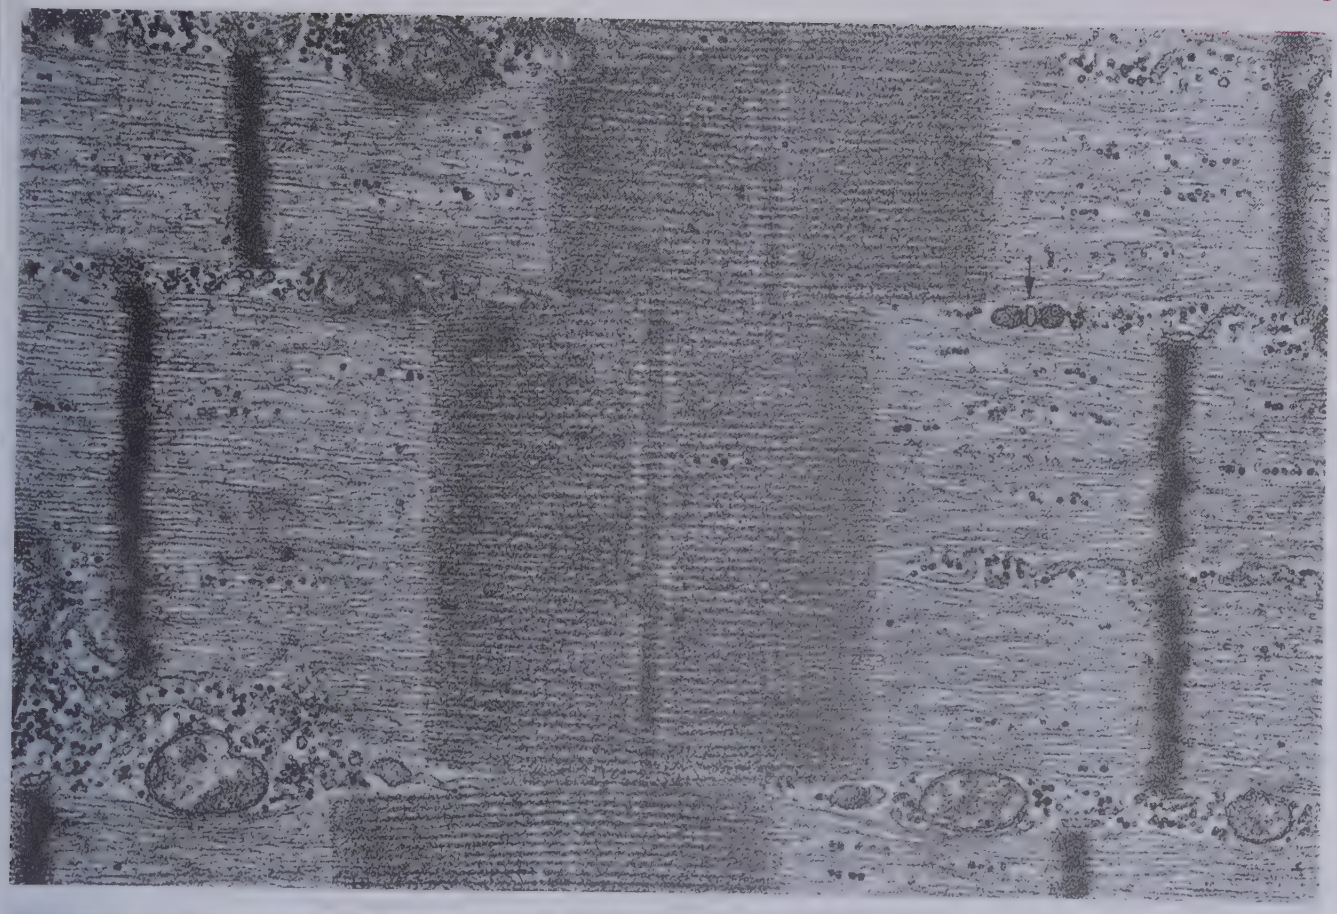
The arrangement of actin and myosin in transverse sections is highly regular (H E Huxley 1972), the myosin filaments forming triangular arrays with each myosin surrounded by six actin filaments (5.5C, 6, 7). However, in the I band region, the actin filaments have a quadrilateral spacing, attaching in this configuration to the Z band, which has a corresponding square lattice substructure.

Sliding Filament Mechanism of Contraction

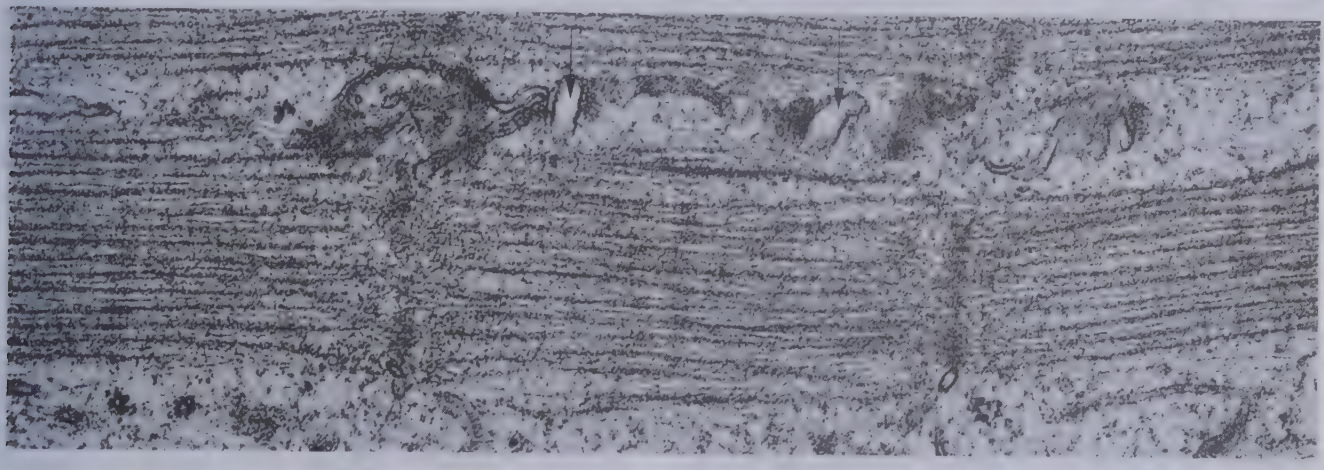
Electron microscope studies of the lengths of the filaments in muscle fixed in different degrees of contraction show that the actin and myosin filaments do not change their lengths during muscle shortening but slide over one another to draw the Z bands towards the middle of each sarcomere (5.4, 7). This behaviour has also been confirmed in X-ray diffraction studies of living muscle. This sliding movement is generated by the activities of the projections from the sides of each myosin filament, which can sequentially attach to and briefly pull on the adjacent actin filament before letting go and swinging back to repeat the process (5.8B). As many such cross-bridges are active but not synchronously during muscle contraction, the net effect is to exert a continuous pull on the actin filaments. Interestingly, because of the cyclical nature of cross-bridge activity, they can exert a tractive force not only when the muscle is shortening but also when it is contracting isometrically, i.e. without shortening, or even when it is being extended, e.g. by the action of opposing muscles, to decelerate a limb movement (p. 567), or opposing gravity in postural readjustments and manipulations.

Measurements of the contractile force developed by skeletal muscles stimulated to generate tension at fixed lengths (isometric contraction) have shown that the power generated by a muscle varies with its degree of stretch. Highly extended muscles are relatively weak but, as they progressively shorten, their contractile force increases to a maximum, then falls again. This behaviour is correlated closely with the amount of overlap between actin and myosin filaments, as might be expected if the contractile force is dependent on the number of cross-bridges which can be formed between them; in a muscle clamped so that its sarcomeres are stretched more than about 3.5 μm, there is very little overlap between myofilaments and little tension developed. At shorter sarcomere lengths, tension rises to a maximum at a sarcomere length of 2.0 μm, when maximum overlap and cross-bridge formation occur. At shorter lengths, tension drops again as the actin filaments slide across the mid-point of the sarcomere and begin to mutually interfere with cross-bridge formation, finally dropping to zero tension at about 1.9 μm; the Z bands are then drawn into contact with the ends of the myosin filaments, distorting the latter to convey the impression of 'contraction bands' when observed with the light microscope.

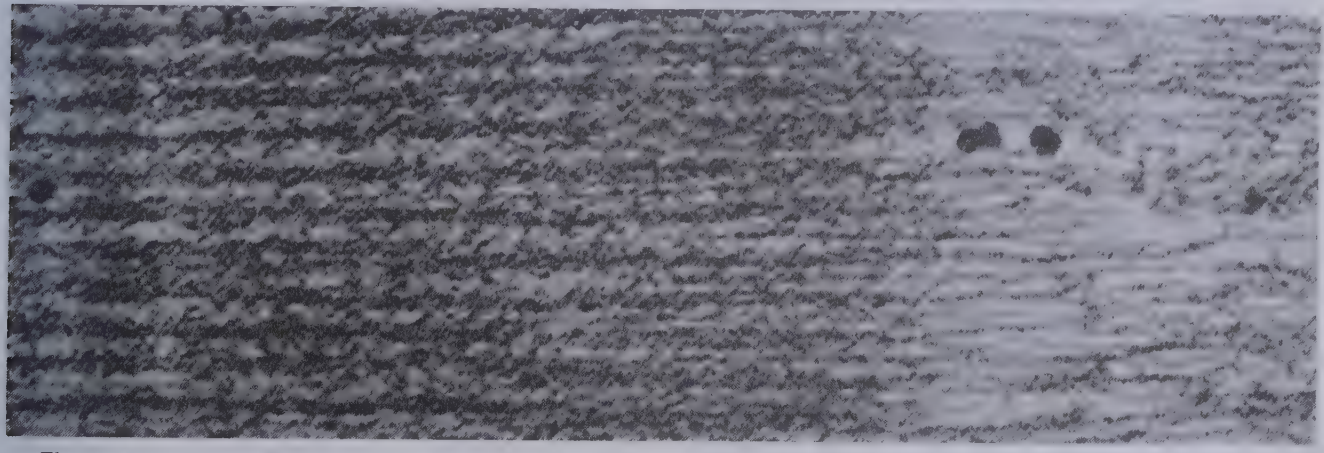
In view of these findings, it is interesting that most skeletal muscles are arranged in the body so that, relative to their overall lengths, they undergo only limited shortening under normal physiological conditions and are thus generally maintained near the right length for most efficient actin–myosin overlap and hence maximal force generation.



Detailed Structure of Myofilaments

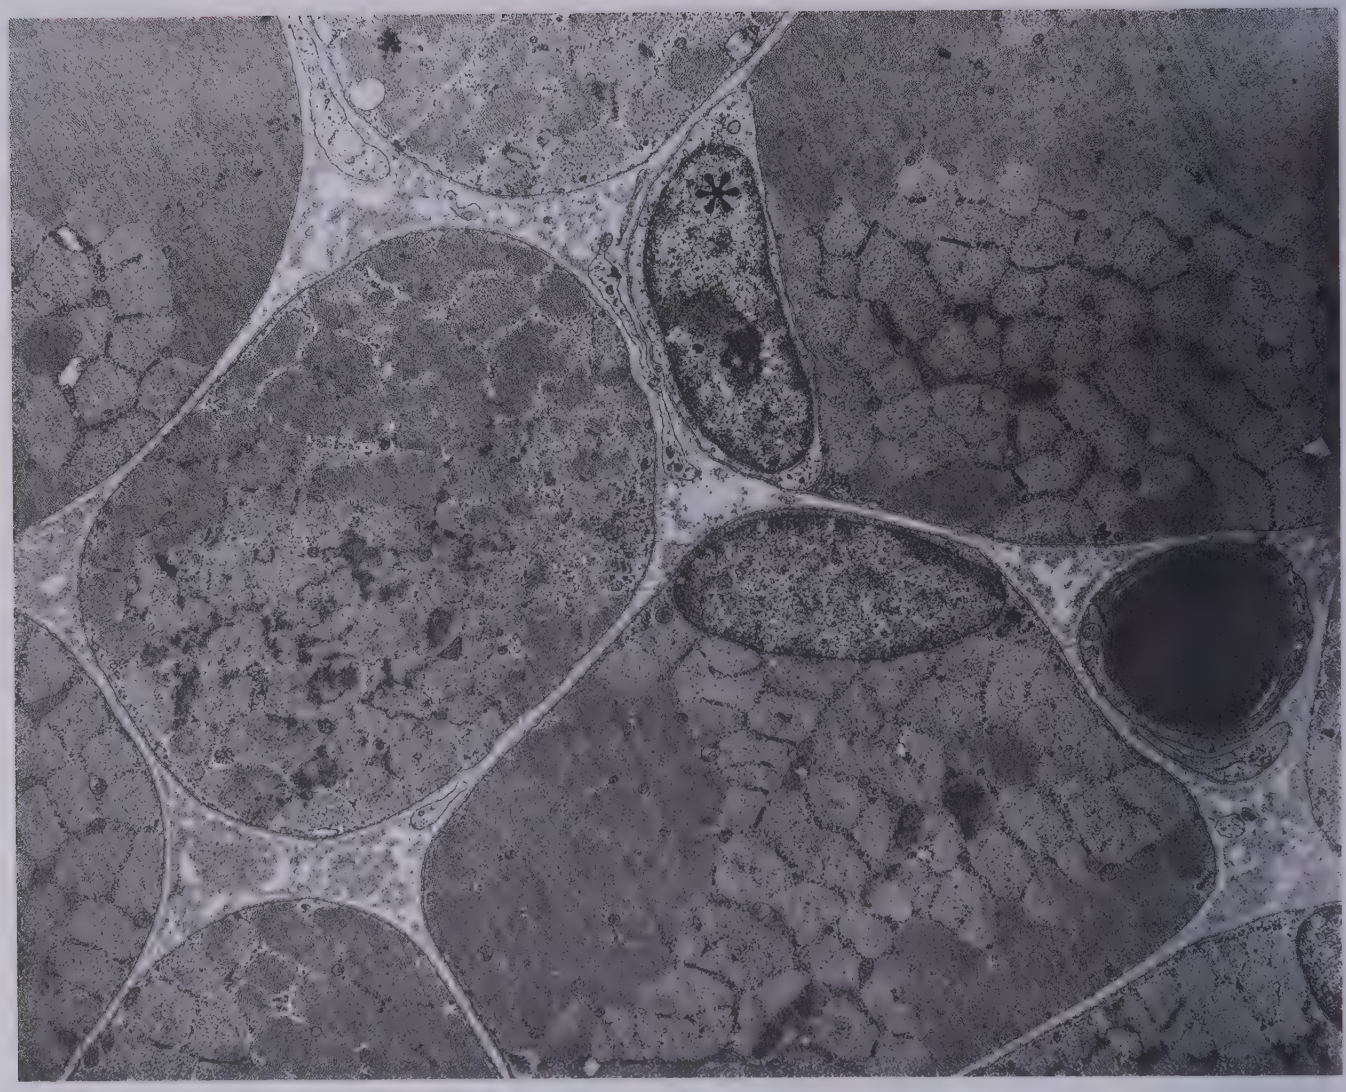


Myosin filaments are about 1.8 μm long and are composed of about 180 myosin molecules each. Myosin molecules have a high molecular weight (Mr = 500 000) and consist of a rod-like tail region, which lies mostly along the axis of the myofilament, and a head region which projects at an angle to it. The myosin molecule has six distinct subunit polypeptides consisting of two heavy chains stretching the whole length of the molecule and four light chains confined to the head. The light chains constitute a pair of 'regulatory light chains' (LC-2) which appear to control myosin ATPase activity and a pair of so-called 'essential light chains' (LC-1 or LC-3, of uncertain function). The heavy chains can be cleaved by proteolytic enzymes into two parts: *light meromyosin* consisting of most of the rod-like portions of the two heavy chains; and *heavy meromyosin*, composed of the cross-bridge forming parts of the myosin molecule, namely the light chains and the remainder of the two heavy chains which can be further cleaved proteolytically into two fragments (S1 and S2). Under the electron microscope, isolate myosin molecules show that the head region has a deep longitudinal cleft, corresponding to the symmetrical arrangement of the heavy and light chains in this region (5.8A). The points of enzyme attack are thought to represent regions where the molecule flexes during muscle contraction. In the presence of ATP and magnesium ions, heavy meromyosin can bind to actin filaments and this property can be used experimentally to demonstrate the presence of actin in electron micrographs and to determine the 'direction' in which the actin filaments are organized at the molecular level, as the myosin heads bind at an acute angle with the actin in an arrowhead configuration, according to the polarity of the filament.



Myosin molecules have a complex chemistry which varies to some extent with the subtype of skeletal muscle fibre they belong to, and this can be exploited immunohistochemically to identify them experimentally or for clinical purposes (see also p. 552).

Myosin molecules can aggregate by their tails to form long filaments. The head, and part of the attached tail of each molecule projects at an angle from the main filament, except in its middle zone where the tails reverse direction. Heads are arranged with great precision, a factor which probably enhances the rapidity and efficiency of muscle contraction; although precise details are not certain, it is likely that the heads emerge in radially symmetrical triplets which are arranged in a spiral pattern, each triplet being rotated by 40° on the adjacent triplet.



The heads are able to swing out from the main filament to attach to actin filaments, as seen in electron micrographs and X-ray diffraction images of contracting muscle, or muscle in rigor.

Detail of unshortened muscle showing cross-bridges between actin and myosin filaments. Arrows indicate the position of the T-system components. Compare with 5.6,7. (Material for A provided by Professor R O Weller; cf. 5.1.). Magnifications: A and B × 15 000, C × 100 000.

5.5A Transverse section of skeletal muscle from a child showing muscle fibres, myofibrils and mitochondria. A satellite cell(*) is also present, lying beneath the basal lamina. Immediately below this is a muscle fibre nucleus. Note the transversely cut endomysial capillary. Magnification × 4000.

B

C

5.5B, C Details of the configuration of actin and myosin filaments in transverse section. B is through the I band and shows only the actin filaments. C is through the A band and shows thin actin filaments arranged round thick myosin filaments, with cross bridges stretching between them. Magnification × 200 000.

Actin filaments (see p. 30) are composed of a staggered helical array of globular actin subunits (M_r = 43 000), 13 in each turn of the helix (5.8A), and are each about 1.0 μm long. In the grooves between the helices (one on each side of the filament) lie the filamentous molecules of another protein, *tropomyosin*, each molecule spanning 7 actin subunits. At 40 nm intervals there is a fourth protein, *troponin*, formed by four polypeptides *(troponins T, I and C)* which are bound to actin. When muscle is resting, the position of tropomyosin prevents the myosin heads from binding to actin but, when muscle is activated, raised levels of calcium cause the troponin to change its shape, displacing tropomyosin and allowing myosin to attach to actin.

The precise mechanism by which force is generated when myosin and actin interact is still uncertain, but it is likely that it involves first a binding of myosin heads to actin, then a change of angle in the hinge region of the stalk connecting the myosin head to the main filament, followed by detachment of the head from the actin and a swinging back of the stalk to its original angle (5.8B).

5.5D Longitudinal section through a group of myofibrils, showing the sarcoplasmic reticulum and associated transverse tubules (arrow). Note the darkly granular terminal cisternae of the sarcoplasmic reticulum where it lies adjacent to the transverse tubules. Magnification × 40 000.

As mentioned, this cyclical process is dependent on the presence of magnesium ions, ATP and sufficient calcium ions to unblock the myosin binding sites on the actin filament and also to activate certain other enzyme systems of the myosin heads which regulate their ATPase activity.

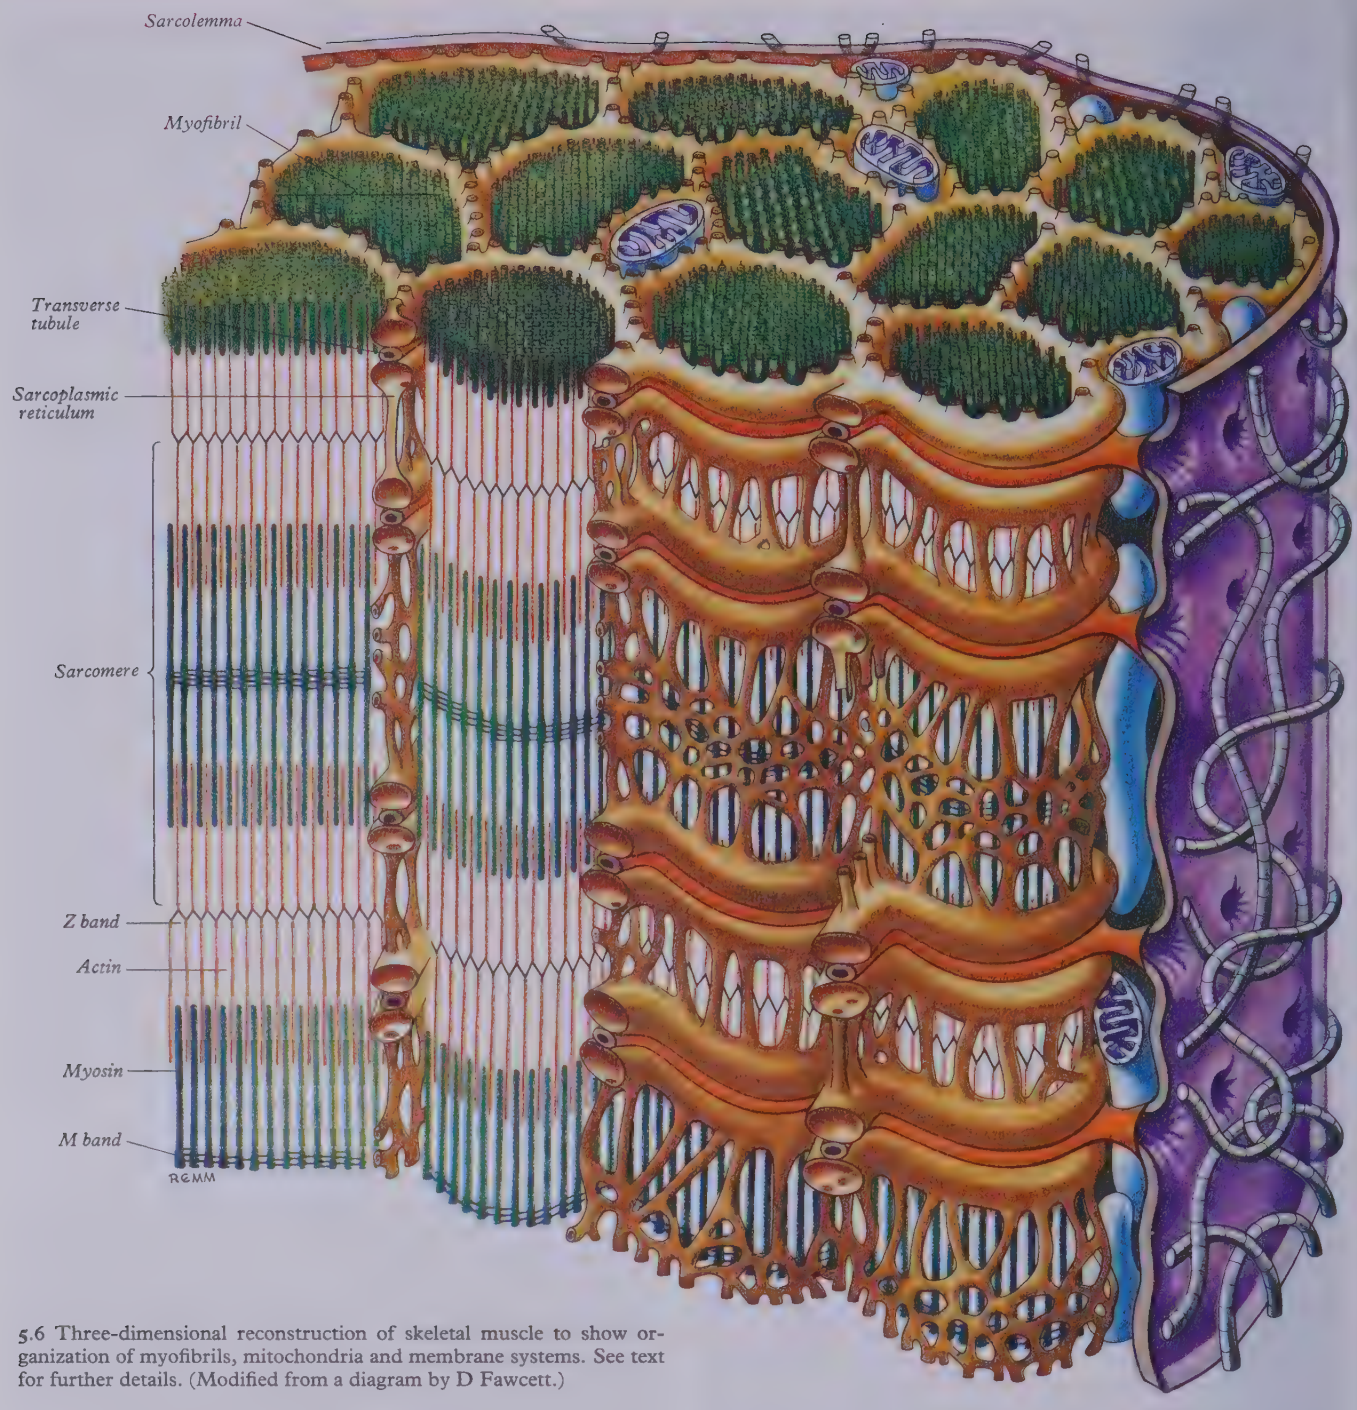
The direction in which active sliding occurs is also dependent on the orientation of actin filaments, the helices of which spiral in opposite directions on either side of each Z band.

Other components of myofibrils. The Z bands are complex structures which in section present a zig-zag appearance, to the points of which the actin filaments are attached. Viewed face on, the Z bands appear as a square lattice of fine filaments, embedded in a densely staining granular matrix. The precise organization of this array is not entirely certain but may be in the form of numerous regularly linked tetrahedra, from the apices of which actin filaments emerge (see e.g. Landon 1970, Kelly & Cahill 1972, see also the review by Wang 1985). The predominant protein of Z bands is α-actinin, which may form the dense matrix component, but various other proteins are also present.

In addition there are many other proteins associated with the contractile apparatus, some soluble and therefore not localized to any particular structure, others bound to the myofilaments, including: the 'C proteins' (Offer 1973) bound at regular positions on the myosin filaments; a creatine kinase associated with the filaments of the M band; and the proteins *titin (connectin)* which are thought to form an additional set of myofilaments within the sarcomeres, providing a degree of *elasticity* to muscle fibres (see Wang 1985). The existence of such elastic filaments has long been postulated and there have been various reports of thin (3–4 nm) filaments in addition to actin and myosin which may be responsible for the known elastic properties of muscle fibres and for helping to maintain their coherence during actin–myosin sliding. The presence of the rather mysterious N bands in the I band region may reflect the architecture and possible interlinking of these fine filaments.

The Non-myofibrillar Structures of the Sarcoplasm

These include the essential organelles required for cellular metabolism, such as ribosomes, mitochondria, Golgi apparatus, lysosomes, transport vesicles, lipid droplets; the majority of these organelles are located around the nuclei near the cell periphery and to a lesser extent scattered between the myofibrils. During active growth either during normal development or as a response to exercise (p. 554), these organelles are particularly numerous. Glycogen is also distributed in small granular clusters between myofibrils and among the actin filaments (5.4A); it is an important energy store and can be rapidly mobilized close to where it is needed. In addition to these usual cellular organelles there are some specialized features, as follows.



The sarcolemma has the ultrastructure typical of a normal plasma membrane, with an external basal lamina to which adhere the collagen fibres and other components of the endomysium. Narrow tubular invaginations of the sarcolemma penetrate deeply into the sarcoplasm, branching and anastomosing around the myofibrils; these are the *transverse tubules* or *centrotubules* (Franzini-Armstrong 1975, Ishikawa 1983). In most mammalian skeletal muscle, as also in reptiles and birds, these systems lie perpendicular to the sarcolemma, penetrating among myofibrils transversely at the planes of the A–I band junctions. Commonly in lower vertebrates, including amphibians and fishes, they lie at the level of the Z bands. The lumina of these tubules are of course in continuity with the extracellular space, as shown by the infusion of colloidal tracer substances into the endomysium; such markers can diffuse within the T-tubules, reaching into the deepest parts of muscle fibres, but do not pass into any other of the cell's membranous channels. Physiologically the sarcolemma has special properties in that it can generate and conduct action potentials rapidly to all parts of the muscle fibres, both along its external surface and into the interior via the T-tubules, as these are invaginations of the sarcolemma. In this way all parts of the muscle fibre can be activated rapidly and nearly synchronously to produce a characteristic twitch. The specialized region of the fibre which initiates this event is the *sole-plate*, part of the neuromuscular junction, which will be considered in detail elsewhere (p. 847).

The sarcoplasmic reticulum is a specialized form of agranular endoplasmic reticulum which plays a vital role in muscle contraction. It is a plexus of anastomosing membranous channels filling much of the space between myofibrils (5.5D, 6), expanding into larger sacs (terminal cisternae) where it comes into close approximation to the T-tubules. The combination of a T-tubule and the terminal cisternae on either side is known as a *muscle triad*. The membranes of terminal cisternae and the centrotubule are connected by rows of regular, hollow filaments ('feet') about 8 nm long, which may have a role in coupling the electrical excitation of the sarcolemma and the intracellular release of ions, leading to muscle contraction (Franzini-Armstrong 1970, Somlyo 1979).

Electron micrographs of the sarcoplasmic reticulum often show a densely staining granular interior (5.5D). This system can concentrate calcium ions to much higher level than found elsewhere in the sarcoplasm; when an action potential sweeps down the membrane of the T-tubules, the sarcoplasm releases free calcium ions into the myofibrils, initiating actin–myosin cross-bridge activity and causing muscle contraction. As the sarcolemma becomes electrically stable once more, calcium ions are re-bound to the sarcoplasmic reticulum and the muscle fibre relaxes.

Mitochondria (5.5D, 6) are usually elongate and have closely packed cristae. Their number varies according to muscle type, being much greater in slow twitch than in fast twitch muscle (see p. 552).

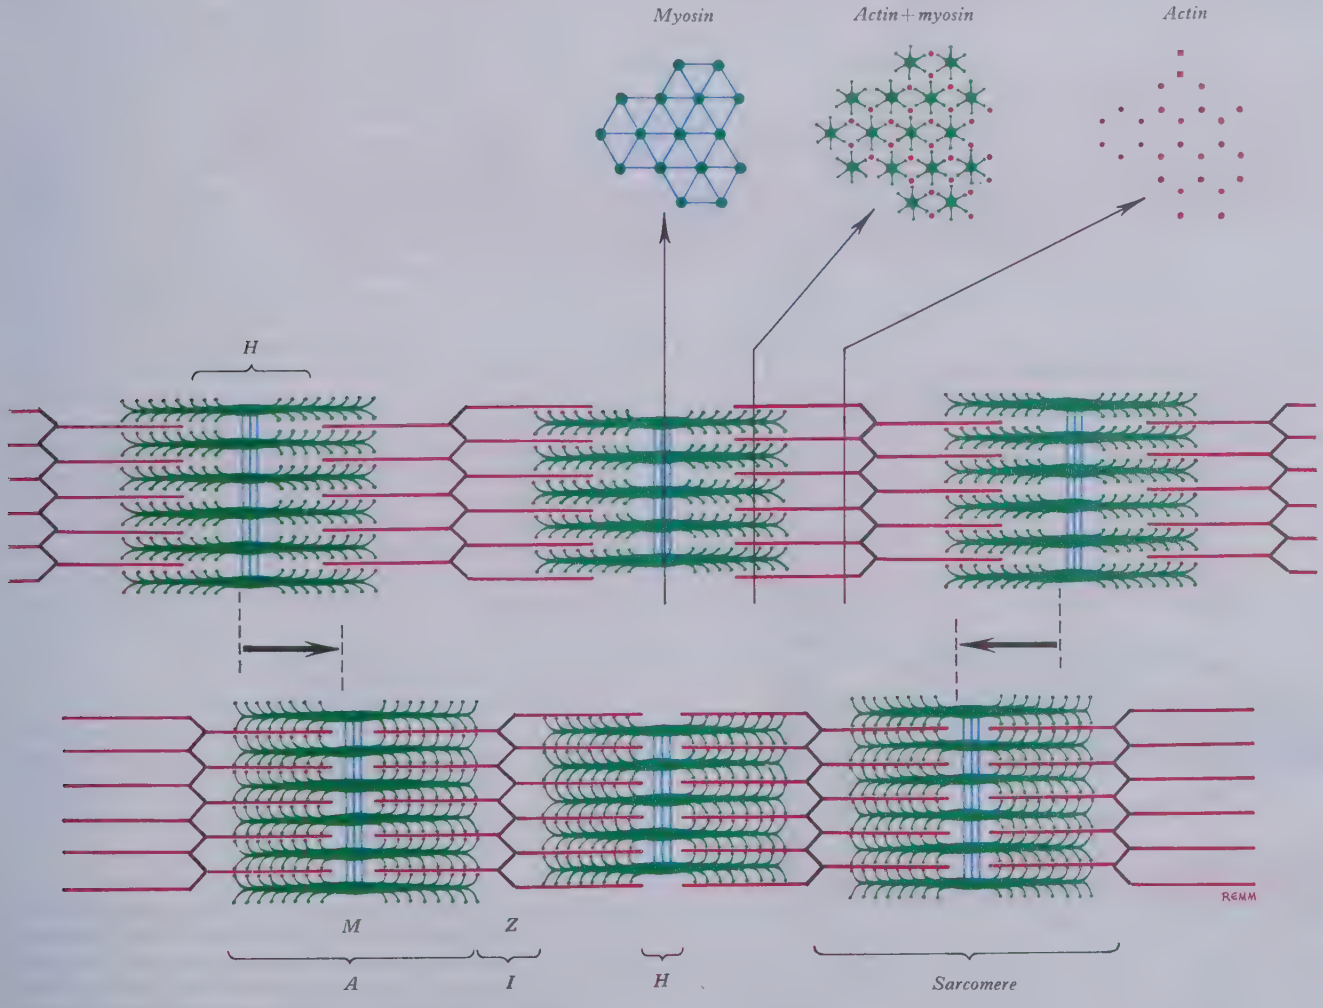
The cytoskeleton of skeletal muscle fibres has recently been investigated in detail (see Wang 1985) and it is now known that the class of intermediate filaments termed in muscle *desmin* filaments (p. 30) plays an important part in maintaining the relative positions of myofibrils and other organelles within the muscle cell, connecting adjacent myofibrils and also lying parallel to them in a manner suggesting that they may participate in transmitting contractile forces to the sarcolemma and throughout the muscle cell.

5.6 Three-dimensional reconstruction of skeletal muscle to show organization of myofibrils, mitochondria and membrane systems. See text for further details. (Modified from a diagram by D Fawcett.)

CLASSIFICATION OF SKELETAL MUSCLE FIBRE TYPES

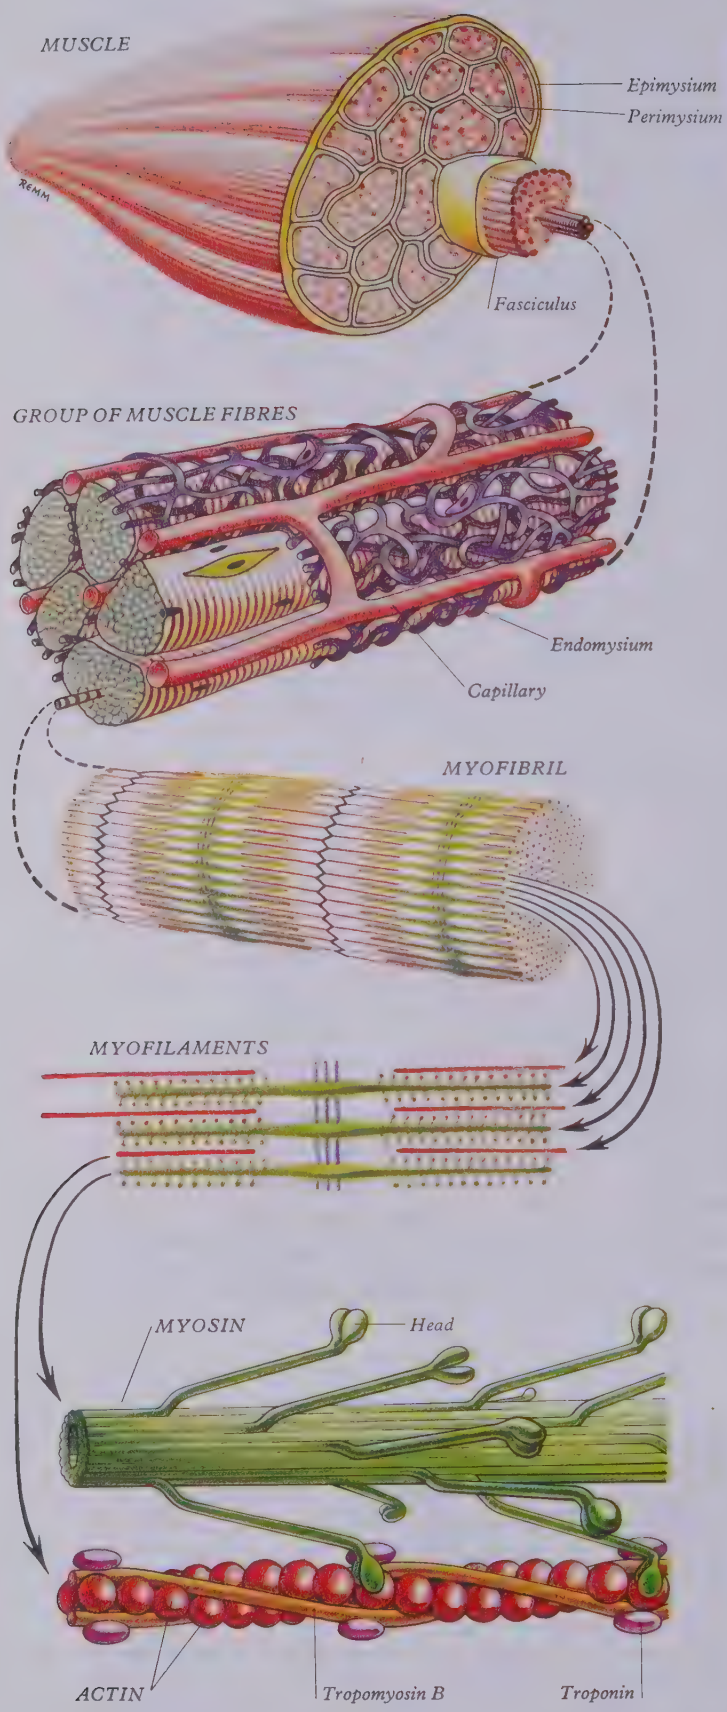
Although all skeletal muscle fibres have the same basic sarcomeric organization, a number of distinct types have been described according to structural, physiological and biochemical criteria. In all mammals the great majority can be divided into three main types (Brooke & Kaiser 1970): red slow twitch (Type I), white fast twitch (Type IIA) and intermediate (Type IIB). Beside these are some highly specialised fibres, including slow tonic (non-twitch) components of extrinsic ocular muscles, the stapedius muscle of the middle ear and also the intrafusal (bag and chain) fibres of the neuromuscular spindle (see p. 858). (For a review of slow tonic muscle, see Morgan & Proske 1984.) In most muscles, Types I and II fibres are intermingled, although there is usually a predominance of one or the other; their ratio is closely related to the contractile properties of the muscle as a whole. There is also some evidence that other types of muscle fibre may exist, e.g. 'visceral' striated muscle in the pharynx and upper oesophagus where the motor innervation is from the vagus nerve (Whitmore & Notman 1987). Many vertebrates other than mammals show a wide range of muscle fibre types, including those of conspicuously red and white muscles, e.g. of birds, but there is no simple relationship between these and mammalian fibre classes.

Type I, red or slow twitch muscle fibres (slow oxidative fibres), take about 75 ms to complete their contraction and such fibres have other distinctive properties; they are red even when exsanguinated, because of a large concentration of myoglobin, an oxygen-storing pigment similar to haemoglobin, and can undergo extensive repetitive contraction without fatigue. Their sarcoplasm is rich in mitochondria and they are strongly positive for the oxidative enzymes of the Krebs cycle and cytochrome chain. Structurally their fibres tend to be narrower than Type II fibres, have thicker Z and M bands, more glycogen (Eisenberg & Kuda 1976) and tend to show a staggered arrangement of sarcomeres (5.2,4A). Their neuromuscular junctions also tend to be



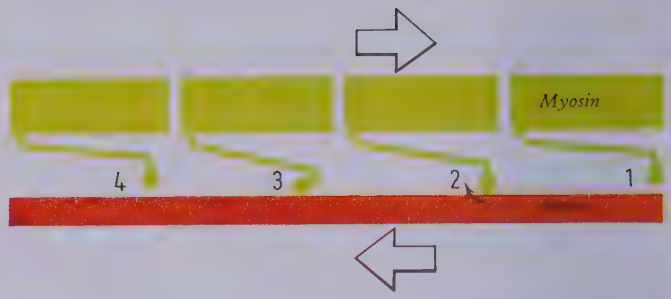
less extensive (p. 904) and their vascular supply is denser, their oxygen demands being more marked. When stretched during contraction, their fibres are also much stiffer than fast muscle, due to a slower rate of actin–myosin cross-bridge cycling, and are thus well suited for resisting or decelerating stretch, as seen in a particularly marked form in postural muscles, but also as a variable property of most skeletal muscles.

Type II, fast twitch muscle fibres, in contrast, can contract in as little as 25 ms. Two subclasses are usually distinguished: *IIA (fast oxidative and glycolytic or intermediate fibres)* and *type IIB (fast glycolytic fibres)*. Type IIA fibres obtain their energy from glycolysis and oxidative phosphorylation, having more mitochondria and being more resistant to fatigue than type IIB. The latter is dependent mainly on glycolysis for energy. There are also many other features which separate these types, for instance their myofibrillar ATPases are optimally active at different pHs and their myosin molecules are chemically distinct, so they can be readily separated histochemically. In general, Type II fibres appear to dominate in non-postural limb muscles, being able to generate powerful forces over a relatively short period (e.g. biceps brachii); while type I fibres form a high proportion of some postural muscles, e.g. thoracic erector spinae muscles and soleus (Brooke & Engel 1969, Johnson et al 1973, Širca & Kostevc 1985). However, these ratios are to some extent variable within a population and may change considerably during development and ageing (Larsson et al 1978).



Variations in enzyme content of muscle fibres appear to depend partly on their activity, as shown by crossing nerves supplying fast and slow muscles, which induces a partial change in enzyme patterns (Buller 1970, Close 1972). This might be caused by secretion of a neural 'trophic factor', but subsequent work indicates that type of muscle fibre is determined primarily by frequency of neural activity in its axon (Riley & Allin 1973). Muscle fibre ratios are also affected by training, the proportion of IIA fibres increasing with exercise, giving the muscle a better ability to resist fatigue (Maxwell et al 1973).

DEVELOPMENT, GROWTH AND REGENERATION OF SKELETAL MUSCLE



The precursors of myocytes are embryonic mesenchymal cells of myotomes or various other regions (pp. 136, 138, 175). The different stages of differentiation into mature muscle fibres have been the subject of much controversy and several schemes of nomenclature have been proposed (see e.g. Boyd 1960, Fischman 1972, Murray 1972). It is generally agreed that specific mesenchymal cells (*promyoblasts*) grow into fusiform elements up to 400 μm long (*myoblasts*), which cease to divide and fuse end to end (5.8c), forming long multinucleate *myotubes*, their nuclei initially lining up in a central row with a surrounding 'tube' of cytoplasm. Myotubes elongate by further fusion of myoblasts at their ends and sides, to form fetal muscle fibres. After this, assembly of myofilaments begins, forming myofibrils with organized sarcomeres. Myofibrils first appear near the cell's centre; more myofilaments are added outside existing ones and nuclei are thus displaced to the periphery. Later, the sarcoplasmic

reticulum begins to form, followed by ingrowth of the transverse tubules.

Myotubes show three grades of increasing maturity. For a period areas of their surfaces are enveloped by a multinucleate syncytium with numerous pseudopodial projections invaginating the surface, especially opposite myotube nuclei (Kelly & Zacks 1969, Landon 1970, Yamashiro et al 1984). This superficial syncytium has been interpreted as a stage in fusion with the myotube or a close conjunction of morphogenetic significance without fusion, the surface syncytium eventually disappearing. The final number of fibres in a muscle is attained before birth (Jaubert 1955). Subsequent longitudinal growth is primarily due to an increase in sarcomeres added at the ends of fibres by progressive fusion of myoblasts. Elongation is also due to small increases in the resting lengths of sarcomeres. Growth in muscle fibre diameter is by addition of the myofilaments around myofibrils which, reaching a critical width, appear to split longitudinally. Growth continues into postnatal life, myoblasts probably fusing with established fibres to increase their nuclear number. Some myoblasts may persist as *satellite cells* which lie in contact with fibres, enclosed within their basal laminae (5.5A) (Schmalbruch & Hellhammer 1976). Fibre diameter is subsequently affected by use, reacting to exercise by hypertrophy and to disuse by atrophy (Rowe & Goldspink 1969). The postnatal growth of skeletal muscle is also much affected by hormone levels, particularly anabolic steroids such as testosterone, responsible for greater development of fibre size in males, and by thyroid hormones and somatotropin. Denervated fibres progressively diminish in diameter and degenerate, being eventually replaced by connective tissue, which becomes increasingly fibrous and may show contracture.

Limited regeneration occurs in human skeletal muscle; fibres near a damaged zone break into short nucleated cylinders of cytoplasm; macrophages arrive and engulf debris but leave the basal laminae intact. The cylinders now fuse and grow back inside original basal laminae to form myotubes, until the growing undamaged ends finally fuse to fill the gap (Carlson 1973). Varying degrees of maturation follow. Satellite cells (*myosatellitocytes*) may participate in regeneration, fusing at the ends of existing sarcoplasm to contribute to the new fibres (Bischoff 1975, Hall-Craggs 1974). If damage is great, regeneration may not occur; lost muscle is then replaced by connective tissue.

INNERVATION OF SKELETAL MUSCLE

Each skeletal muscle is supplied by one or more nerves. In the limbs, face and neck, the nerve supply is often single (but may stem from several neural segments), but where they originate from successive embryonic segments, e.g. muscles of the abdominal wall, their nerves of supply are correspondingly multiple. Neurovascular bundles usually enter the deeper surface of a muscle near its less habitually mobile attachment, at a position which is approximately constant for each muscle (see Brash 1955, Coërs & Woolf 1959).

5.8C Early development of skeletal muscle, showing different stages including early differentiation of myoblasts from mesenchymal cells and fusion of myoblasts to form a myotube maturation into a striated myocyte.

Muscle nerves have a wide variety of motor and sensory components. **Motor fibres** include large myelinated alpha-efferents, which supply most muscle fibres, small gamma-efferents to muscle spindles and fine non-myelinated autonomic efferents (C fibres) to vascular non-striated muscle. **Sensory fibres** comprise myelinated afferents of a range of diameters, from the large spindle and tendon organ fibres to the fine non-myelinated fibres supplying pain and other sensory terminals in the connective tissue of the muscle sheaths. For a fuller consideration of this topic, the reader is referred to pp. 898 and 915.

Within muscles, nerves form plexuses in the epi- and perimysial septa before entering the endomysial spaces around the muscle fibres. Alpha-efferents branch repeatedly before losing their myelinated sheaths and terminating on muscle fibres. The position of such motor terminals is usually to be found in a narrow band across the central zone of the muscle (*the motor*

band). Many gamma-efferents to muscle spindles end in the same region, although muscle spindles may also be present elsewhere. Autonomic fibres ramify in the endomysium throughout the muscle, supplying its vessels. For the innervation of tendon, see pp. 563, 913.

Each muscle fibre receives a single terminal branch of an alpha-efferent axon which ends at a *neuromuscular junction*. This is composed of the axon terminal, the *motor end plate*, giving off a few short branches over a discoidal patch of sarcolemma, the *sole plate*. In a slow tonic fibre (vide supra) the terminals branch to form several small neuromuscular junctions with a muscle fibre over an extended distance (*en grappe endings*). Some or perhaps most of such muscle fibres may receive the terminal branches of more than one motor neuron; intrafusal (muscle spindle) fibres also have in some cases multiple innervation and their neuromuscular terminals take a number of different forms, e.g. *en plaque* endings of a discoidal form and long *trail* endings (see p. 916). Neuromuscular junctions are considered in more detail elsewhere (p. 904).

A motor unit is essentially a functional entity, defined as the combination of a single alpha motor neuron with all of the muscle fibres which it innervates. (The term *myone* for the scattered group of muscle fibres forming the *structural* equivalent of a motor unit has also been proposed by MacConaill & Basmajian 1977 and the muscle fascicle or *myoneme* is the *kinematic unit*. However, these terms are not in widespread use but are mentioned below.) Motor unit size varies greatly, units being smaller where precise control is required, e.g. in extraocular muscles where each motor neuron innervates only 6–12 muscle fibres (Bors 1926); in large limb muscles the ratio may reach 1 to 2000. The total force which can be developed by each unit is therefore inversely related to precision of control.

Muscle fibres innervated by one motor neuron are often widely spread throughout a muscle and do not correspond to fascicles or any other obvious structural division (Burke & Tsairis 1973). Even when only a few motor units are active, the force they generate is transmitted diffusely within the muscle. Each axon probably gives motor terminals to a rounded territory, with overlap between adjacent zones of innervation (Sissons 1969).

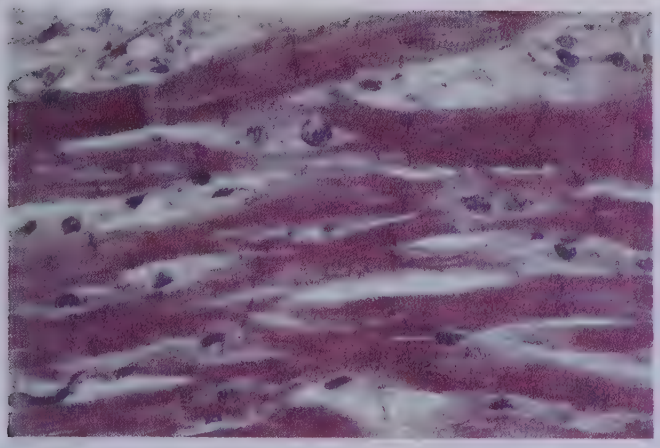
CONTROL OF MUSCLE CONTRACTION

Excitation of muscle fibre occurs when a volley of action potentials passes along the motor neuron axon to reach its motor end plate. This causes the secretion of acetylcholine into the gap between nerve ending and sarcolemma. This neurotransmitter is rapidly inactivated by the enzyme acetylcholinesterase at the surface of the sarcolemma but, in the brief period before this happens, acetylcholine is bound by receptor molecules in the membrane of the sole-plate, causing a change of conductance in the membrane and a local graded depolarization (the *end-plate potential*) from the normal resting potential of about 80 mV (inside negative). The size of the end-plate potential depends on the rate of acetylcholine release, which in turn is related to the frequency of action potential conduction in the motor axon. If the sole-plate membrane is depolarized beyond a certain critical level, the surrounding sarcolemma undergoes an abrupt but transient reversal of potential due to an influx of sodium ions, becoming about 20 mV, inside positive, before returning to the resting potential as potassium ions carry positive charges out of the cell. Such action potentials are propagated along the sarcolemma at about five metres per second and penetrate to the deepest parts of the muscle fibre along the transverse tubule system (p. 551). This event elicits a twitch of contraction lasting 25–75 ms. Repeated action potentials and corresponding twitches can be evoked by continuing neural activity, although there is a limit to twitch frequency, as a *refractory period* of about 10 ms follows each muscle action potential.

Since action potentials are all the same size, they are termed 'all or none' responses. Similarly, muscle twitches are maximal if they occur at all but the degree of contraction also depends on the initial length, loading and metabolic state of the muscle fibre. Contraction in whole muscles is graded by the differential activity of motor units (p. 939). Individual motor units can vary much in twitch frequency and the number of units active also fluctuates. In small contractions only a few units are active but, as contractions increase, more motor units are recruited, summating as a steady contraction of a whole muscle, the single muscle fibres twitching repetitively but asynchronously. Under experimental conditions above a critical stimulation frequency, the relaxation of individual muscle fibres cannot occur before the next contraction starts, resulting in partial or complete fusion of twitches or *tetanus*. The threshold for tetanic stimulation varies with muscle type: for slow twitch muscles it is about 30 and for fast twitch, 100 per second, or more. Since all muscle contractions are summations of individual twitches, even those which appear 'steady' show fine oscillation on closer examination. Like energetic states of subatomic particles, release of neurotransmitters is *quantal* and muscle contraction may also be so regarded; for some purposes quantum mechanics may thus prove an appropriate means of analysis.

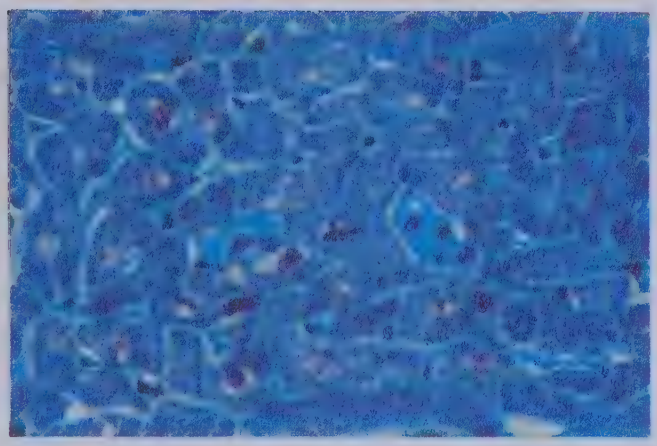
BLOOD VESSELS OF SKELETAL MUSCLE

The blood supply of muscles arises from muscular branches of adjacent arteries. As already stated, in many cases branches of a principal artery, vein and nerve enter together along a strip, the neurovascular hilum, while subsidiary arteries often enter elsewhere. All branch into smaller arteries and arterioles which ramify in perimysial septa, giving off capillaries to the endomysium. These lie mainly parallel with the muscle fibres which they serve and are interconnected by numerous transverse anastomoses (**5**.8A). The density of capillary beds varies; in predominantly 'red' muscles it is higher than in those with a majority of 'white' (fast twitch) fibres, corresponding to the greater oxygen demands of red muscle (see p. 552).



On the basis of various experiments including the use of isotopic sodium as a tracer (Barlow et al 1961) and microscopic examination (Grant & Payling Wright 1968), two distinct circulations have been reported in skeletal muscle. The *nutritive circulation* is fed from arteriolar branches of the hilar arteries which reach the endomysium, where all blood passes through capillaries to collecting venules and veins, leaving by the hilum. Alternatively, some blood passes into arterioles of epi- and perimysium, which contain few capillaries; arteriovenous anastomoses are abundant here, most blood returning directly to veins without traversing the capillaries. This *non-nutritive* pathway allows blood to pass when flow in endomysial capillary beds is impeded, e.g. during muscle contraction (see also p. 693).

The *lymphatic drainage* commences as capillaries in epi- and perimysial sheaths which apparently do not enter the endomysium. They then converge to form larger lymphatic vessels accompanying the veins to the hilum, draining to the regional lymph nodes.



CONNECTIVE TISSUES OF SKELETAL MUSCLE

The general arrangement of connective tissue in muscle has already been described (p. 547). Connective tissue performs important roles in the functional organization of muscles, providing mechanical coherence, allowing independent movement of individual fibres and fasciculi and transmitting contractile forces to adjacent structures such as tendons, aponeuroses and bones. Connective tissue planes are also routes for nerves and blood vessels. The endomysium is of special significance, since it forms the external environment of muscle fibres and is the site of metabolic exchange between fibres and capillaries. Its proteoglycan matrix also mediates the flow of ions during excitation of muscle fibres and acts as an ionic reservoir.

The fibres of collagen (chiefly Type I, see p. 64), reticulin and elastin and their associated proteoglycans, also affect the mechanical characteristics of muscle in contraction and passive extension (Hill 1970). Transmission of contractile force to adjacent structures requires attachments between muscle fibres and their associated connective tissue. These include the junctional regions between the ends of fibres and their tendinous attachments, *myotendinal junctions* (Schippel & Reissig 1968, Hanak & Bock 1971). Here, the various orders of connective tissue sheaths fuse to form the fibrous fasciculi of the tendon. Muscle fibres may

taper or have flattened ends or show a terminal expansion. Electron microscopy shows a highly indented sarcolemma in such regions, with a dense sub-sarcolemmal layer of cytoplasm into which actin filaments of adjacent sarcomeres penetrate. Externally the basal lamina is prominent, with collagen and reticulin fibres in close contact. There are however no desmosomal attachments and it is probable that both here and along the whole fibre contractile forces are transmitted from cell surface to the connective tissue matrix primarily by viscous adhesive forces.

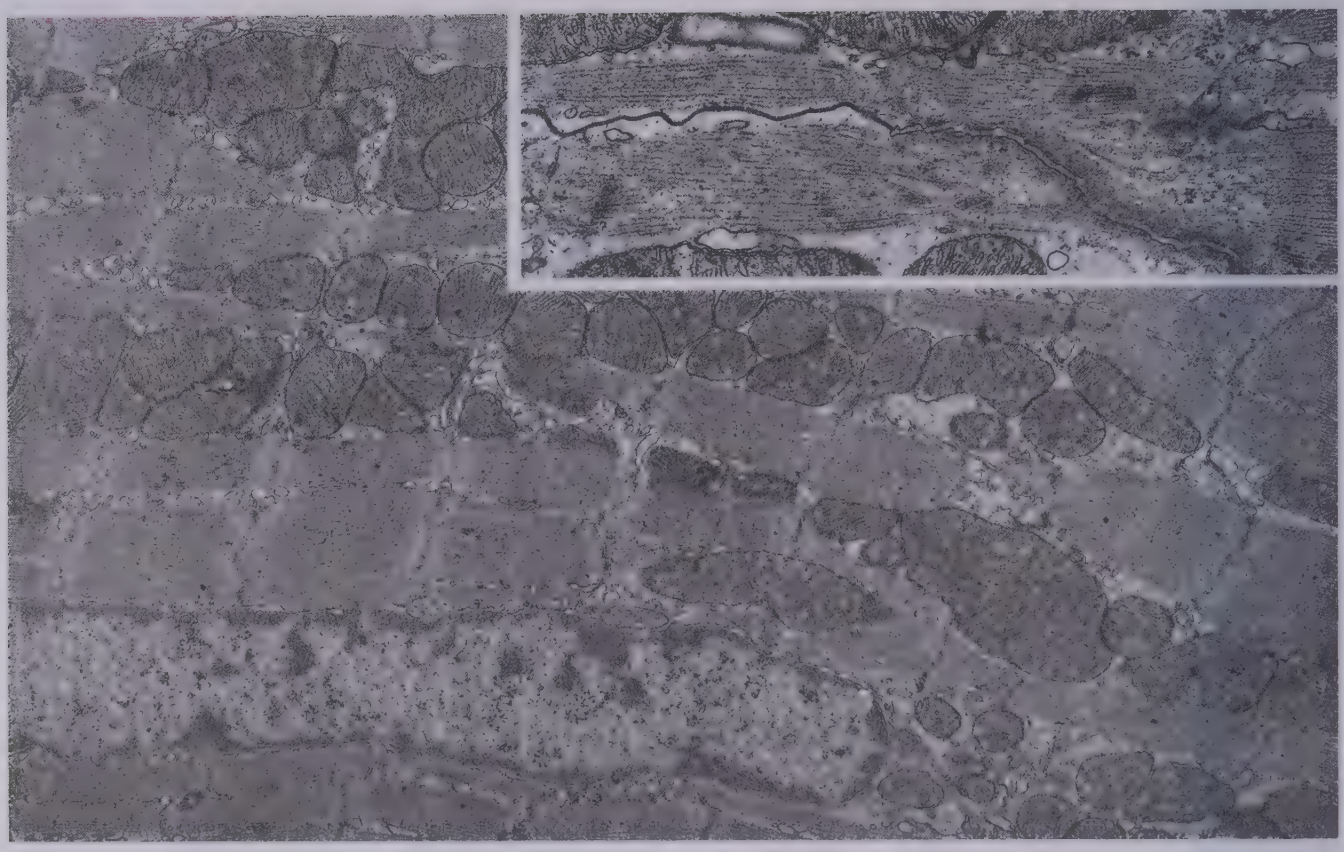
Cardiac Muscle

Heart muscle has distinctive structural and physiological properties which differ in several respects from those of skeletal and non-striated muscle. It is composed of tracts of uninucleate cells (5.9), each up to about 80 μm long and 15 μm in diameter in man, with a central nucleus; each cell may divide into two or more branches at its ends, which abut against other cells, giving the appearance of a network of branching and anastomosing cylinders. Indeed, cardiac muscle was long considered to be syncytial. In the intercellular spaces is an endomysium similar to that of skeletal muscle, containing capillaries and nerve fibres. The larger tracts of myocytes, varying from a few hundred to many thousands, are parcelled into fasciculi by perimysium, as also in skeletal muscle.

Each *cardiac myocyte* shows striations like those of skeletal muscle, with A,I,Z and H bands, although these are not as obvious in routine histological preparations. At the ends of the myocytes are conspicuous densely staining cross-striations, *intercalated discs*. The same pattern of sarcomeres with actin and myosin filaments also exists (Fawcett & McNutt 1969, Page & Fozzard 1973) but these are not arranged in discrete myofibrils. Mitochondria are large and numerous and are interspersed between myofilament clusters (5.11). T-systems are also similar to those of skeletal muscle (Forssmann & Girardier 1970) but penetrate the sarcoplasm opposite the Z bands rather than at the I–A band junction (5.11), possibly reflecting the slower contraction time of cardiac muscle; the sarcoplasmic reticulum is not as abundant. Glycogen and myoglobin are present abundantly and histochemical preparations are strongly positive for oxidative enzymes. These features, like those of mammalian slow twitch skeletal muscle, reflect the high oxygen demand and constant rhythmic expenditure of energy typical of cardiac muscle, as does the richness of the myocardial vascular bed and consequent blood flow. Cardiac myocytes have a spontaneous rhythm of contraction and relaxation, even when isolated. This *myogenic rhythm* has a parallel oscillation in membrane potential dependent on a slow inward leakage of sodium ions. The rhythm of isolated cells is slower than that of the whole heart but, in the intact heart, myocytes are synchronized by the more rapid rhythm of the pacemakers and conducting system (vide infra and p. 720).

Intercalated Discs

Ultrastructurally these are seen to be special regions of the sarcolemma and underlying cytoplasm, present at junctions between myocytes. They may lie transverse to the cell's long axis but are often stepped with alternating transverse and longitudinally orientated planes (5.9,10). At these junctions, adjacent myocytes are anchored together by wide belts of desmosomes alternating with gap junctions (see p. 24), the latter being the means by which cardiac myocytes are electrically coupled. Hence, under normal conditions, excitation and contraction spread rapidly along tracts of interconnected cells and the heart behaves *electrically* as a syncytium. Immediately beneath these membranous junctions, the cytoplasm is dense and appears to anchor actin filaments of neighbouring sarcomeres as well as other cytoskeletal structures, including intermediate filaments, a feature which allows contractile forces to be transmitted effectively from one cell to the next.



Conducting Tissues of the Heart

These tissues are also described with the heart (p. 720). Three major types of cell form the different parts of the conducting system: *nodal myocytes, transitional myocytes* and *Purkinje myocytes* (Sommer & Johnson 1968, James & Sherf 1974).

Nodal myocytes, responsible for pacemaker activities, are mononucleate, rounded, cylindrical or polygonal cells, existing in groups in the sinu-atrial and atrioventricular nodes (5.1). They have a few randomly orientated myofibrils, lack a regular sarcotubular system and show a pale zone free of organelles around a large central nucleus.

Transitional myocytes also occur in nodes, extending into the stem and principal rami of the conducting system as connecting pathways between nodal and Purkinje myocytes. Transitional myocytes are narrower than cardiac myocytes but possess the same type of contractile apparatus. They may conduct more slowly than the larger fibres and this appears to be the basis of the conduction delay in the atrioventricular node and its principal rami.

Purkinje myocytes are large mononucleate cells, wider and shorter (30 μm in diameter and 20–50 μm long) than general cardiac myocytes. They also have larger gap junctions at their ends and also laterally. They contain fewer myofibrils, many mitochondria, abundant glycogen and a well-developed sarcotubular system, all features correlated with rapid conduction in Purkinje fibres (about 2–3 metres per second, compared with 0.6 metres per second in myocardium). It should be noted at this point that Purkinje *fibres* are composed of rows of Purkinje *cells* and it therefore seems inappropriate that the term 'Purkinje fibre' has often been used to denote single Purkinje myocytes.

5.10 Electron micrograph of cardiac muscle in longitudinal section showing abundant mitochondria and intercalated discs. Magnification × 4000. Detail shows part of intercalated disc with gap junction in left half of field and a desmosomal belt on the right. Magnification × 15 000.

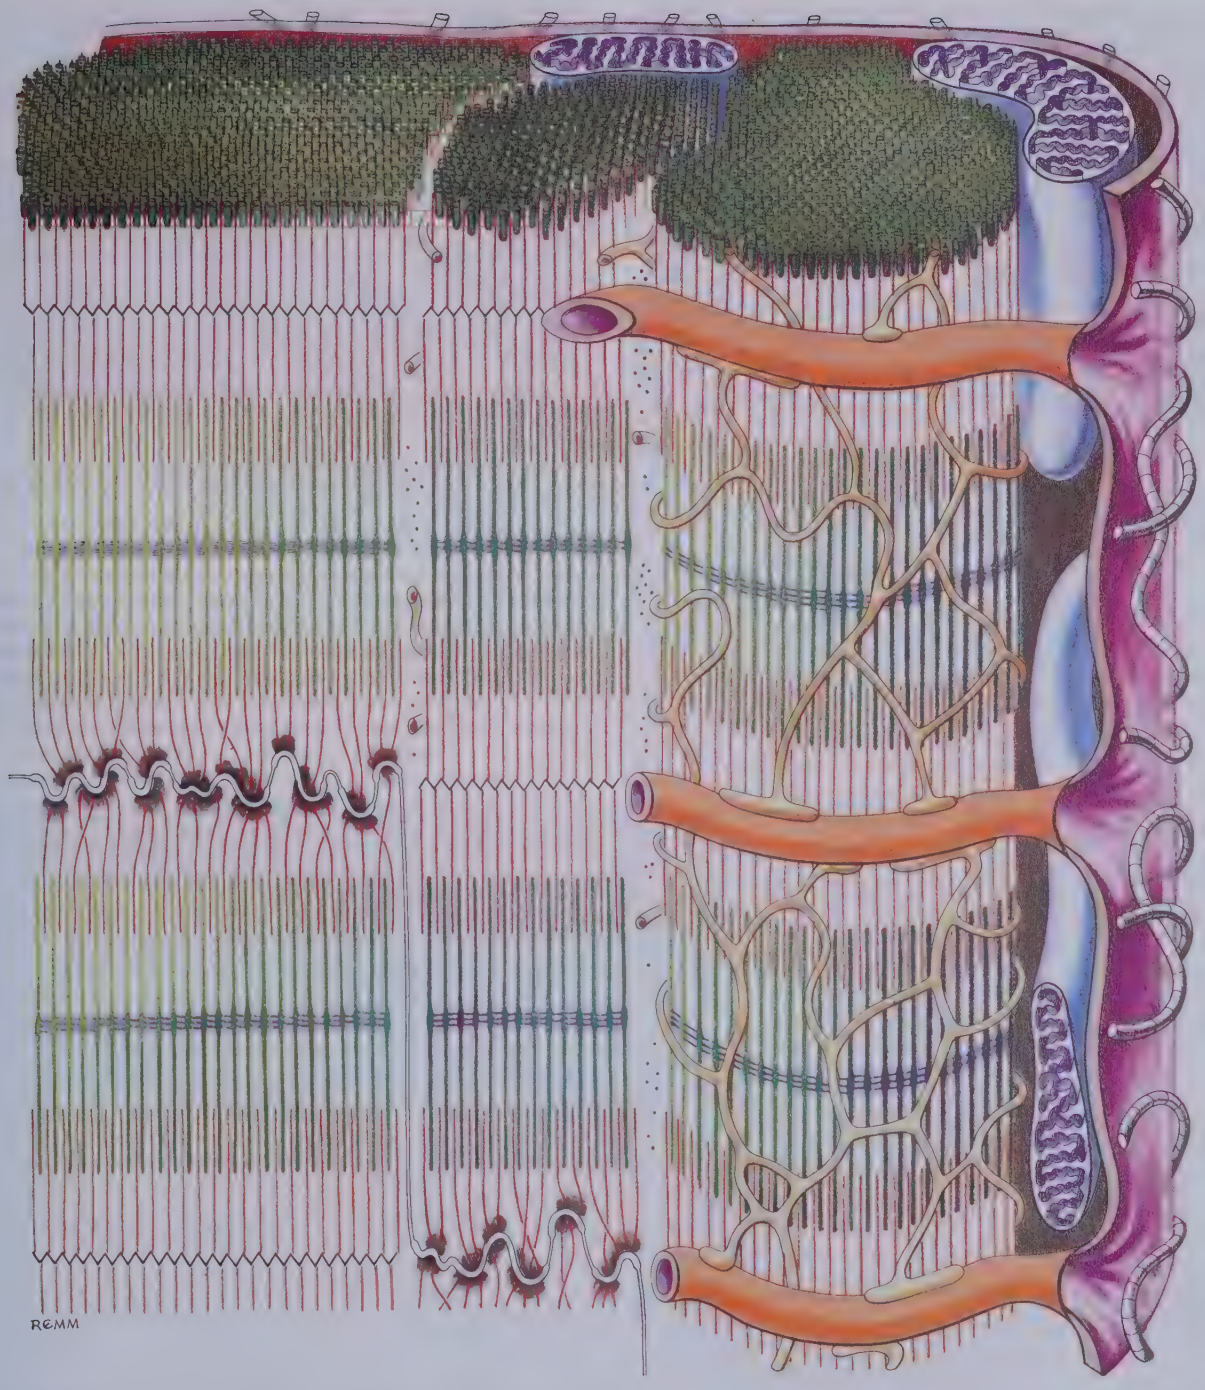
Although these cell types and their arrangement within the major conducting pathways of the heart are well established, there is less certainty about some conducting routes which have been adduced from electrophysiological evidence. These include the proposed pathways from right to left atrium (interatrial), between the sinu-atrial and atrioventricular nodes (internodal) and the accessory atrioventricular bundles. For a further discussion of this topic, see p. 722.

Innervation of Cardiac Muscle

Non-myelinated, post-ganglionic, sympathetic and parasympathetic axons permeate cardiac connective tissue septa and end close to but not in contact with individual myocytes. The quantitative aspects of distribution of autonomic efferent and afferent nerve terminals in all the complex localities of the heart and its vessels are virtually an uncharted field.

Blood Vessels of the Myocardium

The myocardium has a dense vascular bed derived from the coronary vessels (p. 731), which branch to feed a rich endomysial plexus of anastomosing vessels, each cardiac myocyte being no more than about 8 μm from a capillary (Wearn 1941). Vascular channels occupy about 60% of the total interstitial space in rabbits' myocardium (Frank & Langer 1974). Lymphatic capillaries also penetrate the endomysium, unlike those of skeletal muscle.



Development, Growth and Regeneration

Cardiac muscle develops from mesenchyme of the myo-epicardial mantle in the embryonic heart (p. 207), a source confirmed by Morris (1976) in human embryos. Cardiac promyoblasts are at first stellate, adhering by intercellular junctions which later become intercalated discs (Challice & Viragh 1973, Morris 1976). They show repeated mitoses and synthesize myofilaments, thus becoming cardiac myoblasts, which begin rhythmic contraction early in fetal life. Cell proliferation continues into postnatal life but gradually yields to growth by hypertrophy of individual cells, a process to some extent dependent upon their work load. Regeneration of damaged muscle does not seem to occur and it is replaced by fibrous scar tissue (Hudson & Field 1973).

Non-striated Muscle

Non-striated muscle (smooth, involuntary or plain muscle) differs considerably from other muscle tissues in structure and behaviour (5.1,12–15). It is composed of mononucleate, fusiform myocytes, varying in length from 15 μm in small arterioles to 500 μm or more in the myometrium in pregnancy (Csapo 1962, Huddart & Hunt 1975). Disposed with long axes parallel to the direction of contraction, they are usually arranged in small fasciculi, separated by connective tissue septa containing afferent and efferent vessels and nerves. In regions where concerted contraction in one direction occurs, fasciculi lie parallel, as in the muscularis externa of the intestines. Where contraction reduces the surface area, fasciculi interweave in all directions, as in the urinary bladder. In muscular arteries non-striated muscle forms thick sheets devoid of capillaries. Within fasciculi much of each cell is covered almost entirely by a prominent basal lamina; attached to the exterior of this structure (basement membrane), are numerous fine elastin, reticulin, and collagen fibres, forming complex networks around cells. Cells are separated by a space of 40–80 nm, except at intercellular junctions (vide infra). Fibroblasts and other connective tissue cells are usually lacking in fasciculi, and the extracellular matrix is characteristically their own product. At their boundaries connective tissue fibres interweave with those of interfascicular septa, presumably transmitting forces generated by contraction of individual cells.

Two types of non-striated muscle are distinguished by innervation and behaviour: *multi-unit* and *unitary* muscles (Bozler 1948, Burnstock 1970). In *multi-unit muscles*, rich nerve plexuses provide many myocytes with motor terminals; contraction is usually initiated by neural action, i.e. is not spontaneous or due to

5.11 Three-dimensional reconstruction of cardiac muscle showing organization of myofibrils and membrane systems. As in previous diagrams, actin is shown red and myosin green; mitochondria are coloured blue; the sarcolemma and luminal surface of the invaginated transverse tubules are purple, the intracellular surface of the transverse tubule is orange, and the sarcoplasmic reticulum is coloured yellow. An intercalated disc with intermittent desmosomes and communicating 'gap' junctions is depicted on the lower left of the picture. Compare with 5.6, and see text for further details. (Modified from a diagram by D Fawcett.)

stretch, and small groups of cells may act independently. Muscle in larger arteries, the iris and ductus deferens is of this type. *Unitary muscles* have few motor nerves; rhythmic contractions are spontaneous, i.e. *myogenic*, and may be governed by *pacemaker regions* in the muscle or elicited by tension. Examples are muscle layers of the stomach, intestines, uterus, ureter and some smaller blood vessels. Here, neural control enhances or depresses the rate and force of spontaneous, myogenic rhythmic contractions. Intermediate types of muscle exist and the divisions outlined may merely represent the extremes of a wide spectrum of activities.

There are also various structural differences which indicate other types of subdivision, e.g. into visceral and vascular non-striated muscle, although it is likely that many variations in detailed structure and physiology may occur in different parts of the body.

THE STRUCTURE OF NON-STRIATED MYOCYTES

Non-striated myocytes have a central nucleus, much elongated in stretched muscle and ovoid, crenated or sinuous in contraction. The myocytes are weakly birefringent, indicating a longitudinal orientation of filamentous components. Ultrastructurally their cytoplasm consists mainly of closely-packed fine filaments lying parallel to the long axis (5.13,14,15B). Golgi complexes,

agranular and granular endoplasmic reticulum, free ribosomes and lyosomes are positioned near the nuclear poles but groups of mitochondria are located either peripherally or scattered at deeper levels, varying in different types of muscle (Gabella 1973, Huddart & Hunt 1975). An irregular sarcoplasmic reticulum, able to sequester calcium ions, ramifies between the myofilaments (Popescu & Diculescu 1975), its terminal sacs lying under the plasma membrane. The plasma membrane has great numbers of small cup-like invaginations (caveolae), superficially resembling endocytic vesicles but not engaged in uptake of particles. Some of them at least may represent reservoirs of plasma membrane which allow the cell to stretch considerably without rupture. The

surface also shows occasional projections (5.13) and various junctions with other cells. For further details of cell structure see Gabella (1981).

Actin and myosin myofilaments are present in non-striated muscle and their mutual sliding brings about contraction, as in other types of muscle. Actin filaments have long been described in electron microscope studies but it was only with the advent of improved fixation methods that the myosin filaments were regularly seen, as they appear to be much less stable than those of the striated muscles (Somlyo et al 1973). Myosin filaments are thick ribbons or rod-like aggregates of myosin molecules up to 15 μm long and 0.1 μm wide. How the myosin is arranged in these large filaments is still uncertain but they may point in opposite directions on either side of each filament so that interactions with actin filaments may also be in opposite directions on the two sides. It has been suggested that this type of organization is necessary to produce directional contraction, in the absence of any obvious sarcomeric structure (Hinssen et al 1978). Each myosin filament is surrounded by up to 15 actin filaments, forming a type of contractile unit, which may be obliquely orientated in the myocyte (Small 1974). Actin filaments are also attached to cytoplasmic densities within the cell and also to projections of dense material lying under the plasma membranes (Cooke 1976), which may transmit contractile forces to the cell surface and to the

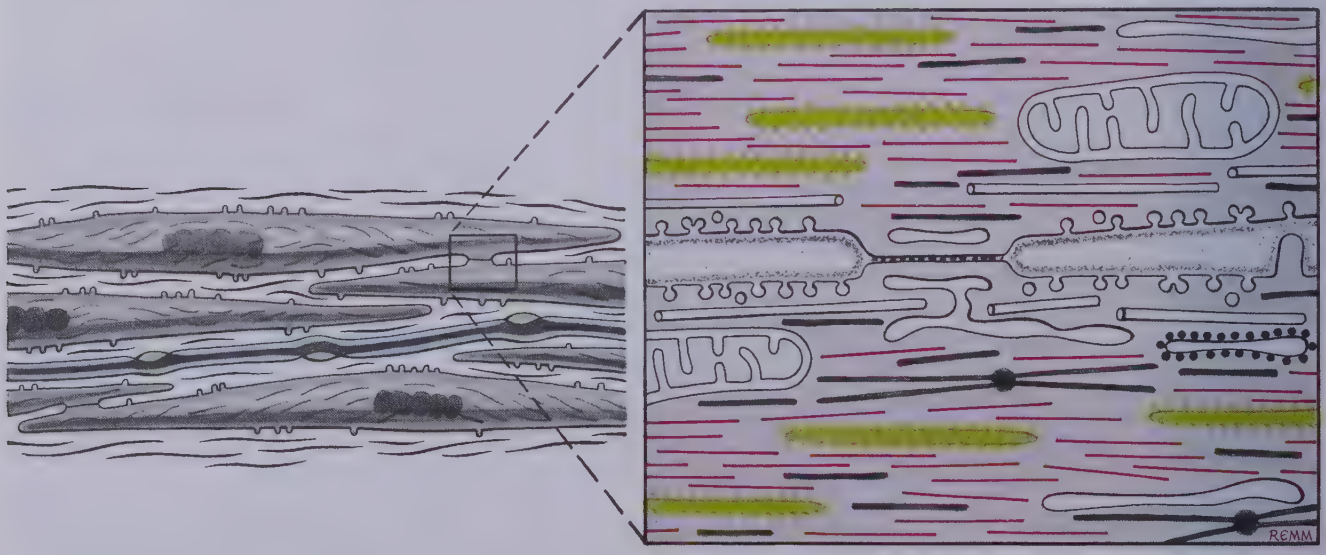
extracellular matrix (Gabella 1984). The chemistry of the myofilaments is also distinct from that of striated muscles; troponin is not present but instead a protein termed Leitonin is attached to actin filaments and appears to have a regulatory function in contraction. Unlike skeletal muscle, non-striated myosin is activated to bind to actin only when its light chain is phosphorylated by a calcium-dependent kinase (Ebashi 1983).

In addition to myofilaments, non-striated muscle contains numerous intermediate filaments (desmin filaments) which appear to provide coherence to the muscle fibre, uniting the various contractile units and transmitting forces throughout the cell.

Excitation of non-striated myocytes involves depolarization of their plasma membranes, caused by a transient influx of calcium ions activating actin-myosin filament sliding systems. Myocytes also excite each other through gap junctions of *maculae communicantes* (5.15A,B) (Cobb & Bennett 1969, Lowry & Small 1970, Watanabe & Yamamoto 1974). In some locations a few score occur on each cell. In the cytoplasm beneath such junctions are often cisternae of smooth endoplasmic reticulum, which may correspond in function to the sarcoplasmic reticulum of striated muscles (Fry et al 1977), perhaps mobilizing calcium stores during excitation. Electrical coupling ensures that myocytes act in concert, enabling one nerve fibre to control many myocytes. Myocytes are also linked to each other by desmosomes and to surrounding matrix by specialized surface features resembling zonulae adherentes of epithelial cells (p. 24).

5.15A A gap (communicating) junction between two non-striated myocytes. Magnification × 70 000.

Other Activities of Non-striated Muscle



Extracellular fibres always surround non-striated muscle fasciculi; in vitro non-striated myocytes secrete elastin, collagen and other matrix components (Scott et al 1977); the ability of non-striated myocytes to synthesize and secrete matrix components suggests strong affinities to fibroblasts and indeed some of the latter cells (e.g. myofibroblasts, p. 58) show pronounced contractile behaviour. In elastic arteries, non-striated myocytes are typically contractile during early years but, as they progressively lay down large quantities of elastin, they appear to lose this ability and come to resemble normal fibroblasts in this respect. However, myocytes are typically present in organized well-defined tracts and are under regular neural control, indicating that they are a distinctive cell type and not merely highly contractile fibroblasts (see Ross 1971).

Development and Regeneration of Non-striated Muscle

As already stated (p. 546), non-striated muscle arises from mesenchymal cells in various parts of the body. In visceral smooth muscle, the first sign of differentiation is the appearance of a cluster of stellate mesenchymal cells which come together in a confluent mass, then differentiate into myoblasts, then into elongate myocytes which may continue to grow. These form fasciculi and individual cells come into contact at gap (communicating) junctions. Finally, fasciculi may associate to form well-defined muscular layers. The later stages of differentiation appear to be accelerated by the ingrowth of autonomic nerves (Burnstock 1981). Non-striated myocytes can also undergo mitotic division and this may be stimulated by hormones and by damage; in the latter case, regeneration of the muscle may be completely effected by myocyte proliferation (Burnstock 1981). New myocytes can originate, even in adults, from persisting mesenchymal cells, e.g. in the walls of regenerating blood vessels; non-striated myocytes are also able to multiply mitotically, e.g. in the myometrium after treatment with progesterone (Crandall 1938); to what extent this occurs naturally is uncertain (Ross & Klebanoff 1967).

Innervation and Blood Supply of Non-striated Muscle

Autonomic motor and sensory nerves from non-myelinated plexuses send branches into muscle fasciculi. Neuromuscular

5.15B Diagram showing the principal features of organization of non-striated myocytes. On the left a group of myocytes shows the fusiform shape of the contracted cells and the arrangement of the autonomic efferent innervation; on the right the main features of the cytoplasmic filaments and membrane systems are depicted. Thick myosin filaments (green) are surrounded by irregularly arranged actin filaments (red); microtubules and intermediate filaments, some with associated dense bodies, are also illustrated. The elongated membranous cisternae correspond to the sarcoplasmic reticulum; endocytic vesicles and a communicating junction between two adjacent myocytes are also visible.

terminals of sympathetic and parasympathetic efferents are considered in detail elsewhere (pp. 905, 906); briefly, they consist generally of long, branched terminals which bear numerous varicosities, each swelling being a possible site of neurotransmitter release. In the slower visceral muscle the nerve terminals are at a much greater distance from the myocyte surface than in the quick-reacting muscle of the iris and neural control is less precise as well as slower. The myocyte plasma membrane has various types of response to a range of neurotransmitters, which vary with location in the body (see also p. 889) and the types of control may be quite complex, involving excitation, inhibition and other types of modulation of contractile behaviour (see Gabella 1974, Bülbring & Shuba 1976, Jones 1981) (pp. 890, 1363).

Capillary networks exist in connective tissue sheaths of smaller fasciculi in most locations, but vascularization is not as dense as in skeletal muscle. In some sites, e.g. tunica media of muscular arteries, capillaries may not penetrate muscle at all, reflecting the low energy requirements in such regions.

MYOEPITHELIOCYTES

These contractile cells, whose embryonic origin is believed to be ectodermal, exist in glandular tissue, close to the secretory parts and ducts. They are either *stellate ('basket cells')* with long dendritic extensions clasping an adjacent glandular acinus, as in salivary and lacrimal glands, or *fusiform*, e.g. in intercalated ducts of salivary glands (p. 55). They also exist around mammary acini and the secretory parts of sweat glands. They are often innervated by the autonomic nervous system; when they contract they initiate a rapid flow of secretion into the glandular ducts. Ultrastructurally (Ellis 1965, Tandler et al 1970) these cells show extensive desmosomal attachments to surrounding tissues and internally large numbers of actin and myosin filaments, similar to those of non-striated myocytes. They also contain numerous intermediate filaments which immunohistochemistry has shown to be of the epithelial class (cytokeratin), strong evidence of an ectodermal origin (Franke et al 1980). They are also rich in alkaline phosphatase, ATPase and adenyl cyclase (Han et al 1976).

ATTACHMENTS, GENERAL FORM AND ACTIONS OF SKELETAL MUSCLES

Tendons, Aponeuroses and Fasciae

Tendons are integral parts of muscles, forming a component which can be considered for practical purposes to be of unvarying length (but vide infra). Being largely made of collagen fibres, they are resistant to stretch, but are also relatively flexible and can be angled round osseous surfaces or deflected under retinacula (vide infra) to change the final angle of pull. Since they are composed of collagen and their vascular supply is sparse, they appear white. Taking the form of cords or straps, they are round, oval or elongate in section and consist of fascicles of collagen fibres, largely parallel to the long axis but also partly interwoven. The fasciculi may be conspicuous enough to give tendons a striated appearance to the unaided eye, or even to form duplicated or multiple cords. Some tendons are commonly double and some have minor strands connecting with adjacent tendons. Their surfaces are smooth but longitudinal ridging by coarse fasciculi is common in large tendons, e.g. the osseous aspect of the angulated tendon of obturator internus (p. 643). Loose connective tissue permeates between fascicles, providing routes for vessels and nerves and condensing on surfaces as a so-called sheath or *epitendineum*, which may contain elastic and irregular collagen fibres. This has no real surface, being continuous with surrounding tissue, whose flexibility imposes minimal drag on tendon movements. Some tendons are, however, separated from their surroundings by synovial membrane, permitting much more extensive movement (vide infra).

Tendons (and aponeuroses, vide infra) are strongly attached to bones, not only via their periostea but also often by tendon fasciculi which may penetrate deeply into cortical osseous tissue. Sections of fresh bone show that at the sites of tendonal attachment there is often a plate of white fibrocartilage (p. 290); where this is thin or absent the bone surface is rough but, when fibrocartilage is present, the bone surface is quite smooth in cleaned skeletal material (Benjamin et al 1986). The functions of such layers of fibrocartilage are not clear; where tendons insert into bones which replace a cartilage precursor relatively late in development, e.g. an epiphysis, fibrocartilage may be particularly thick and may represent a remnant of the earlier state; however, cartilage is also found at other sites and may therefore have a continuing functional importance, as yet unknown.

The tensile strength of tendons is similar to that of bone, i.e. half that of steel, a property much in excess of ordinary demand. A tendon 1 cm^2 in cross section will support 600–1000 kilograms. Though only a little extensile, tendons *are* slightly elastic and some contractile energy is stored in them when muscles contract. They also exhibit viscosity. Arnold (1974) has reviewed their biomechanical and rheological properties, with special reference to human feet. Certain avian wing tendons are highly elastic and have complex, ultrastructural interactions between their collagen and elastin fibres (see Oakes & Bialkower 1977).

The blood supply of tendons is relatively scant; small arterioles from adjacent muscle ramify longitudinally between their fascicles, anastomosing freely, accompanied by venae comitantes and lymphatic vessels. This longitudinal plexus is augmented by small vessels from adjacent loose connective tissue or synovial sheaths (Edwards 1946). At osseous attachments, their vessels are restricted to transverse capillaries and no vessels pass between bone and tendon at these sites; such osseous surfaces are usually devoid of foramina (p. 269). The metabolic rate of tendons is very low but increases in reaction to infection or injury. Repair involves the initial proliferation of connective tissue cells associated with collagen fibres, followed by interstitial deposition of new fibres (Potenza 1963).

The nerve supply is largely or perhaps solely sensory; evidence of any vasomotor control is lacking. Specialized *neurotendinous sensory endings* (Golgi tendon organs, p. 913) exist near musculotendinous junctions; their large, myelinated afferent fibres course centrally within branches of muscular nerves or in small rami of adjacent peripheral nerves (Stillwell 1957).

Postnatally, tendons grow interstitially, particularly at musculotendinous junctions, where high concentrations of fibroblasts occur performing rapid elaboration of collagen. There is a decreasing growth gradient towards osseous attachments.

Synovial sheaths and bursae exist where moving structures are in tight apposition, particularly where tendons are deflected around bone or under retinacula near joints. The simplest arrangement occurs at a few sites, such as over the olecranon and the patella, where skin moves freely over subcutaneous bone, often under pressure. Such *bursae* are simply flat sacs of synovial membrane, supported by dense irregular connective tissue in the loose areolar tissue between skin and bone, by their position termed *subcutaneous bursae*. The extremely flattened form is not perhaps indicated clearly by the name 'sac', for in each the opposed walls are separated by a mere film of fluid; it is an enclosed cleft, its walls tethered to periosteum and dermis and hence sliding over each other as the adjacent tissues move. Although they are often considered devices to reduce friction, they are basically absolute discontinuities between tissues, yielding total freedom of movement over a limited range. The capillary film of lubricant synovial fluid also provides the lining synovial cells with a wet environment and a source of nutrients.

Most synovial bursae lie between tendons and bones or ligaments, or between two tendons (i.e. they are *subtendinous*). Some occur between muscle and a bone, tendon or ligament (*submuscular synovial bursae*). Some separate aponeuroses from bone

(*subfascial bursae*), some are *interligamentous*. Many situated near joints communicate with them, with continuity of their synovial membranes and fluid. Such *communicating bursae* may develop separately, connecting only later with the articular cavity; sometimes they ensheath tendons as they emerge from intracapsular attachments.

Synovial tendon sheaths surround tendons where they pass under ligamentous bands and retinacula or through fascial slings and osseofibrous tunnels. They are composed of an outer and an inner synovial membrane separated by a thin film of synovial fluid, the two layers being continuous at both ends of the tunnel they form to create a closed cylindrical envelope around the tendon. The internal (*'visceral'*) layer is attached by loose connective tissue to the underlying tendon and the external (*parietal*) layer is similarly tethered with adjacent periosteum or other connective tissue structures. It should be added that the precise shape of synovial tendon sheaths varies much, from simple cylindrical to highly complex, depending on the shape of the enclosed tendon and the surrounding tissues and on other mechanical factors (e.g. p. 619). Since the tendon is invaginated into the sheath, the visceral and parietal layers are often connected by a longitudinal *mesotendon*, providing a degree of mechanical stability and a route for neurovascular supply. Some mesotendons are reduced to localized cords, often multiple, e.g. the vincula tendinum of digital tendon sheaths (p. 621).

Where skin undergoes frequent displacement and pressure, as in the forearm or elbow in writing, or the buttock in some sedentary occupations such as hand-weaving, *adventitious bursae* may appear, providing the overlying skin with greater freedom, a phenomenon perhaps indicating that mechanical factors may be important in the evolution of bursae in general. However, the established series of bursae develop in utero and therefore must be determined genetically.

Some bursal mechanisms are more elaborate and share some of the features of synovial articulations (p. 471). Osseous or cartilaginous sesamoids occur in some tendons, closely applied to the osseous surface. In such conjunctions, the apposed surfaces are cartilage-covered and enveloped within a localized bursa, e.g. the sesamoid in the tendon of peroneus longus where it articulates with the cuboid bone (p. 647), in effect forming a synovial joint.

Aponeuroses are sheets of white compacted collagen fibres attached directly or indirectly to skeletal muscles and distributing their contractile forces to fasciae, other muscles, cartilage or bone. They are frequently striated, their large fascicles separated by loose connective tissue, and when the fibres are thin and regularly parallel they may give a general iridescence to the aponeurosis in the fresh stage, since they diffract light like an optical grating. They usually have several layers, fasciculi being parallel within a layer but differently inclined in adjacent laminae. The term 'aponeurosis' was originally applied to any sheet of connective tissue spreading from ('apo-') the edge of a tendon ('neuron', a term once indiscriminately applied to tendons and nerves) and providing additional attachment, e.g. levator palpebrae superioris and the retinacula of the quadriceps extensor tendon. But the term has come to denote any sheet of dense connective tissue associated with muscle. Sometimes a whole attachment is aponeurotic, e.g. obliquus externus abdominis; elsewhere aponeuroses provide large auxiliary attachment areas for muscle fibres (e.g. supra- and infraspinous aponeuroses). Some major aponeuroses interlace at linear (sometimes multiple) *decussations* or *raphes* (see e.g. recent accounts of the ventrolateral abdominal aponeuroses pp. 600–603).

Fascia is a term so vague in usage that it signifies little more than collections of connective tissue large enough to be visible to the unaided eye. The advent of tissue fixatives, especially formalin, which preserve and accentuate areolar loose connective tissue, greatly encouraged regional naming of fasciae; the habit of attaching a local term to any such aggregation sizeable enough to dissect is still current, though perhaps diminishing. During development mesodermal cells differentiate into bone, muscle, vessels, renal and splenic tissue, etc.; but large numbers persist in connective tissues permeating all regions, not only as a loose microscopic component between, e.g. the fibres of muscle, nerve and tendon, but also in macroscopic accumulations between whole muscles and viscera. The arrangement of such connective tissue is highly variable. In dissection it appears as condensations on the surfaces of muscles, etc. and is here named *investing fascia*, although its function is by no means so simple. Between muscles which move extensively it takes the form of loose areolar connective tissue, facilitating movement. Peripheral nerves, blood and lymph vessels lie in loose 'fascia' between other structures, often bound together into *neurovascular bundles*. Sometimes large vessels, such as the common carotid and femoral arteries, have denser sheaths of connective tissue. Their precise functions are conjectural: they may aid venous return by approximating large veins to pulsating arteries but equally they may be generated primarily as tissue responses to the pulsatile forces created by neighbouring arteries.

Lipid may accumulate in cells of loose connective tissue, forming adipose tissue, which is often well-developed between muscles and skin. The dermis is composed of dense irregular connective tissue; deep to and continuous with it is a layer of loose connective tissue, often adipose and of variable thickness, the **superficial fascia**. It increases the mobility of skin and is a thermal insulator as well as a store of energy for metabolic use. Subcutaneous nerves, vessels and lymphatics travel in the superficial fascia, their main trunks lying in its deepest part where adipose tissue is scant. Superficial fascia also contains skin muscles, such as platysma, a remnant of more extensive sheets of skin-twitching musculature found in other mammals. The quantity and distribution of subcutaneous fat differs in the sexes. It is generally more abundant and widely distributed in females; in males it diminishes from trunk to the extremities, and this distribution is more obvious in middle age, when the total amount increases in both sexes. There is an association with climate (rather than race), superficial fat being more abundant in colder geographical regions. The superficial fascia is most distinct on the lower anterior abdominal wall, where it contains much elastic tissue and appears many layered as it passes through inguinal regions into the thighs. It is similarly differentiated in limbs and the perineum but is thinnest over the dorsal aspects of hands and feet, sides of neck and face, peri-anally, and over the penis and scrotum. It is almost absent from the external ears but is particularly dense in scalp, palms and soles, permeated in these regions by numerous strong connective tissue bands binding the superficial fascia and skin to underlying structures; these come under the general term, *deep fascia*, but are known regionally as aponeuroses of the scalp, palm and sole.

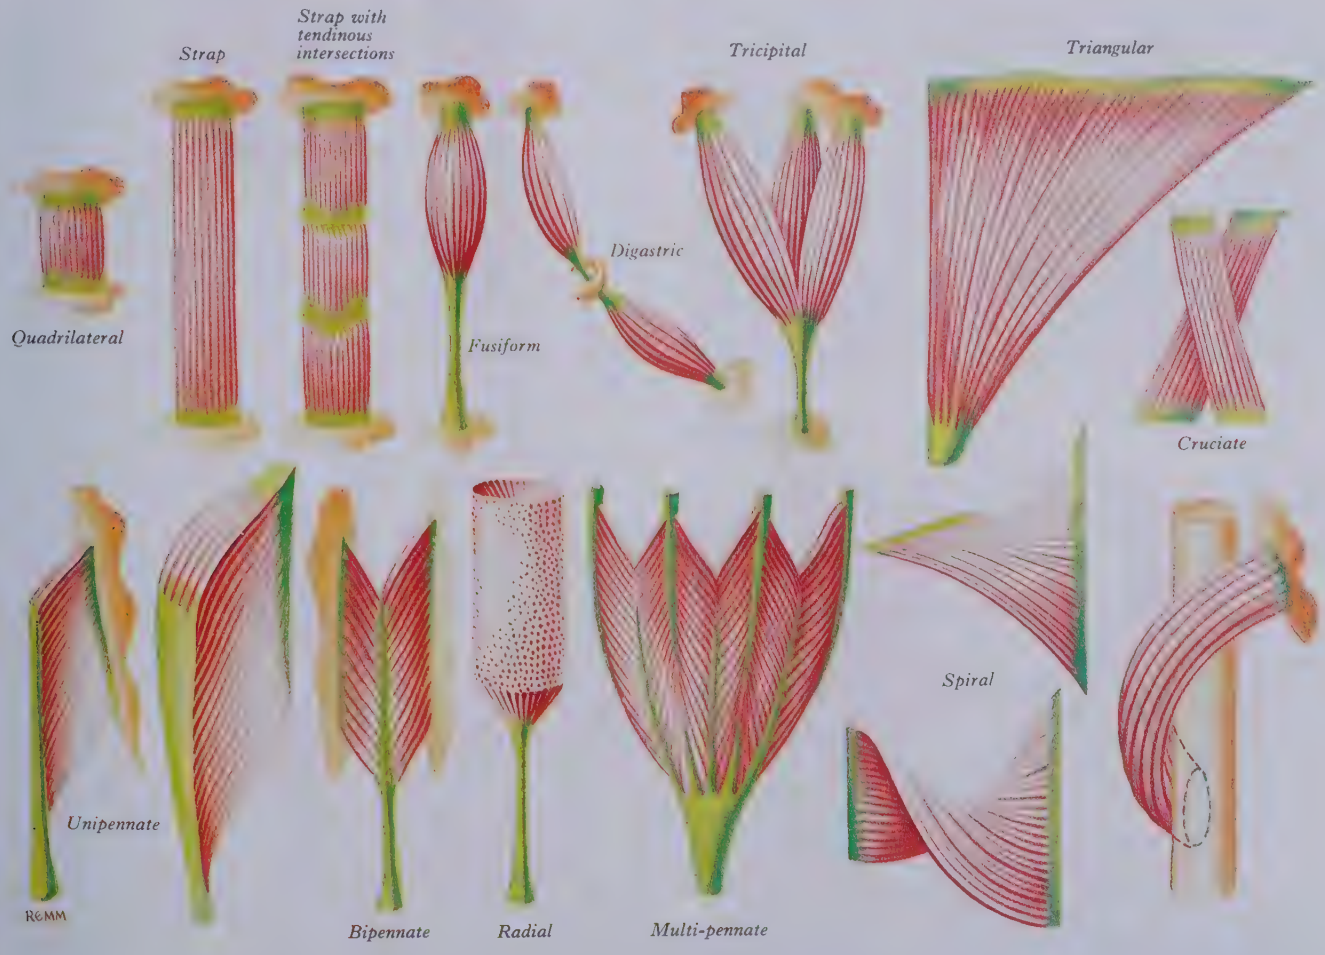
Deep fascia is also composed chiefly of collagenous fibres but these are compacted and often so regularly arranged that the deep fascia may be indistinguishable from aponeurotic tissue as, in the latter, parallel fibres in one layer are usually inclined to those in the next. In limbs, where deep fascia is well developed, their fibres are longitudinal or transverse, condensing into a tough, inelastic sheath around the musculature. In both upper and lower limbs, some muscles are attached to the internal aspects of deep fascia, which functions as an aponeurosis. Wherever deep fascia contacts the periosteal coverings of bone it fuses with it and thus transmits to bone the pull of its attached muscles. A powerful band of deep femoral fascia transmits the pull of tensor fasciae latae and most of gluteus maximus to the femur and tibia (p. 637), as the iliotibial tract. Biceps brachii is partly attached to deep forearm fascia; the palmar aponeurosis is the deep fascia of the palm, receiving the pull of a number of muscles (palmaris longus, when present, and in part the intrinsic muscles of pollex and minimus).

In the neck and limbs laminae of the deep fascia pass between groups of muscles and connect extensively with bone. Such *intermuscular septa* may incidentally separate muscles or groups with different actions, developmental histories and innervations. Except as phenomena of growth, however, most of these 'compartments' are of little except clinical significance. Septa often connect rather than separate muscles which may be attached to both aspects of what is in fact an *intermuscular aponeurosis*.

In some sites, near the wrist and ankle being prime examples, localized transverse thickenings of the deep fascia are attached at both of their ends to local osseous prominences. These are *retinacula*, so termed because they *retain* tendons deep to them from 'bowing' out of position during activity. In such

osseofibrous channels, tendons are deflected to work effectively, smooth action being aided by synovial sheaths. Similar tunnels of deep fascia and bone form fibrous sheaths in which digital flexor tendons of the hand and foot are retained, surrounded by synovial sheaths (pp. 618, 654).

In the lower limb particularly, deep fascia contributes to the efficiency of venous return, containing and compressing distended deeper veins, while regurgitation into superficial veins is largely prevented by numerous valves.



Form of Muscles

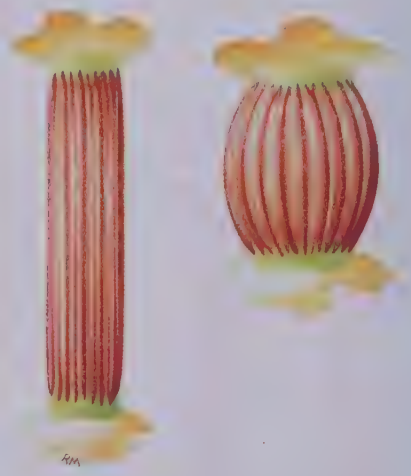
Muscles vary much in size, shape, fascicular architecture and form of attachment; each is adapted to provide a range, direction, velocity and force of contraction appropriate to the habitual needs at articulations on which it acts. Before such features are detailed in individual muscles, general properties must be considered, such as overall geometry, variation in number, size and direction of fibres relative to their line of traction and the aspects of muscle action which such structural variants serve.

Muscle fibres are not uniform in diameter, ranging from 10–60 μm, and they vary in length from a few millimetres to many centimetres (15–30 cm in sartorius). The statistical distribution of fibre diameters varies between whole muscles, or sometimes parts of a single muscle, as does their grouping into *fasciculi* by perimysial septa (p. 547). Visible texture reflects the proportions and distribution of connective tissue; muscles with fine fasciculi are often concerned in precision movement (e.g. extraocular muscles), whereas coarse fasciculation characterizes many larger limb muscles (e.g. gluteus maximus). But biomechanical significance, morphogenesis and vascular and innervation patterns in such *fascicular units (myonemes)* of muscles have been little studied. These must be distinguished from *motor units (myones)*, the basic neuromuscular functional units, which have a different spatial distribution (p. 556); their interrelations are currently under investigation.

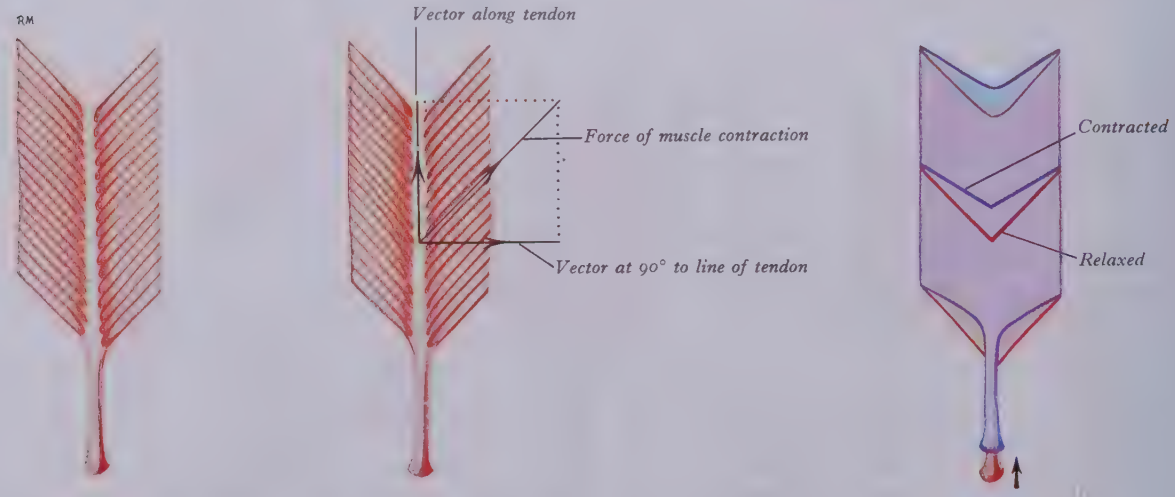
Muscles may be classified by fascicular orientation, which may be *parallel, oblique* or *spiral* relative to the muscle's direction of pull (5.16). Where fasciculi are largely parallel muscles vary from flat, short and *quadrilateral* (e.g. thyrohyoid) to long and *straplike* (e.g. sternohyoid, sartorius); individual fibres often traverse almost the whole muscle or shorter segments between transverse, *tendinous intersections* at intervals along the muscle (e.g. rectus abdominis). Fasciculi also approach the parallel in 'bellies' of *fusiform* muscles, which may be short, converging to a tendon, sometimes lengthy at one or both ends. Tendons concentrate the force of contraction to a small osseous area and may alter its direction of pull; the relative lengths of belly and tendon are closely related to the resultant *range* of contraction, often very limited, a tendon being then a device that causes relatively small excursions at some distance from the muscular attachment.

However, the maximal *force* generated by a muscle finally depends on its effective *mass* of contractile tissue, i.e. the number and dimensions of contained fibres, whereas the maximal *range* of unrestrained contraction depends on the *length* of its fibres. Where fasciculi are parallel to the line of traction, available force and range act at full advantage (5.17A). However, in strap muscles, fibres are relatively few in number but long, making them particularly effective where wide range is coupled with moderate power. Bellies of fusiform muscles may be slender or massive, long or short, with like variation in length and strength of the tendons, yielding various grades of power and range.

5.16 The morphological 'types' of muscle based upon their general form and fascicular architecture.



Where fasciculi are *oblique* to the line of traction (5.17B), muscles may be *triangular* (e.g. temporalis, adductor longus) or *pennate* (feather-like) in construction. The latter vary in complexity (see 5.16) from *unipennate* (flexor pollicis longus), *bipennate* (rectus femoris and dorsal interossei) to *multipennate* (deltoid). Similar general architecture also obtains in other muscles, e.g. in the main part of soleus, where fasciculi pass obliquely between deep and superficial aponeuroses, giving in sagittal section a kind of 'unipennate' form. In other sites muscle fibres start from walls of osteofascial compartments, converging obliquely to a central tendon in *circumpennate* form, e.g. tibialis anterior. (Unipennate and bipennate are unfortunate terms; feathers or *pennae* rarely if ever consist of a one-sided set of plumules attached to a midrib, like a 'unipennate' muscle. They are almost invariably 'bipennate'. More logical would be 'semipennate' and 'pennate'.) In all such forms, only part of the available force and range are effective along the tendon's axis. As shown in 5.17B, force generated by oblique fibres can be resolved into components, one along the tendon, one at 90° to this; the latter is largely counteracted in bi- or multipennate forms by opposed fibres but tends to deviate the tendon's line in unipennate muscles. Similarly, range is restricted and proportional to length of muscle fibre × cosine of its angle of attachment to tendon. Loss of efficiency in transmission of force to tendon is in natural use outweighed by the large numbers of short fibres in such muscles, which typically occur where limited range and considerable power are habitually required.



Some muscles are *spiralized* or 'twisted' in arrangement; the form and degree of spiralling varies with the particular muscular geometries, the state of contraction and posture adopted, e.g. the large triangular trapezius has a long, linear, *vertical*, median attachment and a *horizontal*, curved, lateral attachment, with a 90° twist between, in erect posture with arms pendent. Sternocostal fibres of pectoralis major and latissimus dorsi undergo a 180° twist between their median and lateral attachments. When such muscles contract they approximate their attachments but also tend to bring them into the same plane, undergoing some '*despiralization*' (5.20). Some muscles are spiralled around a bone, forming one attachment, e.g. supinator, which winds obliquely round the proximal radial shaft. Their contraction again reduces the spiral, imparting rotational force to a bone (vide infra). Allied to spiral muscles are those with two or more planes of fasciculi arranged in differing directions, sometimes termed *cruciate* (5.16); examples are sternocleidomastoid, masseter and adductor magnus, all partially spiral and cruciate. Many muscles exhibit regional variations in structure, compounded of more than one of the foregoing and adapted to several contrasting functional roles; in some actions one region only may be active, the remainder quiescent (p. 609).

Actions of Muscles

Analysis of sarcomeric construction and its relation to contraction has made rapid progress (p. 547). Muscle twitch, fusion of mechanical responses to repetitive stimulation, and functional neuromuscular territories or motor units (*myones*) have been discussed (pp. 556, 894). Isotonic and isometric contraction, varying relations between sarcomeric length and tension developed under isometric and other conditions have also been considered (p. 548). These are essential stages in understanding the biology of muscle; but the temporospatial dynamics of such events in a whole muscle, though difficult to analyse by experiment, provide greater range and flexibility of response than would first appear in such cellular analyses.

Repetitive, synchronous stimulation of all or most motor units does not occur in vivo; habitual demands are met by *asynchronous* contraction of a *proportion* of units available. During natural activities, at any instant, a muscle contains a mixture of motor units in quiescent, stimulated, contracting and relaxing states, the overall state being a *summation*. An ever-changing mosaic of active, relaxing and quiescent units thus occurs. During rotation of activities among available motor units the *active proportion* may increase, decrease or remain constant to meet functional demands. Whether a muscle lengthens, shortens or maintains its length and what tensions ensue depends on many factors,

5.17 Simple mechanical considerations related to the actions of (A) strap, and (B) bipennate muscles. (For details of the actions of these different muscle types consult text.)

including initial length, proportion of active motor units and rate of change of this, and the sum of various extrinsic and intrinsic forces to which it is subjected, partly through its attachments. This allows an infinite variety of quantitative responses in any muscle.

At one extreme, a muscle may be fully relaxed, when much electromyographic evidence shows no activity; the muscle is electrically silent (Joseph et al 1955, Joseph 1960). This contrasts with earlier accounts by electrophysiologists, who held that 'full relaxation' was still accompanied by 'background' activity rotating among a few units. Misconceptions concerning such 'muscle tonus' were based on these views. But even a fully relaxed muscle is a complex structure endowed with *passive viscous, elastic* and other properties providing some resistance to deformation (e.g. by stretching). During activity also, such properties of inactive motor units and connective tissues provide a basal resistance, to be overcome by active units before external forces can be opposed and work performed. Such passive attributes contribute greatly to the space–time–force muscular equation during initiation, increase and maintenance of activity and equally during its diminution and/or cessation.

When a muscle fibre or motor unit contracts, it can be considered as attempting to approximate its attachments; whether it does so depends on the force it generates (a function of its geometry, mass and initial average sarcomeric length) balanced against *extrinsic* and *intrinsic* forces transmitted through its connective tissues and opposing contraction. In an active muscle, therefore, the following alternatives are possible: its original length may be *maintained* (with slight fluctuations) and the tension generated may persist nearly unchanged or may increase or decrease, depending on external factors and number and state of active motor units; similarly, the muscle may *shorten*, with tension increasing, persisting or even decreasing with varying conditions; again, a muscle may *lengthen*, its tension decreasing, persisting or increasing with varying demands. Hence, in considering whole muscles it is naive to correlate 'contraction' merely with shortening or increase of tension and 'relaxation' with mere lengthening or decrease of tension. Many more subtle grades of combination are not only possible but are the foundation of the infinitely varied patterns of activity.

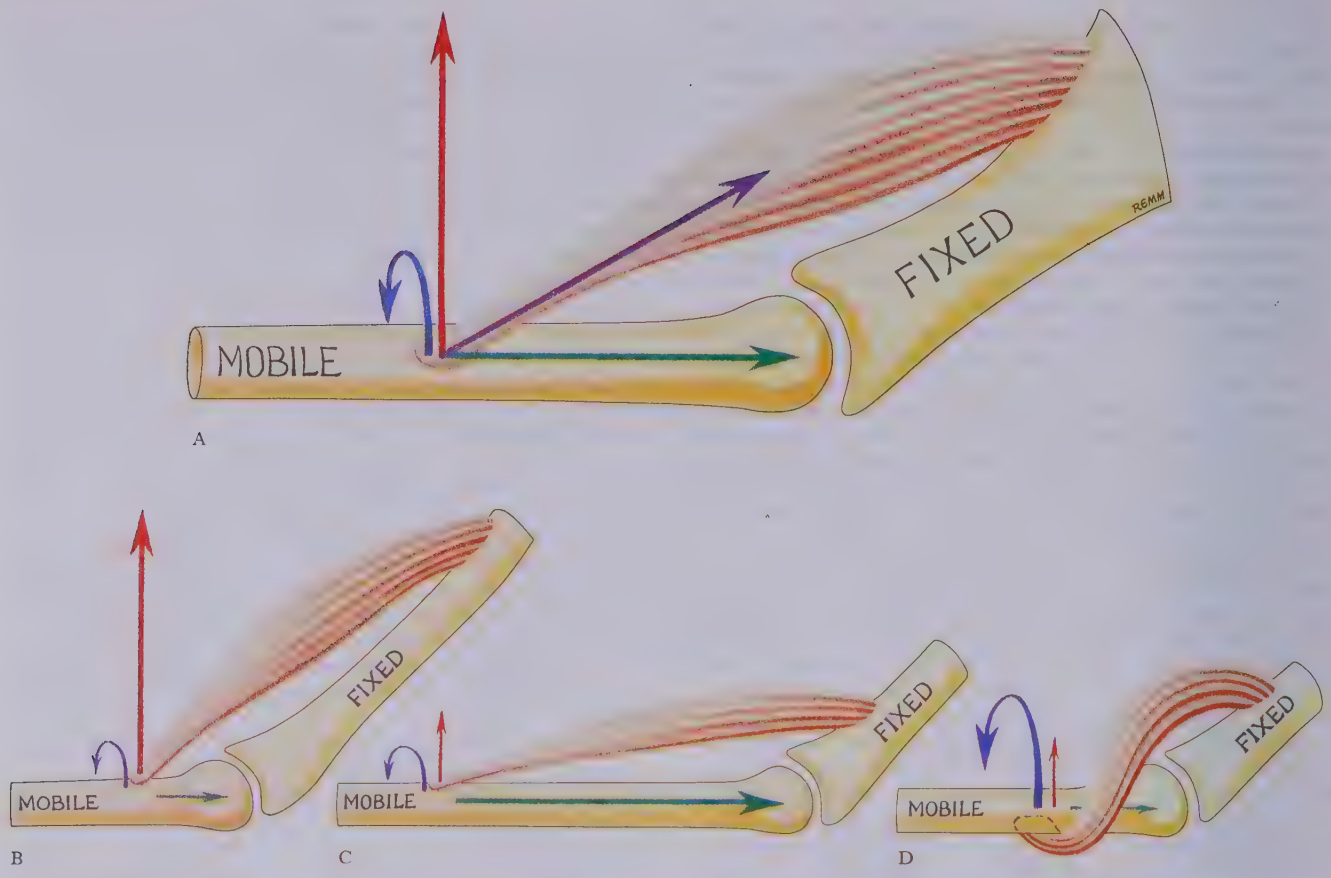
When a muscle contracts to initiate a movement, e.g. a limb muscle across a single joint, factors opposing its shortening are many, including: the passive mechanical properties of muscle mentioned above; similar properties of articular tissues, opposing musculature, and other soft tissues in the region; the contractile state of opposing musculature; the inertia of the part moved and its external load; and finally the effects of gravity on all the foregoing. Sufficient motor units must be activated to overcome these resistances and impart an angular acceleration to a limb segment until the required velocity is reached, beyond which sufficient units continue contracting to achieve the rest of the movement. (Termination of the movement is considered below.)

In natural use, movements at different joints are carried out by *orderly patterns of activity* in muscle groups, which may be classified according to their role.

Apart from movements assisted by gravity (vide infra), one or more muscles are constantly active in initiation and maintenance of any movement and they are its *prime movers* (e.g. brachialis in elbow flexion). Muscle or muscles which wholly oppose this, or initiate and maintain its converse, are *antagonists* (e.g. triceps in elbow flexion). However, views concerning such interrelations have been much revised. A long-held view was that contraction of prime movers to start a movement is accompanied by partial contraction of antagonists, smooth continuation depending upon progressive contraction of prime movers with simultaneous lengthening and 'relaxation' of antagonists, the latter finally increasing contraction to decelerate and end the movement. The neural connections presumed responsible for this co-ordination were incorporated as a *'principle of reciprocal innervation'*. But apart from the variable transient activity in antagonists at a movement's start, they remain electrically quiescent until final deceleration. The active prime movers are not unrestrained, being balanced against the *passive*, *inertial* and *gravitational* effects mentioned above, the last varying, of course, with altering relation of moving parts to the direction of gravity.

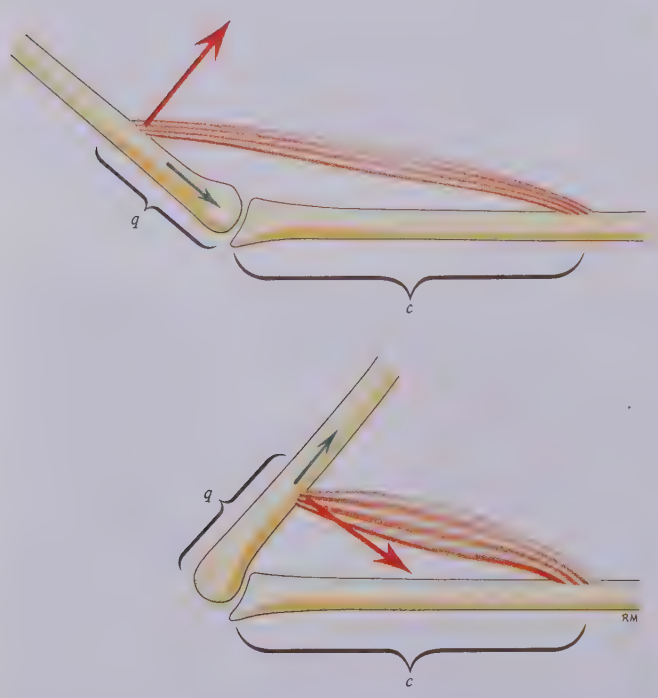
Sometimes prime movers and antagonists *contract together as fixators*, increasing *transarticular compression* (vide infra) which thus *stabilizes* a joint, often to make an immobile base for other prime movers to act. Sometimes stability can be achieved by gravity alone at a joint in or near its close-packed position (cf. knee and hip joints in erect posture, pp. 483, 613), or by prime movers balancing passive forces (cf. stabilization of glenohumeral joint by supraspinatus with a pendent arm, pp. 502, 612). Otherwise, and when powerful external forces are encountered, both groups contract, holding the joint in any required position.

It must be emphasized that all movements (except the theoretically possible but improbable case of a uniaxial joint acting precisely in a horizontal plane) are opposed or assisted by gravity, which profoundly influences the play of musculature in certain movements. Prime-mover activity is always replaced by gravity whenever appropriate, the roles of muscles then often being reversed. For example, the prime mover extending the forearm at the elbow is triceps (e.g. when thrusting). When a loaded hand is lowered, however, extension (by gravity) is controlled by *active lengthening* of *flexors*; similarly, *increasing the length* and *force* of contraction in extensors of the hip, controls flexion of the trunk at hip joints. (Such considerations apply to numerous commonplace activities. Thus the names given to many individual muscles or muscle groups are oversimplifications. They emphasize only one of a number of habitual actions; the functional roles implied by many names are incomplete and should be extrapolated with caution.)



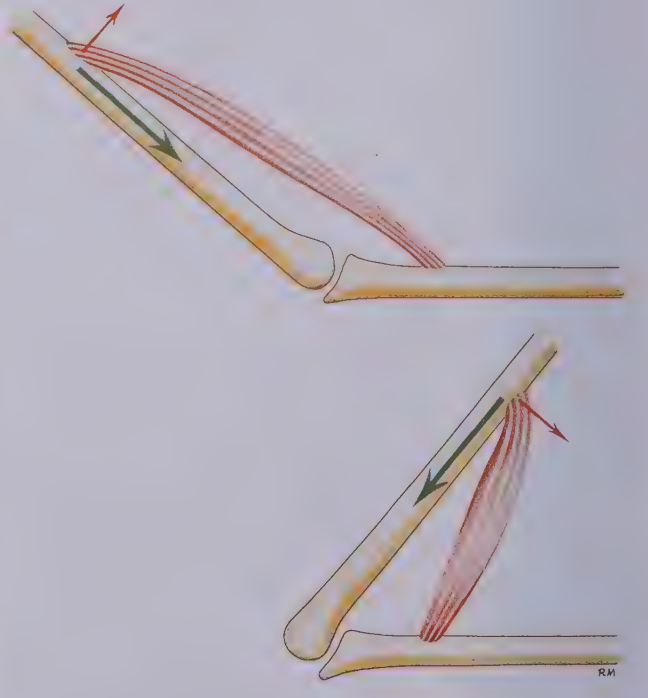
In some cases contraction of a prime mover, across a *uniaxial* joint, produces a simple movement; but at *multiaxial* joints or when muscles cross more than one joint, prime movers may produce additional movements, elimination of which is effected by contraction of *synergic* muscles, often partial antagonists of the prime mover. For example, prime flexors of the fingers at interphalangeal and metacarpophalangeal joints are the long flexors, superficial and deep; but these also cross intercarpal and radiocarpal joints and, unrestrained, they also flex these, with loss of efficiency. But simultaneous synergic contraction of the carpal extensors eliminates this, often producing some carpal extension and increasing efficiency of digital *flexion*. Electromyography shows that movements, wherever feasible, are effected without energy-consuming dependence on synergists; but most complex movements result from graded interplay between external forces, including gravity, inertia, the passive properties of various tissues and integrated patterns of tension–length variations in prime movers, antagonists, synergists and fixators. These patterns and positions of joints are constantly surveyed via receptors in various connective, periarticular and muscular tissues and thus linked to integration and control at all levels in the central nervous system.

Kinesiology



In recent decades interesting concepts and a terminology have emerged from kinesiological studies of articulo-muscular mechanics (MacConaill & Basmajian 1977). These are considered briefly here; for comprehensive treatment, the references quoted should be consulted.

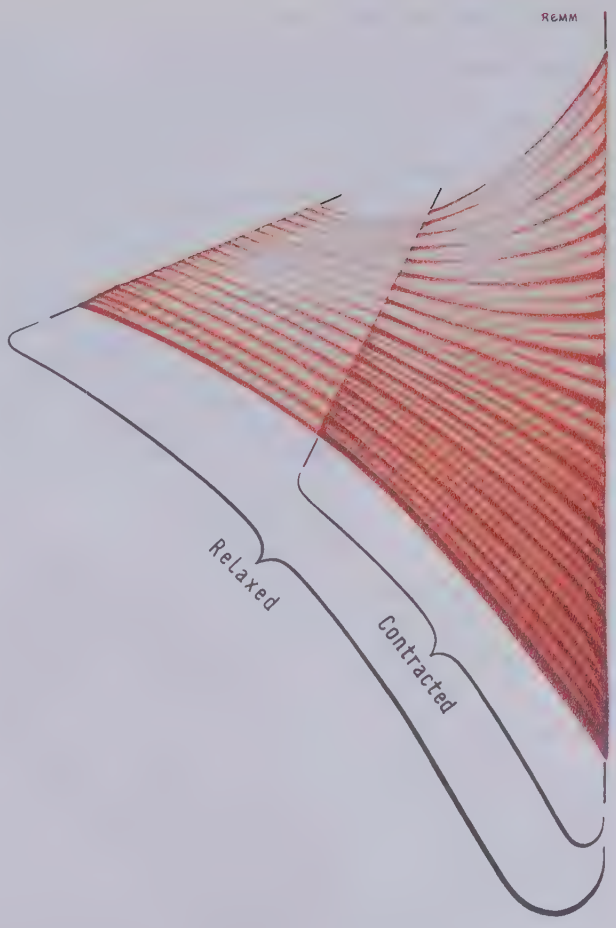
Illustration 5.18A shows two articulating bones, one considered mobile and one fixed. A muscle attached eccentrically to the mobile bone contracts, exerting a force along the line of its tendon which is, relative to the mobile bone, vectorially resolvable into three components: (1) *transaxial*, at right angles to the bone, tending to change angulation at the joint (i.e. *swing or spurt component*); (2) *paraxial*, acting along the shaft towards the joint, tending to compress articular surfaces (i.e. *transarticular* or *shunt component*); and (3) *tangential*, acting around the bone's long axis, tending to rotate it about this axis (i.e. *spin component*). The terms *spurt* and *shunt* may be unfamiliar, although they were used by nineteenth-century British engineers (MacConaill 1949).



Actual movement will depend upon constraints due to articular shape, ligaments, adjacent musculature and extrinsic and intrinsic forces opposing it. Nevertheless, each component has its functional import, enhanced in some muscles, suppressed in others

5.18 A. Vectorial analysis of the *force* of contraction generated by a muscle which is attached to a fixed base, crosses a single multi-axial joint and is attached eccentrically to the shaft of a mobile bone. Colour code of arrows: purple = muscle force; red = transaxial 'swing' vector; green = paraxial 'shunt' vector; blue = tangential 'spin' vector. Similar analyses relating to muscles which are *predominantly* (B) 'spurt', (C) 'shunt' and (D) 'spin' in their actions. It should be appreciated that these diagrams have been constructed to illustrate certain principles discussed in the text; they do *not* represent any specific human bone or muscle. It is also clear that (in B and C), if the fixity and mobility of the two bones were interchanged, B would now operate as a 'shunt' muscle and C as a 'spurt' muscle.

5.19A Some features of a 'spurt' muscle. Note that it has a large 'swing' component of its force which acts to impart an angular acceleration to the mobile bone. Its small 'shunt' component acts towards the joint up to 90° of flexion and thereafter away from the joint. c = cisarticular length; q = transarticular length.



5.19B Some features of a 'shunt' muscle. The large shunt component of its force acts towards the joint in all positions. In Fig. 5.19A and B no specific human muscle or bone is intended; in each case it is clear that the right bone is regarded as fixed whilst the left bone is mobile. Clearly their mobilities (and designations) could be interchanged.

(5.18B,C,D). For example, when a muscle is markedly eccentric in attachment to or even spirals around the mobile bone, it has a spin component; e.g. the transversely wrapped pronator quadratus is an almost pure spin muscle, while the longer, oblique pronator teres has spin, transarticular and swing components. In contrast, femoral flexors exert a powerful swing force (flexion) on knee and a weaker spin (rotation) on the semiflexed leg. Spin components may be used as prime movers, e.g. in pronation/supination of forearm, medial/lateral rotation at hip, etc.; or they may be used synergically to counteract another spin force, ensuring pure swing (*antispin*, p. 480).

Ignoring spin components, relative values of transarticular and swing components vary with distances of fixed and mobile attachments from a joint (5.19), termed *cisarticular (c)* and *transarticular (q) lengths* respectively, c/q denoting the *partition ratio (p)*. When the fixed attachment is more distant from a joint (5.19A), i.e. $p > 1$, there is a powerful swing (spurt) component and a small transarticular (shunt) component; such a muscle is termed a *spurt* muscle (formed by *spurt myonemes*). A typical example is brachialis brachii acting at the elbow joint from a fixed humerus. Such muscles, acting alone, are most effective in initiating and continuing slow movements of swing, whether weak or powerful, and in postural readjustments demanding graded changes of tension and length. The shunt component is often sufficient to maintain articular contact; but when angulation exceeds 90° the component of force along the bone is directed away from the joint.

In contrast, a *shunt* muscle (of *shunt myonemes*) acting from a fixed base near a joint and with a more distant mobile attachment, i.e. $p < 1$, shows a large persistent (shunt) vector along the bone towards the joint in all positions but only a trivial swing component (5.19B); an example is brachioradialis acting at the elbow joint from a fixed humerus. Shunt myonemes or muscles are necessary wherever other factors act to separate articular surfaces, which may be due to loading, e.g. of a pendent arm. But it is suggested that during *rapid* swings centrifugal force tending to separate joint surfaces is too great for spurt musculature alone, which may be assisted synergically by shunt muscles exerting a centripetal force towards the articulation. Generation of either force would be independent of direction of swing; shunt activity of brachioradialis has been shown electromyographically in both rapid flexion *and* extension of forearm (vide infra). In this brief analysis one attachment is regarded as fixed (i.e. functional 'origin'), the other ('insertion') attached to a mobile unit. Relative fixity and mobility of attachments are often reversed in natural use and a spurt myoneme would then operate as a shunt. Moreover, both attachments may be in motion. For these and other reasons the terms *origin* and *insertion* have been here abandoned in descriptions of individual muscles, the general term *attachment* being preferred. (For other vocational purposes, however, see the comments on colour coding for muscle attachments in Osteology, p. 325.)

Since its first proposal, refinement and mathematical development (MacConaill & Basmajian 1977, MacConaill 1978a,b,c), the anatomicokinetic classification of myonemes and whole muscles into spurt and shunt types has prompted much discussion and some adverse criticism (Stern 1971, Rozendal & Molen 1972, Joseph 1973, Jackson et al 1977, Stanier 1977). However, MacConaill has strongly argued the validity of his *classification* but has withdrawn some *hypotheses* based upon it. In an attempt to provide a 'generalized mechanics of articular swing' the interesting proposal has been made, that centripetal force acting along a bone moving at *any* speed is a *consequence* of its curvilinear motion, not a *cause* of it.

5.20 The 'detorsion' or untwisting which follows the contraction of a spirally disposed muscle.

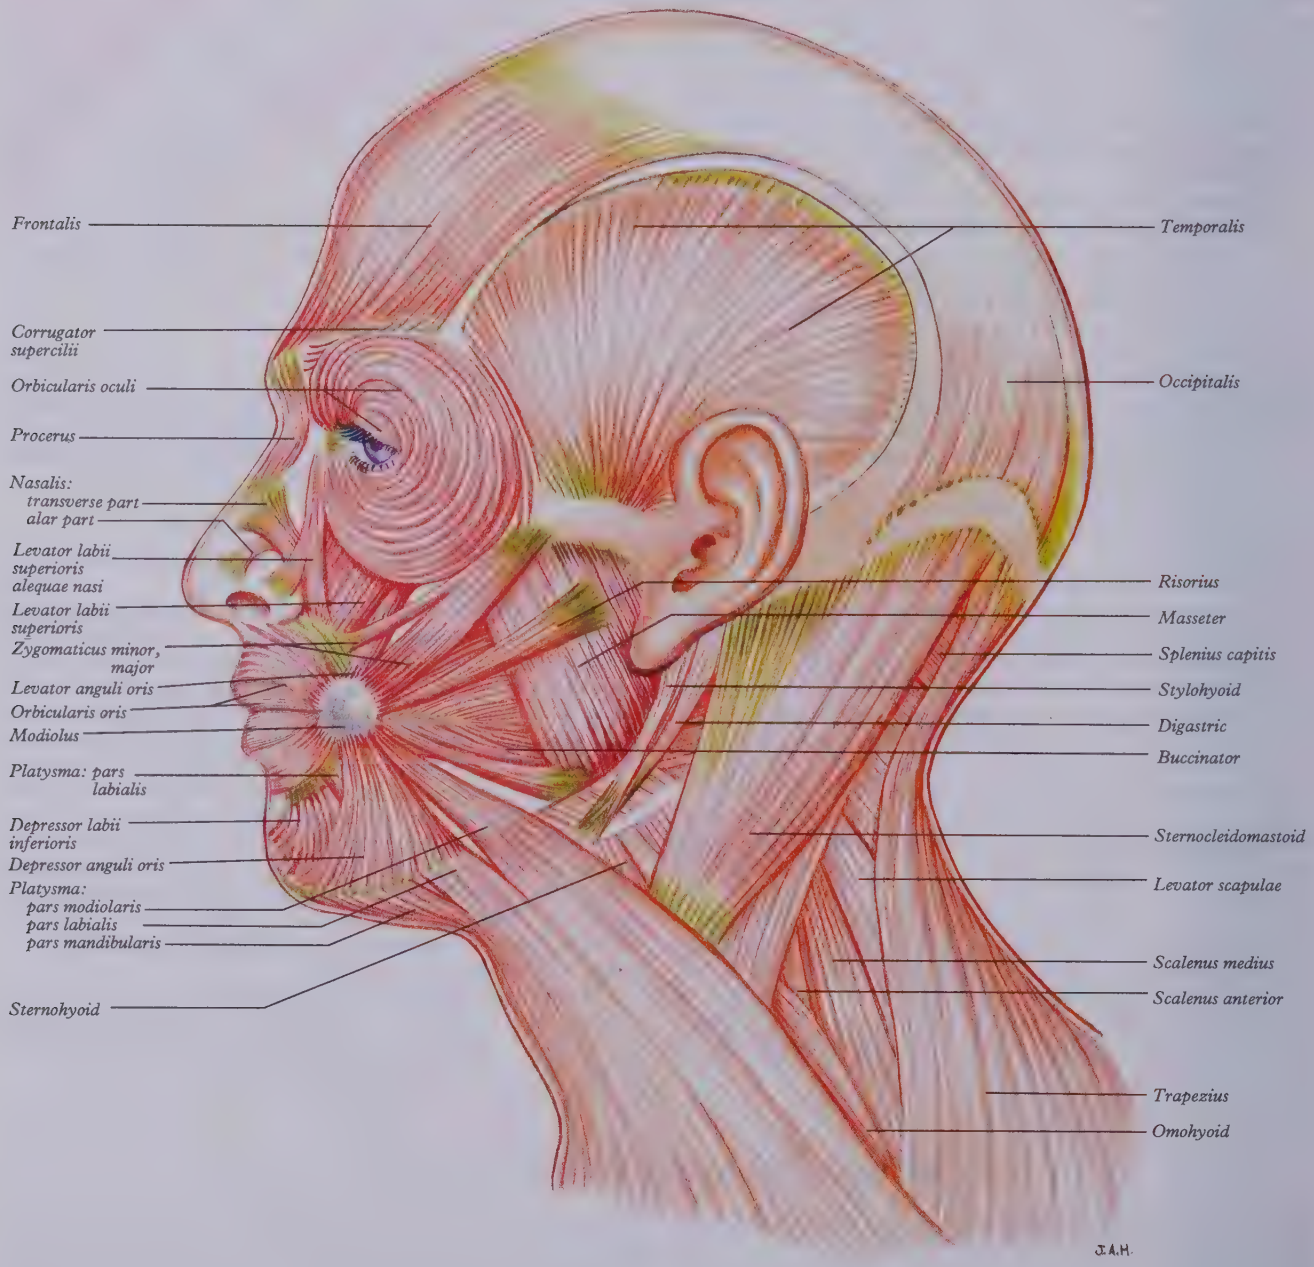
Another absorbing problem currently concerning thoretical and experimental kinesiologists is analysis of *patterns* of sequential muscle contractions occurring when two or more muscles can produce the same movement (Joseph 1973, Jackson et al 1977). The latter contend that a 'primary' muscle always initiates movement and that 'secondary' muscles are recruited only when a critical level of activity is reached in the primary, as applied to both isotonic and isometric contraction. Variations in force and velocity as determinants of sequential patterning are emphasized. However, values of parameters which constitute in combination a critical level of 'activity' have not yet been adequately determined. Few observers have discussed the phenomenon of *increasing length* accompanied by *increasing tension* in a myoneme or whole muscle, a combination commonplace in habitual movements and clearly not 'relaxation'.

These recent considerations of activities of myonemes, muscles and groups of muscles render much customary myological nomenclature redundant, often inaccurate and misleading.

FASCIAE AND MUSCLES OF THE HEAD

Muscles of the head are customarily divided into *facial muscles*, related to orbital margins and eyelids, external nose, lips, cheeks and mouth, pinna, scalp and cervical skin (all often grouped as 'muscles of facial expression') and *masticatory muscles*, primarily concerned with temporomandibular movements. This division reflects different embryonic origins and innervations; but in most activities, such as mastication, deglutition, vocalization, communicative and emotional expression, respiration, ocular, aural and nasal actions the two groups are interdependent.

The other muscle groups of the head are described elsewhere: these include *ocular* and *extraocular muscles* (pp. 1193, 1188, 1207), *auricular* and *tympanic muscles* (pp. 1220, 1227), *lingual, palatal* and *upper pharyngeal muscles* (pp. 1320, 1289, 1326).



Craniofacial Muscles

These muscles all receive their innervation from branches of the facial nerve. Those described here are grouped (topographically and functionally) as epicranial, circumorbital and palpebral, nasal and buccolabial. With the same innervation but described elsewhere are platysma (p. 583), posterior belly of digastric and stylohyoid (p. 584) and stapedius (p. 1227). Most muscles clearly belong to one of the major groups named above; others, however, cross the boundaries between groups and functionally may affect both; their allocation to one of these groups alone is arbitrary. Variation between individuals is common and some pronounced racial differences are recognized. Furthermore, investigators specializing in craniofacial myology often use different criteria for categorizing parts of a muscle (often multiple 'heads' of attachment) or of groups of muscles; in parallel, over the decades, the associated nomenclature has changed. The latter, sometimes imprecisely defined, compounded in some locations by insufficient data, adds to the difficulty of making comparisons between different accounts. What follows is a brief account of widely accepted features; for further details of this highly complex structural and functional region consult the references with bibliographies quoted below; see also 'anatomy of speech' p. 1257. For a general survey see 5.21.

(A) EPICRANIAL MUSCULATURE

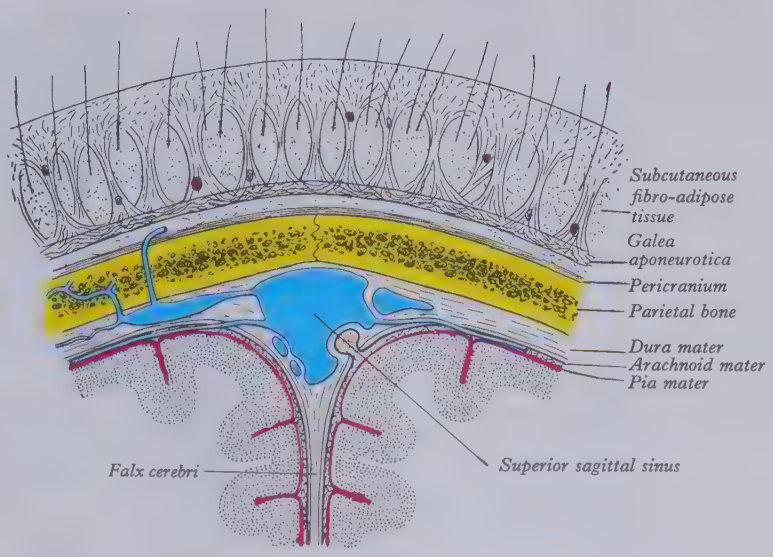
Epicranius consists of M. occipitofrontalis and M. temporoparietalis. The **superficial fascia** in the scalp is firm, dense, fibro-adipose and closely adherent both to skin and the underlying epicranius including its *epicranial aponeurosis* (galea aponeurotica); posteriorly it is continuous with the superficial fascia of the neck. Laterally, looser in texture, it is prolonged into the temporal regions.

Occipitofrontalis, a broad, musculofibrous layer, covers the cranial vault from the highest nuchal lines to the eyebrows. It has

5.21 Muscles of the head and neck (superficial lateral view) including these groups: circumorbital, buccolabial, nasal, epicranial, masticatory and cervical. The auricular muscles are omitted. Risorius, a variable muscle, here has two fasciculi; the lower is unlabelled. The nature of the modiolus, the modiolar muscles and their co-operation in labial control is detailed in the text. The direct labial tractors to both upper and lower lips have been transected, showing their coronal laminae and revealing subjacent orbicularis oris.

two occipital and two frontal muscular parts, connected by a fibrous aponeurosis. Each *occipitalis*, thin and quadrilateral, is attached by tendinous fibres to the lateral two-thirds of the highest nuchal line and mastoid temporal bone. It ends in the aponeurosis. Each *frontalis* (5.21), also thin and quadrilateral, is adherent to overlying superficial fascia, particularly of the eyebrows, but it is broader and its fibres longer and paler than occipitalis. It has no direct bony attachment but its medial fibres are continuous with procerus, the intermediate blending with corrugator supercilii and orbicularis oculi, the lateral also blending with orbicularis over the zygomatic process of the frontal bone. All fibres ascend to join the epicranial aponeurosis anterior to the coronal suture. The medial margins of these frontal bellies blend above the nasal root, the occipital bellies being separated by a variable interval occupied by the aponeurosis.

The temporoparietalis is a variably developed muscular sheet between frontalis and the anterior and superior auricular muscles.



The epicranial aponeurosis covers the cranial vault, forming with the epicranial muscle a continuous fibromuscular sheet from occiput to eyebrows. Posteriorly, between the occipital parts of occipitofrontalis, it is attached to the external occipital protuberance and highest nuchal lines; anteriorly it encloses the frontales, with a narrow prolongation between them. On each side the anterior and superior auricular muscles are attached to it; here it is thinner and continued over temporal fascia to the zygomatic arches. Over the cranial vault, the aponeurosis is intimately united to the skin by fibrous superficial fascia but it is loosely connected to the pericranium by areolar tissue and hence moves with the skin of the scalp (5.22). Subdivision of this subaponeurotic tissue into three layers has been described (Chayen & Nathan 1974), the intermediate being dense and like the aponeurosis in its attachments.

Nerve supply. Occipitals is supplied by the posterior auricular branch, the frontalis by temporal branches of the facial nerve.

Actions. The occipitales retract the scalp; during contraction the frontales raise the eyebrows and nasal skin; simultaneously they protract the scalp, thus progressively creasing the forehead (at five to ten major transverse 'lines' and variable intermediate minor ones). Although loosely termed 'transverse' these lines form a series of roughly concentric arches above the orbits and parallel to the superior orbital margins, i.e. convex upwards. The medial ends of many of the arches are continuous across a median strip about 2 cm wide but here the curvature is reversed, i.e. convex downwards. The two parts of the muscle, acting alternately, move the entire scalp back and forwards. The frontales elevate the eyebrows commonly in glancing upwards, also in expressions of surprise, horror, fright, etc.

A thin slip, *transversus nuchae*, occurs in about 25% of people, extending from the external occipital protuberance or superior nuchal line, passing superficial or deep to trapezius, usually to fuse with auricularis posterior but it is sometimes blended with sternocleidomastoid.

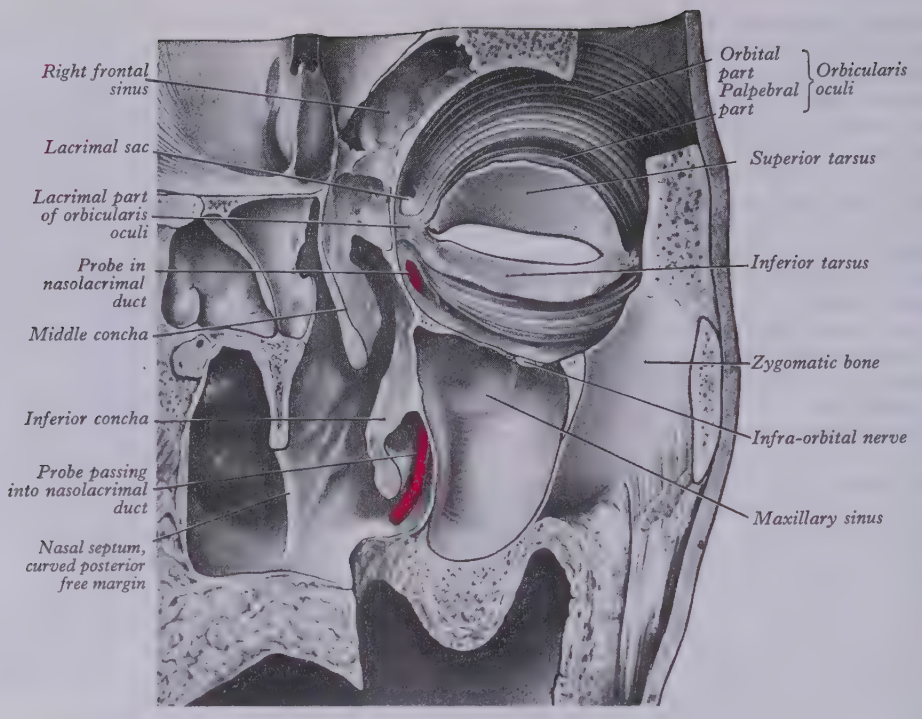
Applied Anatomy. The scalp has five layers: skin, subcutaneous tissue, epicranius and its aponeurosis, subaponeurotic areolar tissue and pericranium (5.22). The first three form a unit; when torn off in accidents, they remain firmly connected. Due to the density of subcutaneous tissue, inflammatory swelling is slight; wounds which do not involve epicranius or its aponeurosis do not gape. Contraction and retraction of arteries is impeded by this dense tissue and haemorrhage from scalp wounds is often copious. Subaponeurotic areolar tissue is surgically important; it is through this that avulsion occurs and surgical exposures are made. Vessels remain in the partly avulsed tissue and anastomose freely; hence necrosis is unusual.

5.22 Coronal section through the scalp, skull and brain. Note: loculated fat between fibrous septa blending with dermis and galea; loose subaponeurotic areolar tissue; emissary, diploic, dural and neuropial veins. The superior sagittal sinus and lateral lacunae are more complex than depicted, see p. 800.

(B) CIRCUMORBITAL AND PALPEBRAL MUSCULATURE

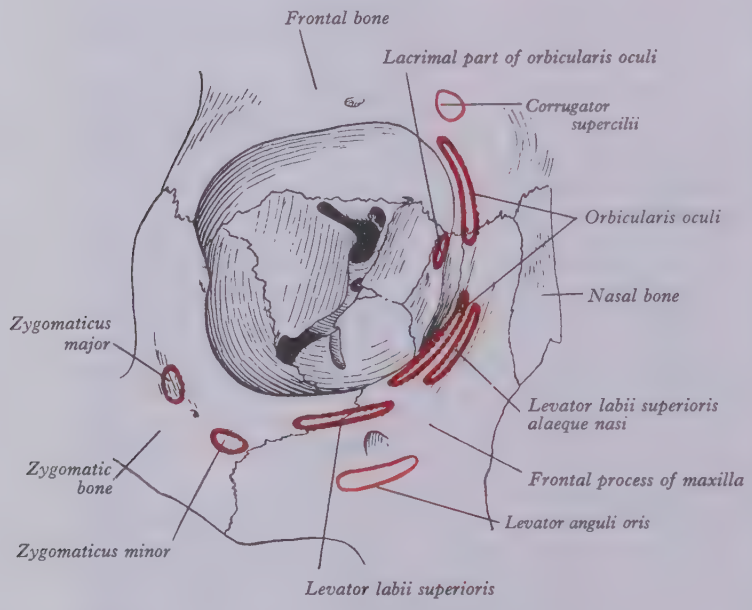
Of the muscles in this group, orbicularis oculi, corrugator supercilii and levator palpebrae superioris, the last is described with the ocular adnexa (p. 1207).

Orbicularis oculi (5.21,23) is a broad, flat, elliptical muscle invading the eyelids, surrounding the orbital opening and spreading into the anterior temporal region, the infraorbital cheek and the superciliary region. It has orbital, palpebral and lacrimal parts.



The *orbital* part, reddish and thicker than the palpebral fasciculi, is attached to the nasal part of the frontal bone, the frontal process of the maxilla (5.24) and to the medial palpebral ligament between them. Its fibres form ellipses, complete laterally, where there is no bony attachment, their upper parts blending with frontalis and corrugator supercilii and many reaching skin and subcutaneous superciliary tissue, forming a **depressor supercilii**. Inferiorly, the ellipses overlap or partially blend with the attachments of levator labii superioris alequae nasi, levator labii superioris and zygomaticus minor; medially some ellipses may reach the upper lateral fibres of procerus. Most laterally and peripherally sectors of complete (but sometimes parts of incomplete) ellipses have a loose areolar connection with the temporal extension of the epicranial aponeurosis. (The inferomedial margins of the orbital part may be continuous with the variable musculus malaris, vide infra.)

The *palpebral* part, thin and pale, starts from the medial palpebral ligament, chiefly its superficial but also its deep surface, though not its lower margin; it is attached to bone above and below the ligament and its fibres sweep across the eyelids anterior to the orbital septum (p. 1215) interlacing at the lateral commissure as a *lateral palpebral raphe*. A slip of fine fibres, near the margin of each eyelid behind the lashes, is the *ciliary bundle*.



The *lacrimal* part is behind the lacrimal sac, separated from it by lacrimal fascia; it is attached to this fascia, to the upper part of the lacrimal crest and adjacent lateral surface of the lacrimal bone (5.24). Passing laterally behind the sac it divides into upper and lower slips, whose fibres are partly attached to the tarsi near the lacrimal canaliculi, most fibres continuing anterior to them to the lateral palpebral raphe.

The *medial palpebral ligament*, about 4 mm long and 2 mm broad, is attached to the frontal process of the maxilla, anterior to the nasolacrimal groove. Crossing the lacrimal sac, separated by lacrimal fascia, it divides to be attached to the medial ends of both tarsi. The *lateral palpebral raphe*, a weaker structure, consists of the interlacing lateral palpebral fibres of orbicularis oculi, strengthened by the orbital septum. A few lobules of the lacrimal gland, but more often of fat, may separate it posteriorly from the lateral palpebral ligament.

Nerve supply: temporal and zygomatic branches of the facial nerve.

5.23 Dissection to expose the right orbicularis oculi from behind.

5.24 Attachments of muscles around the right orbital opening.

Actions. Orbicularis oculi is the palpebral sphincter. The palpebral part, voluntarily or by reflex, closes the lids gently in sleep or rapidly in blinking; the orbital part is usually voluntary in action. Although the major factor in closure is lowering the upper lid, there is some elevation of the lower. The palpebral muscle has upper *depressor* and lower *elevator* fascicles. When the entire muscle contracts, the frontal, temporal and malar skin is drawn towards the *medial* orbital angle; the lids are firmly closed and displaced medially in toto; in this activity skin folds are formed, radiating from the lateral palpebral angle; in the middle decades these wrinkles often become permanent. Levator palpebrae superioris opposes the superior palpebral depressor fibres. The lacrimal part also draws the lids and lacrimal papillae medially, also pulling on the lacrimal fascia and perhaps dilating the sac (p. 1219) to aid drainage of tears. It is said to influence pressures in the lacrimal gland, ducts and orifices and may affect the sinuous flow of tears across the cornea; it may also direct the puncta lacrimalia into the lacus lacrimalis and express secretions of ciliary and tarsal glands. The orbicularis oculi is also involved in facial expression and various ocular reflexes. Narrowing the palpebral fissure with protrusion of the eyebrows reduces the entry of light; the upper orbital fibres may thus cause largely vertical furrows above the nose (vide infra), a feature markedly developed in people much exposed to strong sunlight.

The corrugator supercilii, a small paired pyramidal muscle at the medial end of each eyebrow, is deep to frontalis and orbicularis oculi. Attached to bone at the medial end of the superciliary arch it ascends laterally, interlacing and blending with the foregoing muscles, thus exerting traction on the skin above the midpart of the supra-orbital margin.

Nerve supply: temporal branches of the facial nerve.

Actions. The muscle draws the eyebrow medially and down, producing, with orbicularis oculi, mainly *vertical* wrinkles on the supranasal strip of the forehead. (Commonly most prominent are a bilateral pair of major vertical wrinkles of variable length, 2–4 cm, above eyebrow level and about 1 cm apart; however, their lower ends curve laterally around or through the medial end of the eyebrows. Lesser vertical wrinkles occur in variable numbers, mainly lateral to the major ones.) The corrugator assists in shielding the eye in bright sunlight. It is also involved in frowning.

(C) THE NASAL MUSCULATURE

This group comprises Mm. procerus, nasalis and depressor septi (5.21).

Procerus is a small pyramidal slip near and often partially blended with the medial side of frontalis. From a fascial aponeurosis covering the lower part of its nasal bone and adjoining lateral nasal cartilage it passes to the skin of the lower forehead between the eyebrows. Normally its lower aponeurosis blends with that of nasalis transversus; occasionally, however, a few muscular fascicles of procerus continue to the nasal ala, some even reaching the upper lip.

Actions. It depresses the medial end of the eyebrow, producing transverse wrinkles over the nasal bridge and root. Active in frowning and 'concentration', it aids in reducing the glare of bright sunlight.

Nasalis has transverse and alar parts, sometimes continuous. The *transverse part, compressor naris*, is attached to the maxilla,

lateral to its nasal notch, and proceeds superomedially to a thin, expanded aponeurosis, continuous with its fellow across the dorsum nasi and also blends with the aponeurosis of procerus. The *alar part, dilatator naris*, attached to the maxilla, inferomedial to and partly blended with the compressor, passes to the cartilaginous ala nasi. (However, see also depressor septi, below.)

Actions. The transverse part compresses the nasal aperture at the junction of the vestibule and nasal cavity; the alar part depresses the ala laterally, widening the anterior nasal aperture, visibly in deep inspiration, and thus is associated both with exertion and emotional states.

Depressor septi (often described as part of dilatator naris) is attached to the maxilla above the central incisor; it ascends to the mobile part of the nasal septum, deep to the superior labial mucous membrane.

Actions. It assists the alar part of nasalis in widening the nasal aperture.

Nerve supply. All muscles of this group are supplied by superior buccal branches of the facial nerve.

(D) THE BUCCOLABIAL MUSCULATURE

The buccal orifice and labial postures are controlled by an intricate three-dimensional complex of muscular slips (5.21), including: the *elevators, retractors* and *evertors* of the upper lip and buccal angle (levator labii superioris alaeque nasi, levator labii superioris, zygomaticus major and minor, levator anguli oris and risorius); the *depressors, retractors* and *evertors* of the lower lip and buccal angle (depressor labii inferioris, depressor anguli oris and mentalis); antagonists of the foregoing, a complicated *sphincter* (orbicularis oris with its subregions, incisivus superior and inferior) and buccinator. Some labial fascicles are clearly intrinsic, others extrinsic; a large proportion are, however, so closely interwoven, or even continuous, that their satisfactory investigation and terminological allocation have proved difficult, sometimes controversial and, in some locations, as yet impossible.

Levator labii superioris alaeque nasi is attached to the upper part of the frontal process of the maxilla, then descends inferolaterally, dividing into a medial slip attached to the greater alar cartilage and the skin over it and a lateral slip prolonged inferolaterally to blend with levator labii superioris and orbicularis oris. The superficial fibres of the lateral slip curve laterally across the ventral aspect of levator labii superioris and attach successively to the dermal floor of the upper part of the nasolabial furrow and ridge.

Actions. The lateral slip raises and everts the upper lip and raises, deepens and increases the curvature of the nasolabial furrow's superior part; the medial slip dilates the nostril and displaces laterally and modifies the curvature of the inferolaterally convex *circumalar furrow*.

Levator labii superioris descends from the inferior orbital margin, being attached to the maxilla and zygomatic bone above the infra-orbital foramen, and converges into the upper lip between the lateral slip of levator labii superioris alaeque nasi and zygomaticus minor with, more deeply, levator anguli oris.

Actions. It elevates and everts the upper lip. Its contraction indirectly modifies the variably prominent, but permanent *nasolabial furrow* (*groove* or *sulcus*), often deepened in sad or serious expressions. The furrow descends laterally from the lateral nasal margin at the upper limit of the ala, to become indistinct, in an adult, about 1.25 cm lateral to the labial commissure (buccal angle), over the *modiolus* (vide infra). In some faces the furrow is a highly characteristic feature. The furrow's prominent superolateral rim, the *nasolabial ridge*, delimits the *infra-orbital cheek*; its flatter, more deeply placed inferomedial rim bounds *the superior labial area*. The disposition of the furrow varies with the position of the modiolus and posture of the lips and nasal ala. These indirect influences are supplemented directly by the state of contraction of levator labii superioris alaeque nasi (lateral slip), zygomaticus minor, levator anguli oris and, when present, malaris. In the nasolabial ridge the buccal panniculus adiposus is maximally thick; in the labial area the panniculus is extremely thin, often virtually absent.

Zygomaticus minor, attached to the zygomatic bone behind the zygomaticomaxillary suture, descends medially into the upper lip; it is separated superiorly from levator labii superioris by a narrow triangular interval (5.21) but inferiorly blends with this muscle.

Actions. It elevates the upper lip exposing maxillary teeth and, as mentioned, assists in deepening and elevating the nasolabial furrow. With the other main elevators it curls the upper lip in smiling and in smugness, contempt or disdain.

(Some earlier investigators regarded the foregoing three muscles as individual 'heads', named respectively angularis, infra-orbitalis and zygomaticus, of one compound *musculus quadratus labii superioris*.) For further discussion of corporate activities see below.

Levator anguli oris (*caninus*) is attached to the canine fossa below the infra-orbital foramen, whence it converges and mingles near the buccal angle (at the modiolus, vide infra) with zygomaticus major, depressor anguli oris and other muscular bands including orbicularis oris. Between it and levator labii superioris are the infra-orbital vessels and nervous plexus (5.26). Some of the levator's superficial fibres have curved directly anteriorly to gain a dermal attachment to the floor of the lower part of the nasolabial furrow.

Actions. It raises the modiolus and buccal angle, incidentally displaying the teeth in smiling, and contributes to the depth and contour of the nasolabial furrow. It assists in momentarily fixing a translocated modiolus.

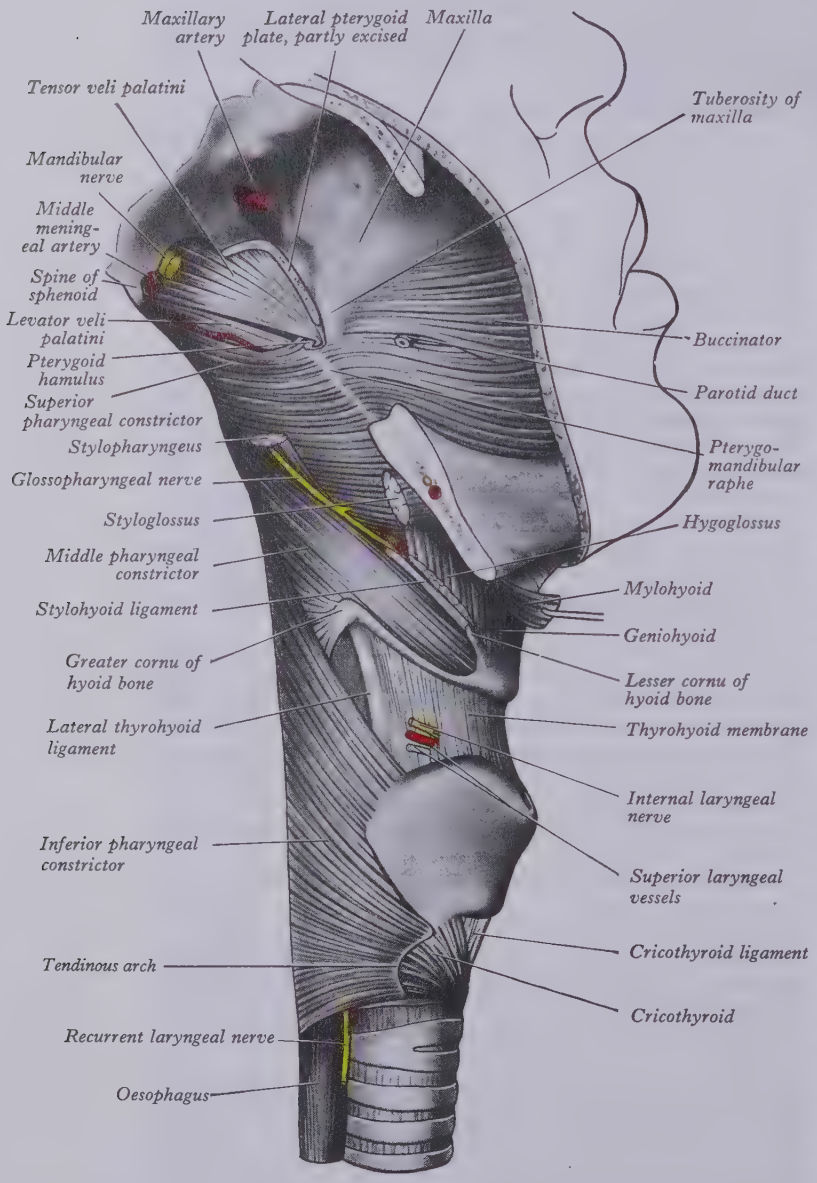
Zygomaticus major extends from the zygomatic bone, in front of the zygomaticotemporal suture, to the modiolus near the buccal angle, blending here with levator anguli oris and orbicularis oris and also, more deeply, with other modiolar muscles.

Actions. Zygomaticus major retracts and elevates the modiolus and buccal angle, as in laughing. It is also a fixator of the modiolus. **Malaris** is subject to much individual and racial variation; sometimes absent, when present it may be represented by a few superficial fascicles, a partial or complete thin sheet, or occasionally a substantial complete sheet. It is continuous with the inferior limit of orbicularis oculi from the temporal fascia to its medial palpebral attachment; it is possibly derived from orbicularis oculi (Lightoller 1925). Its fibres incline medially and downwards, covering zygomaticus major and minor and levator labii superioris, its deep fascicles blending and distributed with these muscles. Of its superficial fascicles, a proportion have a dermal attachment to the nasolabial ridge and sulcus; some pass directly to the modiolus; the remainder enter the outer third of the upper lip and intersect with bundles of orbicularis oris.

Nerve supply. All six preceding muscles are supplied by buccal branches of the facial nerve.

The inferior labial area is bound by the free red-lip margin above, by the centrally transverse *mentolabial sulcus*, separating it from mental skin and dense fasciae below, while laterally are the short curved *inferior buccolabial sulci*; the latter descend from the buccal angle and sweep medially to meet the down-curved ends of the mentolabial sulcus. The inferior labial area may be arbitrarily considered as completed by a projection from the centre of the inferior buccolabial sulcus passing a short distance upwards and laterally to the modiolus.

Mentalis, a conical fasciculus lying lateral to the inferior labial frenulum, is attached in the mandible's incisive fossa and descends to the mental skin.



Actions. It raises the mental tissues, mentolabial sulcus, (wrinkling the mental skin) and base of the lower lip, aiding its protrusion/ eversion, as in drinking, speech and also expressing doubt or disdain. Electromyography shows prolonged activity in mentalis, even in sleep, an unexplained finding.

Depressor labii inferioris is quadrilateral and attached to the mandible's oblique line, between symphysis menti and the mental foramen, ascending medially into the skin and mucosa of the lower lip (vide infra), blending and intersecting with its fellow and with orbicularis oris. It is continuous below and laterally with platysma (pars labialis); its superficial part contains some admixed fat but its overlying panniculus adiposus is very thin.

Actions. It depresses the lower lip laterally in mastication, may assist its eversion and contributes to expressing irony, sorrow, melancholy, doubt etc.

Depressor anguli oris ascends from the mandible's mental tubercle and its continuation, the oblique line, inferolateral to depressor labii inferioris, then converges into a narrow fasciculus blending with other muscles at the modiolus near the buccal angle. It is continuous below with platysma and cervical fasciae; at the modiolus it is continuous with orbicularis oris and risorius; some fibres continue into levator anguli oris. (Some earlier investigators regarded many, or all, of these continuations and blendings as accessory parts or 'heads' of one large compound *musculus triangularis.)* In association with but below the fibromuscular bundles attached to the mental tubercle, some fascicles may bypass the tubercle inferiorly then, crossing the midline, interlace with their contralateral fellows as the *musculus transversus menti* (or 'mental sling').

Actions. It depresses the modiolus and buccal angle laterally in opening the mouth and in expressing sadness. During opening of the mouth the buccolabial sulci are stretched, flattened and become indistinct; the mentolabial sulcus becomes more horizontal and its central part deepened.

5.25 Buccinator and the muscles of the pharynx. The zygomatic arch, the masseter, the ramus of the mandible, the temporalis and a large part of the lateral pterygoid plate and the pterygoids have all been removed. In addition, the upper parts of the stylopharyngeus and styloglossus have been excised, together with the posteroinferior part of the hyglossus and all the infrahyoid muscles.

Nerve supply. Mentalis, depressores labii inferioris and anguli oris are supplied by the mandibular marginal branch of the facial nerve.

The buccinator (5.25), a thin quadrilateral muscle between maxilla and mandible, is attached linearly to the external surfaces of the alveolar processes of maxilla and mandible, opposite the molar teeth; curving posteromedially around the sites of the third molar teeth, the *upper* part crosses the maxillary tuberosity then a tendinous band to the pterygoid hamulus, the *lower* crossing the junction of the ramus and body of the mandible to the posterior end of the mylohyoid line, and thence from the anterior border of the pterygomandibular raphe, which is interposed between it and the superior pharyngeal constrictor. Between the maxillary tuberosity and the upper end of the raphe a few fibres spring from the tendinous band between the maxilla and pterygoid hamulus; this encloses the tendon of tensor veli palatini that pierces the pharyngeal wall in a small gap behind this band (5.25). Thus, the posterior part of buccinator is deeply placed and internal to the mandibular ramus and its attachments and in the plane of the medial pterygoid plate; its anterior part *curves out* behind the third molar teeth to assume a submucosal position in cheek and lips. Buccinator fibres converge towards the modiolus near the buccal angle, the central fibres decussating, so that lower and upper ones continue into upper and lower parts of orbicularis oris respectively, while the highest and lowest fibres of buccinator enter their corresponding lips without decussation.

Relations. Buccinator *posteriorly* is in the plane of the superior constrictor, and here is covered by buccopharyngeal fascia. *Superficially* over its posterior part fat separates it from the mandibular ramus, masseter and part of temporalis. (The fat is not clearly linked with suckling.) *Anteriorly* the superficial surface of buccinator is related to zygomaticus major, risorius, levator and depressor anguli oris and the parotid duct, which traverses it near the third upper molar; the facial artery and vein and branches of both facial and buccal nerves cross it. Its *deep surface* is related to the buccal glands and mucous membrane.

Nerve supply: lower buccal branches of the facial nerve.

Actions. The buccinators compress the cheeks against the teeth, passing food between them in mastication, or expelling air when the cheeks are distended (*buccinator* = a trumpeter!). Its labial extensions are mentioned below.

The pterygomandibular raphe is a strand of tendinous fibres passing from the pterygoid hamulus to the posterior end of the mylohyoid line. *Medially* it is covered by buccal mucous membrane, where it is easily palpable; it is separated *laterally* from the mandibular ramus by adipose tissue. *Posteriorly* the superior pharyngeal constrictor is attached to it; *anteriorly* the central part of buccinator arises from it (5.25).

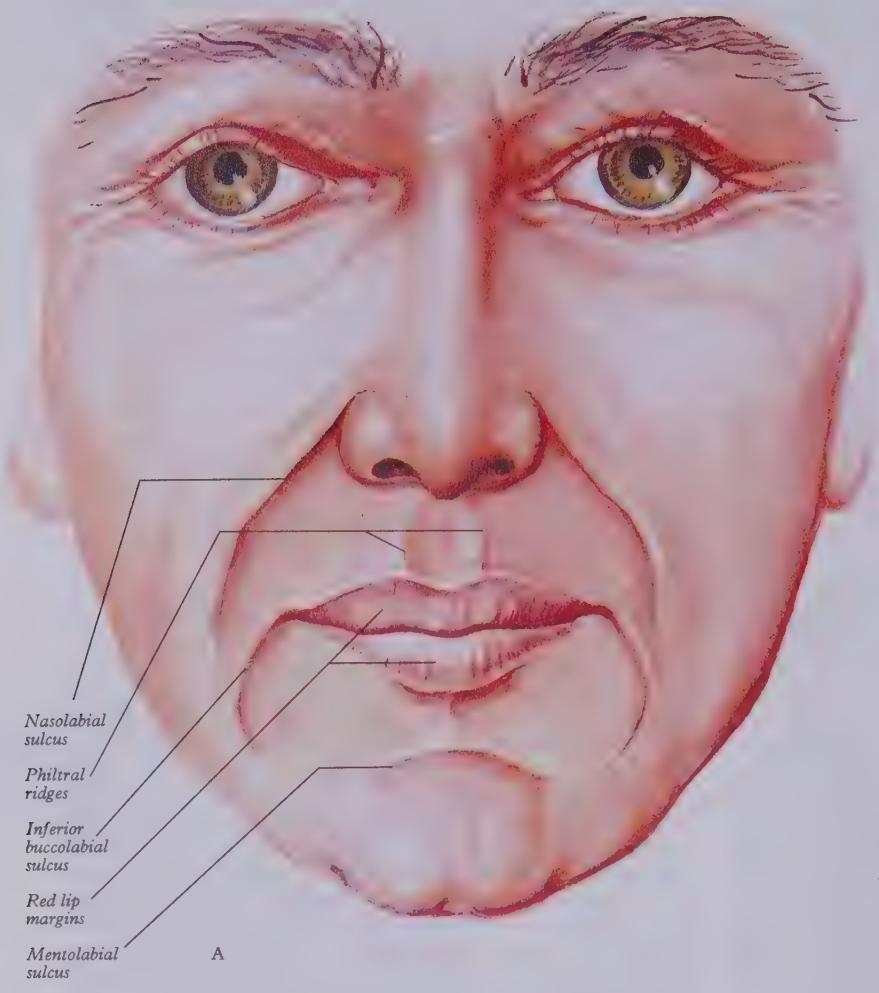
ORAL SPHINCTERS, TRACTORS AND MODULATORS

The almost endless variety of neuromuscular controls of the lips and oral fissure during speech and non-verbal expressive communication are commonly integrated with fluctuating patterns in the masticatory, linguopharyngeal, laryngeal, circumnasal, circumorbital and palpebral, and also intraocular and extraocular muscle groups. Yet to be detailed are: the compound oral sphincter, *orbicularis oris*; its closely associated bilaterally paired *incisivus superior and inferior*; the patterned labial attachments of upper lip elevators and lower lip depressors; also the mode of force-transmission to the lips from those muscles that converge towards dynamic palpable loci (the *modioli*), their centres about 1.25 cm lateral to the buccal angle. Before providing these descriptions it is convenient, despite some repetition, to summarize, but with more information, the limits of the labial area and its superior and inferior parts, the general architecture of a lip including the oral fissure and the free 'red-lip' margin and the concept of bilateral modioli (and their distinction from 'the buccal angles'). See 5.21,26A–E.

The labial area. When the face is in repose, the lips in gentle contact and the teeth maintaining a narrow interocclusal clearance, the area is approximately a hexagon (borders: superior, inferior, paired superolateral and inferolateral). The *superior*

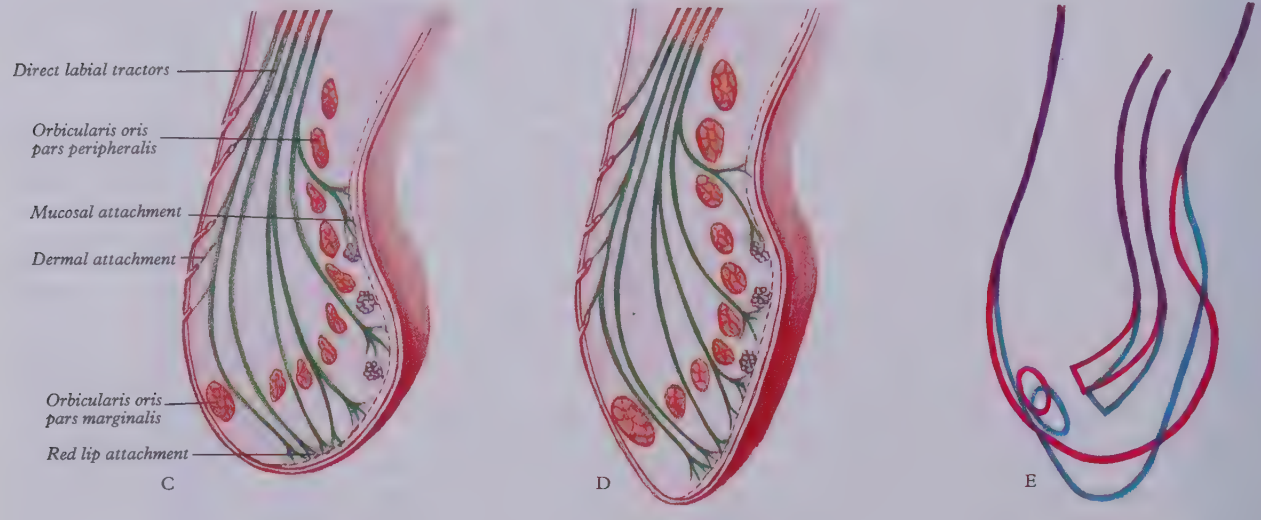
border is between the attached margin of the lower external nose and the upper lips and includes the bilateral curved circumalar sulci, the ridge forming the posterior rim of each nostril; it then continues beneath the junction of the anterior nasal spine of the maxillae and the mobile part of the nasal septum. (Although not so-named this superior border is strictly nasolabial.) The *superolateral boundaries*, described above, incline downwards and laterally from the upper end of the circumalar sulcus to the modiolus and correspond to the so-called nasolabial sulci (superior buccolabial would be more accurate, but transgresses long-established custom). The *inferolateral boundaries* extend downwards and medially from the lateral angles of the hexagon over the modioli to the down-curved lateral ends of the centrally transverse mentolabial sulcus, the latter forming the *inferior boundary*. A transverse line between the external angle (i.e. between the equilibrium 'resting' positions of the modioli) separates the larger (upper two-thirds) superior labial area from the inferior area, and crosses the level of the usually slightly undulant line of contact between the apposed free 'red-lip' surfaces at the closed oral fissure. The considerable variation (between individuals, sexes and races) in the dimensions and curvatures of the exposed red-lip surfaces is commonplace. The junction between external hair-bearing skin and red hairless surface in the upper lip almost invariably takes the form of a double-curved Cupid's bow; centrally convex downwards, then bilaterally rapidly rising to an apex corresponding to the lower end of each ridge of the philtrum, it descends thereafter, laterally retaining a gentle superolateral convexity, to its termination which is often horizontal but sometimes slightly curved upwards, infrequently downwards. The line of contact between the red-lip surfaces is often almost horizontal but quite frequently takes the form of a much less undulant cupid's bow. In the lower lip the skin/red-lip junction varies greatly between individuals in its central vertical depth; in all individuals, however, the lateral extremities descend medially for a few millimetres. In 'shallow' lower red-lips the junctional line curves to form an upward convexity almost parallel to the line of the closed oral fissure. With the deepest lower red-lips, the junctional line follows a continuous downward convexity; many intermediate states exist, the deep downward convexity having a flat (i.e. horizontal) section centrally; the latter may have a varying degree of reversed curvature with an upward convexity.

It may be noted that the highest parts of the superior labial area are paired bilateral, curved, pointed cornua that embrace the external attached margins of the nasal alae. The principal factors affecting the disposition of the lips, oral fissure and circumlabial hexagon are mentioned further below.



Labial architecture. In both upper and lower lips, about the central three-fifths consists mainly of a thick epithelialized fold of tissue, which has free external (cutaneous) and internal (mucous) surfaces and is continuous through a specialized red-lip transitional zone bounding the oral fissure. Above the reflexion of labial mucosa into gingival mucosa the upper lip's perimeter has a narrow band of non-cavitated tissue related to the subnasal maxillae. Similarly, the reflexion in the lower lip approximately coincides with the mentolabial sulcus and here labral and mental tissues are continuous. Radiating from the lateral ends of the oral fissure and buccal angles the labial epithelia and internal tissues cross the external angles and adjacent boundaries of the labial hexagon to become continuous with those of the cheek.

Some aspects of general lip structure, either upper or lower, may be examined in simple vertical parasagittal section; however, this presents some difficulties because, as indicated, the red-lip surface is not simple, plane and horizontal; many prominent muscle bundles run transversely *parallel* to the red surface, whereas, in some lip regions, the principal labial tractors run at right angles to the surface and transverse muscle bundles. Elsewhere, the tractors enter the lip with varying degrees of obliquity. For these reasons histological geometry is most effective when full thickness sections of the lip are made at right angles to the red-lip surface and in the long axis of the tractors, e.g. the segment extending 1 cm lateral to the philtral ridge. The sectional profiles of the lips differ, neither being a simple fold of uniform thickness throughout, although their upper and lower halves extending from their attached bases approach this. The rimal half of the upper lip has a bulbous sectional profile that is asymmetrical, the adjoining skin and red lip being slightly convex ventrally, while the adjoining red lip and mucosa have a pronounced internal convexity. (This mucosal ridge or 'shelf' can be wrapped around the incisal edges of the parted teeth.) The lower lip is on a more posterior plane than the upper and, in the position of neutral lip contact, its ventral surface curves forwards (with a ventral concavity) to the prominent skin/red-lip junction; posteriorly, a mucosal elevation is minimal or absent.



A thick, approximately central stratum in each lip consists of striated muscle, either parallel bundles of contractile fibres or their dermal, mucosal or intermuscular connective tissue terminal attachments. The muscles are the elements grouped collectively as the *orbicularis oris*, with *incisivus superior and inferior* (all having multiple putative attachments or continuations, vide infra), also the patterned attachments of the direct labial tractors (described below). The skin covering the external lip surfaces has a thin epidermis but, with all the layers that characterize fully keratinized compound epithelia, the dermis is well vascularized and accommodates numerous hair follicles (many large in the male), sebaceous glands and sweat glands. Subcutaneous panniculus adiposus is scant. The mucous membrane lining the labial aspect of the oral vestibule is clothed with a thick non-keratinizing stratified squamous epithelium. Its flattened dying or dead surface cells contain some eleidin and keratohyalin, retain their nuclei and are continuously shed into the saliva, to be replaced by mitosis in the deep germinative layer. The substantial submucosa is well vascularized and lodges numerous labial mucous glands, up to a few millimetres in diameter, the largest being palpable with the lingual tip. Because of the thickness of its semi-opaque epithelium the everted lip's mucosa appears moist, glistening and pink. Between the skin and mucosa, the free, red-lip margin is covered with a specialized stratified squamous epithelium which is thin near the skin, increasing in thickness slightly as the mucosa is approached, then with an abrupt increase in thickness when true mucosa is reached. The epithelium is covered with dead squames that are filled with eleidin and transparent; its deep surface is deeply pitted and grooved receiving the abundant long dermal papillae. The latter carry a rich capillary plexus accounting for the dusky red colour of these labial surfaces; their rich innervation accords with their high discriminative sensitivity. These surfaces are, of course, hairless and the dermis carries no sebaceous, sweat or mucous glands; they are intermittently moistened with saliva by the lingual tip.

Orbicularis oris, so named because for long it was assumed that the oral fissure was surrounded by a series of complete ellipses of striated muscle and that by their concerted action, a simple sphincteric compression of the lip margins, labial mucosa against teeth and indrawing of the buccal angles followed. This was, perhaps, surprising because simple functional inspection during different activities, the effects of neurological deficits, and improving stimulating and recording techniques clearly demonstrate that the muscle consists of independent quadrants (upper, lower, left and right) that co-operate in many contrasting ways in the great variety of labial actions. There is some interlacing and transmedian overlap of corresponding right and left quadrants, while there is, at least, close juxtaposition of upper and lower quadrants at their lateral (modiolar) attachments. Each quadrant consists of a larger *pars peripheralis* (common to many mammals) and a *pars marginalis* (absent in non-primate mammals, slightly marginally different in non-human higher primates, uniquely developed in vocalizing mankind). Formally, then, orbicularis oris as a whole is composed of eight segments each systematically named according its location; as is the case with most modiolar muscles (vide infra), each segment resembles a fan with its stem at the modiolus. Each fan is open in peripheral segments and almost closed in marginal segments. The region of apposition of marginal and peripheral parts is indicated by the lines of junction between the red-lip area and the skin ventrally and the mucosa posteriorly.

Pars peripheralis in each quadrant has a lateral stem attached to the full thickness (apex to base with its related upper or lower cornu) of the labial aspect of the modiolus. The majority of these stem fibres are thought to have a terminal attachment within the tissues of the modiolus, although the fine structural details and

5.26 A. The principal sulci, creases and ridges of the face which are noted at various points throughout the text. Note particularly those surrounding the 'labial hexagon', the superior and inferior labial areas and one form of the red-lip margins. B. The disposition of the modiolus and orbicularis oris pars peripheralis and pars marginalis (on the left); the successively transected laminae of the direct labial tractors of both upper and lower lips (on the right). C–E are parasagittal sections of the upper lip. In each, on the left is thin skin with oblique hair follicles; on the right thick mucosa with mucous glands and mucosal shelf; between them the red-lip margin. C in repose, D slightly contracted forming a narrowed profile of a labial cord. E. Superimposed outlines of C (magenta) and D (purple).

geometry of these have not, as yet, been satisfactorily demonstrated. Neither has the derivation of a limited number of orbicular fibres from direct continuations of one or more (perhaps all) the other modiolar muscles (vide infra). It is commonly stated but clearly an oversimplification that orbicularis has direct reinforcements in the upper lip from buccinator ('upper' or maxillary fibres, decussating 'lower' central or pterygomandibular fibres) and depressor anguli oris; in the lower lip from buccinator ('lower' or mandibular fibres, decussating 'upper' central or pterygomandibular fibres), levator anguli oris and the superficial modiolar attachment of zygomaticus major. (Upper and lower incisivus muscles have a medial osseous attachment and are mentioned below).

The lateral stems (upper and lower) of orbicularis oris enter the lateral angles of their respective superior and inferior labial areas and diverge into bundles arranged as muscular sheets that occupy the central tissue stratum of their triangular hemilabia. These triangular sheets of muscle extend vertically from the level of the red lip/cutaneous junction where the sheet is thickest, then progressively to the thinner region until their respective upper or lower labial borders (vide supra) are reached. The greater part of each sheet enters the free lip where its fibres aggregate into a series of cylindrical bundles, each approximately concentric and parallel to the oral fissure's red-lip margin. Adjacent bundles are separated by extensions of the labial tractors passing to their submucosal attachments; similar extensions separate the rimal bundle of pars peripheralis from the basal bundle of pars marginalis. In the upper lip, the highest fibres course near the nasolabial sulcus, a few fibres attaching to the sulcus; while the others have occasional attachments to the nasal ala and septum. In the lower lip the lowest fibres reach and attach to the mentolabial sulcus. While crossing its quadrant of free lip, the main body of fibres is often held to have a small population that ends in the labial connective tissue, dermis or submucosa. This has not been demonstrated satisfactorily. Most fibres continue medially and as the median plane is approached they start for some 5 mm into the opposite half-lip, until the fibres gain their mainly dermal but partly submucosal attachments. Interlacement occurs beneath the hollow of the upper lip's philtrum and the less marked corresponding depression in the loci in the lower lip. During oral fissure compression a median philtral vertical sulcus becomes more prominent, as do a pair of paramedian vertical wrinkles in the lower lip. (For studies on fetal lips see Latham & Deaton 1976.)

Pars marginalis of the orbicularis oris, as mentioned, is uniquely developed in human lips and closely associated with speech and the production of some varieties of musical tone. In each quadrant the pars marginalis consists of a single (or in some individuals and races double) band of narrow diameter muscle fibres lodged within the tissues of each red-lip margin. Medially, the marginal fibres meet and interlace with their contralateral fellows, then gain attachment to the red-lip dermis a few millimetres beyond the median plane (cf. pars peripheralis). Laterally, the fibres converge and continue to an attachment at a horizontal strip level with the buccal angle, across the deepest (submucosal) part of the modiolar base.

The relations between pars marginalis and peripheralis are not simple. In a full thickness section of an upper lip at right angles to the red-lip margin, the cylindrical bundles of peripheralis fibres are not all in one plane. Their profiles, considered together, are slightly convex forwards above but reversing to a more pronounced forward concavity in their rimal half; i.e. they are classically likened to the shank and initial curved part of a hook. Beyond the rimal bundle of peripheralis, the hook is completed by the blunted triangular (elliptical or oval) profile of marginalis; its base is near the lower border of peripheralis, the remainder extending upwards and forwards occupying the core of the red-lip, its apex approaching the red-lip/cutaneous junction. In the lower lip, peripheralis bundles form, in section, a continuous curve concave forwards; this is surmounted by the flattened, curved, triangular marginalis that descends anteriorly, it apex again nearing the red-lip/cutaneous junction. In both lips, therefore, throughout their rimal red zones, marginalis lies substantially anterior to the rimal bundles of peripheralis. Passing laterally, however, beyond the red-lip and crossing the buccal angle, this relationship alters. Marginalis is spirally wrapped around the rimal edge of peripheralis to reach its deep (submucosal) surface and this deep position of marginalis (with the vertical positioning of its fibres now reversed) is maintained as it continues to its attachment at the modiolar base. The functional roles implicit in these structural arrangements and other co-operate labial controls are mentioned below (see Lightoller 1925, Burkitt & Lightoller 1926, Duckwork 1947).

Incisivus labii superioris, an accessory muscle of the oral orbicular complex, has an osseous attachment to the floor of the maxilla's incisive fossa superior to the eminence of the lateral incisor tooth and at first lies deep to the upper part of pars peripheralis of the orbicularis. Arching laterally, its fibre bundles become intercalated between and parallel to the orbicular bundles. Approaching the modiolus it segregates into superficial and deep parts; the former partly blends with levator anguli oris and attaches to the intermediate (body) and apical modiolar zones; the latter attaches to the superior cornu and basis moduli.

Incisivus labii inferioris, also an accessory orbicular muscle, has many features in common with superioris. Its osseous attachment is to the floor of the mandible's incisive fossa, lateral to mentalis and below the eminence of the lateral incisor tooth. Curving laterally and upwards, it partially blends with pars peripheralis inferior of orbicularis oris, then has similar modiolar attachments; superficial bundles reach the apex and body; deep bundles reach the base and inferior cornu.

Before a more detailed consideration of the attachments of the direct labial tractors and a brief account of the modiolus are attempted, mention of three further, but variable, muscle aggregates must be made.

Platysma: a general account of this muscle is furnished on p. 583. At its superior end mention is made of the submental transmedian interlacement with its contralteral fellow; thereafter its *pars mandibularis* attaches to the lower border of the body of the mandible. Posterior to this a substantial flattened bundle diverges superomedially to the lateral border of depressor anguli oris, where a few fibres join this muscle while the remainder continue deep to the muscle to reappear at the depressor anguli's superomedial border. Here they continue within the tissue of the lateral half of the lower lip as its direct tractor *platysma pars labialis*. The latter occupies the interval between depressor anguli oris and depressor labii inferioris; it is in the same plane as the labial depressor and their contiguous margins blend. They have similar labial attachments. *Platysma pars modiolaris* constitutes all the remaining bundles posterior to pars labialis except for a few fine fascicles that pass directly to end in the buccal dermis or submucosa. The modiolar bundles curve superomedially posterolateral to the depressor anguli oris, pass deep to risorius and attach to the apex and subapical part of the modiolus.

Risorius: an ineptly named muscle subject to great variability ranging from one or more slender fascicles to a wide, thin superficial fan. Its peripheral attachment may include some or all of the following: the zyomatic arch, parotid fascia, masseteric fascia anterior to the parotid, fascia enclosing the modiolar part of platysma and the mastoid fascia. Its fibres converge to an apical and subapical attachment at the modiolus. It is not particularly associated with laughter any more than many other modiolar muscles; equally it is active in numerous facial activities in addition to laughter. (Some authorities, as mentioned, recognize a large compound *musculus triangularis* which, when fully developed, has the following 'heads' or *capita* of attachment peripherally: *c.menti*—cf. transversus menti; *c.longum*—from the mental tubercle; *c.latum*—from fascia and the oblique line, cf. depressor anguli oris; *c.buccale*—widely called risorius.)

Direct labial tractors pass, as their name suggests, directly into the tissues of the lips without intervention of the modioli (although, of course, activity of the modiolar muscles profoundly affects, and is integrated with, activity of the tractors). Broadly, the contraction of tractors exerts a force at, or approximately at, a right angle to the oral fissure serving to elevate and/or evert the whole or part of the upper lip, also to depress and/or evert the whole or part of the lower lip. In the upper lip the tractors are, from medial to lateral; the labial part of levator labii superioris alaeque nasi, the levator labii superioris and zygomaticus minor. These blend into a continuous sheet that, as it enters the free lip,

divides into a series of superimposed coronal sheets anterior to the muscle bundles of pars peripheralis orbicularis oris. In the lower lip the tractors are, medially, depressor labii inferioris and, laterally, platysma pars labialis. Again, these form a continuous sheet that divides into coronal sheets ventral to pars peripheralis orbicularis oris. In both upper and lower lips the sheets may be considered as three groups increasingly deep from the surface skin and each with a distinct zone of attachment. The superficial group of sheets gives a succession of fine fibre bundles that curve ventrally a short distance before gaining attachments as a series of horizontal rows to the dermis between the hair follicles, sebaceous glands and sweat glands. The intermediate sheets are attached to the dermis of the red-lip rimal modified skin which they reach by two routes. The more anterior sheets continue past the skin/red-lip junction, then curve posteriorly over the anterior aspect of pars marginalis orbicularis oris to their punctate attachments on the ventral half of the red-lip dermis. The deeper intermediate sheets pass, first posteriorly between the rimal bundle of pars peripheralis and the base of pars marginalis, then curve anteriorly to their, also punctate, attachments to the dorsal half of the red-lip dermis. The deepest sheets of the tractors are closely applied to the ventral aspect of pars peripheralis orbicularis oris, between the parallel bundles of which fine tractor terminals curve posteriorly to their submucosal and periglandular connective tissue attachments. these various attachments may act in concert or selectively and their effects may involve a complete labial quadrant or be restricted to a short labial segment. Thus bilateral activity involving upper and/or lower lips, balanced against varying activity in their antagonists, the compound orbicularis oris and modified by the modiolar muscles, may range from delicate adjustments of the tension and profile of the lip margins to large increases in the oral fissure with lip eversion. Lip movements are modified to accommodate separation of the teeth by mandibular depression at the temporomandibular joints. Beyond a certain range of mouth opening, labial movements are almost completely dominated by mandibular movements.

The modiolus. As mentioned above, an early view, long subscribed to, regarded the oral sphincter, orbicularis oris, as consisting of complete circumoral ellipses supplemented by bundles from the major extrinsic muscles converging on the buccal angles. Ultimately it became clear that complete ellipses were rare, or indeed absent, and the bundles of roughly parallel transverse labial fibres were *wholly* allocated as *direct* extensions from the extrinsic muscles. Some decussated 'at the buccal angle'; others passed without decussation into their corresponding lips. This view is often perpetuated in elementary accounts. However, meticulous dissection of the buccolabial musculature, with particular reference to the tissues embracing the lateral extremities of the oral fissure and radiating about 2 cm superiorly, inferiorly and laterally from the buccal angle, despite a minority of exceptions, in the main failed to support the earlier propositions (Lightoller 1925, Burkitt & Lightoller 1926, 1927). The dense, compact, mobile, fibromuscular mass, the *modiolus*, consists of the interlacing arrays of fibre terminals of muscles converging towards or diverging from it. Bidigital palpation is most effective with the opposed thumb and index finger compressing the mucosa and skin simultaneously. The name modiolus was adopted because, in surface view, the mass was fancifully thought to resemble the hub of a wheel and the radiating stems of its component muscles, the spokes thereof. Unlike spokes, however, the muscles do not all occupy the same plane and their modiolar stems are often spiralized and most divide into at least two (superficial and deep) bundles, (some into three or four), each with its distinctive interlacements and zones of attachment. Since nine muscles (or more depending on the classification employed) are attached to each modiolus, and they undergo the transformations mentioned, each mass has a high degree of three-dimensional structural complexity and has proved correspondingly difficult to analyse. Sound quantitative stereology has not yet been achieved, while the results of careful microdissection, although often leading to similar broad conclusions, has also led to controversy about some details. Such minutiae will be disregarded here.

The shape and dimensions of the modiolus are necessarily approximations because there are individual, sexual, racial and, of course, age variations; also there are no precise distinct histological boundaries but rather a highly irregular zone where dense, compact interlacing tissue grades into the stems of individually recognizable muscles. The modiolus has some features resembling a blunt 'cone' but with modifications and additions. The base of the cone, lateral to a vertical line through the buccal angle, is adjacent and adherent to the mucosa; this *basis moduli* is roughly elliptical in outline and, as intimated, extends vertically about 2 cm above, and 2 cm below, a horizontal through the buccal angle; it also extends laterally a similar distance from the angle. The blunt *apex* of the cone, about 4 mm across, is centred about 1 cm lateral to the buccal angle, deep and adherent to the panniculus fibrosus; panniculus adiposus is absent here. From mucosa to dermis, therefore, this mass presents axially a base, a central part or body and an apicosubapical part, each about 3.5 mm thick, i.e. the whole is approximately 1 cm thick. The body has an oblique fibrous cleft or channel that transmits the facial artery and possibly limits its compression during buccolabial musculature interplay. The cone shape is further modified by the presence of two blunt, round-edged, flanges that extend into the lateral free lip tissues above and below the lateral extremity of the oral fissure. These superomedially and inferomedially directed flanges (or *cornua*) are extensions of the body but more prominently the base of the modiolus. The tip of the superior cornu extends 0.5–1.5 cm medial to the buccal angle, whereas the tip of the inferior cornu only 0.3–0.5 cm. Thus, the modiolar base including the cornua, with its profile viewed from the mucosal aspect, is sometimes dubbed crescentic but is more reniform, with the buccal angle projecting towards the hilum. Another useful analogy is the resemblance of the whole modiolus and its attached muscular stems to a short conifer and its main branches. The muscles traced outwards from their pericentric modiolar stems have been picturesquely described as an array of fans, some almost closed and strap-like, others widely open and varying from sagittal, through degrees of obliquity, to almost coronal. In some, the 'rays' of the fan do not remain in a single plane but curve in conformity with buccal and labial tissue planes. On occasion muscles may be grouped and considered as forming a large compound fan. Thus, when well developed, zygomaticus major, risorius, platysma pars modiolaris and depressor anguli oris together have been likened to a wide hemicircular fan centred on the modiolus and extending peripherally from the zygomatic bone to the mental tubercle. Spiralization of muscle stems as they converge towards the modiolus is usual, as noted, but particularly clear examples are provided by depressor anguli oris and the quadrants of orbicularis oris. The peripheral attachment of the depressor, long and linear, lies in the plane of the body of the mandible whereas its bundles of modiolar attachment are to parts of an apicobasal column. Similarly the orbicular bundles in the free lip are arranged as a vertically curved but roughly coronal fan; its spiralized stem, however, thickens dorsoventrally to reach a series of modiolar attachments arranged from apex to base. Both muscles have undergone an overall spiral of at least 90° between their attachments. Detailed analysis shows that this general pattern is further complicated by the mutual spiralization of adjacent individual muscle bundles.

Modiolar muscles: classification. Some investigators have found it helpful to group the muscles in terms of their general geometric relation to the modiolus (with the face in repose, the teeth just short of full occlusion, the lips in light contact and the modiolus in its 'resting' or neutral position).

Cruciate modiolar muscles whose profiles, when viewed from the apical aspect, resemble a compound X, are: zygomaticus major, levator anguli oris, depressor anguli oris, platysma pars modiolaris.

Transverse modiolar muscles include buccinator, risorius, the various parts of orbicularis oris, incisivus superior and inferior.

Of the foregoing, some writers have segregated a few of these muscles as a separate group of *accessory modiolar muscles*; any sound logical basis for this is obscure.

Modiolar muscles: attachments. As intimated, a satisfactory complete three-dimensional analysis of modiolar attachments is not yet available. Heavy reliance has been placed on careful dissection unsupported by microreconstruction, and results are

often presented as long, detailed verbal descriptions in which the terms used to denote relative positioning are sometimes open to misinterpretation. Some notes concerning the main conclusions will be given or reiterated here. A minority of muscles (risorius, platysma pars modiolaris, occasionally malaris and pars marginalis orbicularis oris) may be regarded as having a single zone of attachment each; the remainder have superficial and deep (or multiple) zones. Attachment involves interlacement of neighbouring bundles but most profusely with their direct physiological antagonists; thereafter the majority of fibres end within the modiolus. Occasional bundles may be traced from one muscle to another, although few in number, theoretically such modiolar strands could form tenuous links between any pair of muscles. They are not regarded as vectorially active generators of modiolar forces but merely as one structural feature resisting modiolar disruption during activity of its dominant, interlacing, terminating bundles.

Zygomaticus major inclines to the modiolus and divides into superficial and deep parts, the two being separated by the converging fibres of levator anguli oris, many of which interlace with ascending bundles of depressor anguli oris (at the 'angular complex'; i.e. the caninotriangular complex of earlier anatomists). The superficial fibres of zygomaticus major spread into the apex moduli where they interlace with the attachments of risorius, modiolar parts of platysma and malaris and with the underlying angular complex. Any or all of these muscles may interchange scattered fascicles apically and subapically. The deep fibres of zygomaticus cornu attach to the centre of the modiolar body and to the superior cornu of its base. The central fibres interlace with corresponding ones of buccinator and with the overlying angular fibres; interchange may occur with depressor anguli oris. Both the superficial and deep parts of zygomaticus major may send extensions into pars peripheralis orbicularis oris.

The modiolar attachments of orbicularis oris (marginal and peripheral parts), incisivus superior and inferior and the muscles forming the *apical rosette* have been mentioned above and in previous paragraphs. Levator anguli oris, as indicated, enters the modiolus between the superficial and deep parts of zygomaticus major where it is closely adherent to the superficial part. Thereafter its fibres radiate in many planes and intermesh with adjacent bundles. Many pass superficially and blend with depressor anguli oris. Deep bundles attach to the modiolar base inferior to the buccal angle. Some fascicles are continuous with orbicularis oris pars peripheralis inferior, others with buccinator. Most of its fibres end blindly in the modiolus. Depressor anguli oris also has superficial and deep bundles: the superficial interlace with all the muscles of the apical rosette; both superficial and deeper bundles interweave with levator anguli oris; basal fibres attach near the deep fibres of zygomaticus major. Some continuous fascicles pass into the territories of buccinator and orbicularis oris peripheralis, both superioris and inferioris. Buccinator blends with the whole lateral aspect of the basis moduli and continues to interlace with many of the muscles attached to the base. However, there is little convincing evidence of a significant number of buccinator fibres passing directly into the tissues of the lips. In contrast, as buccinator courses ventrally through the cheek and modiolar base there is sound evidence that substantial numbers of its fibres successively curve internally to punctuate attachments on the buccal and modiolar submucosa.

The panniculus fibrosus is adherent to the apex moduli and extends posteromedially as a thin sloping sheet to the *buccal angle* where its free border forms a crescentic, narrow, flexible, subcutaneous fibro-elastic cord that accommodates the varying postures of the modioli, lips and oral fissure and jaws.

Modiolar Movements and Shape Changes

The complex, controlled, three-dimensional mobility of the modioli enables them to provide functional loci for integrated activities of the cheeks, lips and oral fissure, the oral vestibule and the jaws bearing teeth. Such activities include: biting, chewing, drinking, sucking, swallowing, changes in vestibular contents and pressure, the innumerable subtle variations involved in speech, the modulation (and occasional generation) of musical tones, harsher sounds in shouting and screaming, crying, and the equally endless permutations of changes in facial expression ranging from the merest 'hint' to gross distortion, either symmetrical or asymmetrical. Adequate consideration of many of these activities would merit individual monographs and cannot be attempted here. However, a few general points, sometimes ignored, will be indicated. During a complex action there is required simultaneous recording of length, direction and tensional force of numerous muscles (or parts of muscles) over an adequate time interval. Such data are not yet available. Theoretical predictions from an estimated 'average line of pull' *if* the muscle acted in isolation are of little value. The resultant of vectorial combinations of two or more such lines affords limited assistance in the absence of experimental verification. With major modiolar movements it appears likely that many if not all its associated muscles are involved to some extent. While the most obvious determinant of modiolar position and mobility is the state of balanced contraction of its directly attached muscles, another factor having a pronounced influence is the degree of separation or 'gape' between the upper and lower teeth. Starting from the occlusal position and maintaining the lips in contact, the teeth may be separated, near the midline by about 1.25 cm, and the mentolabial sulcus descends a similar distance. The lips now part and gape continues to its maximum: interlabial and interdental distances now approach 4.0 cm and the mentolabial sulcus has descended a further 2.0 cm. In this posture the modiolus has *descended* about 1.0 cm to lie over the interdental space and into which its basal and surrounding buccal mucosa projects a few millimetres. Thus positioned the modiolus is *immobile* and its cornua (and their attached stems of orbicularis oris peripheralis, superior and inferior) diverge into their respective lips at an obtuse angle to each other; the dispositions of the other modiolar muscles change accordingly. During mouth closure teeth glide over the buccolabial mucosa which is progressively retracted from their occlusal surfaces by buccinator and the other submucosal attachments mentioned above. The general shape of the hexagonal labial area is accordingly modified with progressive opening of the mouth and jaws. In maximal opening, its central vertical height (between superior and inferior boundaries) has increased by 3.0–3.5 cm; the transverse distance between its lateral angles is reduced by about 1.0 cm and the angles are obtuse; the nasolabial sulci are longer, straighter and more vertical; and the inferior buccolabial sulci are less deep and curved. These soft tissue changes radiate from the bilateral modiolar loci.

With the lips in contact and the teeth maintained in tight occlusion, modiolar mobility, although moderately free, is not maximal but restricted by a few millimetres in all directions. Maximal mobility is present when there is an interdental clearance of 2–3 mm. Movement may occur from the neutral 'resting' position to any location within the boundaries of its *envelope of movement* which approximates to half a wide, flattened ovoid (or spheroid). The apex of the modiolus (and its apicobasal axis) may move vertically upwards about 1.0 cm, downwards 0.5 cm, posterolaterally 1.0 cm and anteromedially 1.0 cm, these movements occurring in the curved planes of the cheek and lips. Specific movements may be of lesser extent or may occur along any oblique path between the orthogonal ones just mentioned. As indicated above, with wide mouth opening there occurs a mandatory increased lowering and interdental sinking, with fixation of the modiolus. From the neutral position the modiolus may be displaced superficially along its apicobasal axis for distances up to 0.5–1.0 cm by the presence of liquid or a solid bolus in the vestibule, or by increased air pressure in part or the whole vestibule 'ballooning' the cheek and lips.

In all movements (elevation, depression, retraction, protraction or any oblique intermediate combination) the modiolus with its cornua, the buccal angle and lip margins bordering the lateral segments of the oral fissure, maintain the same fundamental relationships. Lateral projection of a line that bisects the buccal angle (and therefore the intercornual angle) passes through the centre of the modiolus, intersecting its apicobasal axis at a right angle. Thus during elevation of the modiolus (and angle) the line of intersection inclines upwards and laterally and is accompanied by medial rotation of the modiolus around its apicobasal axis. Lowering of the modiolus is combined, similarly but to lesser degree, with lateral rotation.

Many activities involve: first, the dominance of a particular modiolar muscle group over its antagonists with rapid relocation of the modiolus; secondly the transient fixation of the modiolus in this new site by simultaneous contraction of principally the cruciate muscles; thirdly, acting from this fixed base the main physiological effectors, buccinator and orbicularis oris engage in their specific actions. Buccinator, having fixed posterior and anterior attachments and by variations in length and tension of its contractile bundles, can control pressure and volume changes in gaseous, liquid or solid contents in the oral vestibule; it can direct materials between grinding molars or compress the cheek against the teeth and gums.

Like buccinator, orbicularis oris may first initiate or permit movement of the modiolus to an advantageous location, where secondary fixation occurs, and from this momentarily static base orbicularis operates. These activities are commonly integrated with partial separation or closure of the jaws and with variable activity in the direct labial tractors. All these factors operate in determining the momentary dispositions of the lips and oral fissure. Modiolar movements and repositioning may be bilaterally symmetrical, unilateral (the other remaining neutral or static) or bilateral but in contrasting directions. Thus the modioli (and buccal angles) may be at their (simultaneous) posterolateral limits and the oral fissure at its greatest horizontal length; then activity in orbicularis oris causes compression between 'thin', stretched, smooth lips. In contrast, with modioli and the angles at their anteromedial limits, fissural length is minimal and orbicularis compresses 'thick' pursed i.e. wrinkled and protruded lips. Fine close wrinkles cross the ventral half of the (mainly lower) red-lip margin and prominent cutaneous wrinkles, more widely spaced, are vertical centrally but elsewhere decline laterally. Lip protrusion is passive in its initial stages and may be suppressed by powerful contraction of the whole of orbicularis; conversely protrusion may be increased by combined selective activity in parts of the direct labial tractors. The functional posterolateral or anteromedial extremes of the modioli and buccal angles mentioned in bilaterally symmetrical movements are not their absolute extremes; the latter are achieved in horizontal asymetrical movements, e.g. both modioli (and angles) may move either in succession or simultaneously to the right. The ranges of anteromedial movement of the left modiolus and posterolateral movement of the right modiolus are now maximal. The oral fissure is markedly eccentric, the rimal ends of the philtrum with its ridges and the paired vertical sulci (originally paramedian) of the lower lip curve sharply to the right of the midline; and the effectiveness of lip compression is highest in the (original) left quadrants and lower in the right quadrants.

One modiolus may remain static or slightly lowered while the other is raised; other possible combinations and quantitative variations are endless. It is to be appreciated that in many expressive modifications the *movement* (e.g. modiolar translocation) is often more functionally significant than the *position* reached.

During the last 2.5–3.0 cm interincisal distances of wide jaw separation, strong contraction of orbicularis oris cannot effect lip contact but causes full-thickness inflection of upper and lower lips including their red-lip rims, around the incisal edges, canine cusps and premolar occlusal surfaces towards the oral cavity.

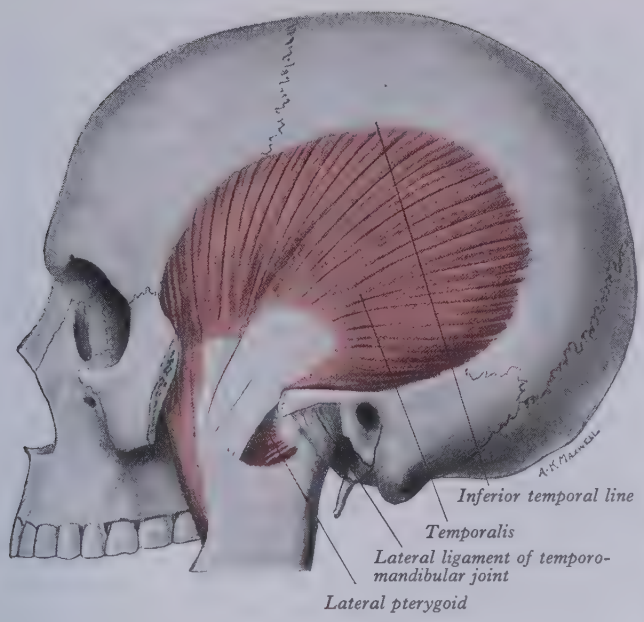
The multitude of temporospatial labial controls involved in speech, intonation and less patterned sounds are mentioned elsewhere (p. 1257) and cannot be pursued here. Nevertheless, views concerning some aspects of the actions involving orbicularis oris pars marginalis deserve comment. The disposition of pars marginalis, a sharply recurved hook in the upper lip and a progressive curved 'half' hook in the lower lip, the spiral relation of marginalis to the rimal bundle of peripheralis and their linear, equatorial, deep submucosal attachment to the basis modioli has been surveyed. Contraction of marginalis is considered to alter the sectional profile of the red-lip rim; both the gentle bulbous profile of the rimal part of the upper lip and the smooth posterosuperior convexity of the lower lip transform to a narrower blunt, truncated isosceles triangular one. The narrow, blunt 'apices' (i.e. rims) of variable, but delicately controlled length and tension have been evocatively named *labial cords*. Their formation in the production of some (labial) consonantal sounds has been confirmed. A labial cord may also have a function as the so-called 'lip' of a closed organ pipe or as a frequency variable vibrating 'reed' in whistling or playing a wind instrument such as the trumpet.

Localized triangular elevation of a segment of the upper lip exemplifies partial contraction of the superior labial tractors (levators) resulting in a postural expression reminiscent of the 'canine snarl' of a number of mammals.

Masticatory Muscles

Directly concerned with mandibular movements in mastication (and speech) are the masseteric, temporal and pterygoid muscles; all are innervated by branches of the mandibular division of the trigeminal nerve. (Sharing this innervation, and in the first two instances less direct functional associations, are the mylohyoid and anterior belly of digastric, also the tensor veli palatini and the tensor tympani.) A layer of deep cervical fascia, the **parotid fascia**, covers masseter, which is firmly connected to it and then attached to the lower border of the zygomatic arch; it invests the parotid gland (p. 1291).

Masseter (5.34), a quadrilateral muscle, has three layers blended anteriorly. The *superficial layer* is largest and attached by a thick aponeurosis to the maxillary process of the zygomatic bone and anterior two-thirds of the inferior border of the zygomatic arch; it descends backwards to the mandible's angle and lower posterior half of the lateral surface of its ramus; intramuscular tendinous septa in this layer mark the ramus. The *middle layer* extends from the medial aspect of the anterior two-thirds of the zygomatic arch and lower border of its posterior third to the central part of the mandibular ramus. The *deep layer* extends from the deep surface of the zygomatic arch to the upper part of the mandibular ramus and its coronoid process. Middle and deep layers together constitute the *deep part* in Nomina Anatomica (MacDougall 1955); they form a *cruciate* muscle (p. 565). The muscle is easily palpable. MacConaill (1975) described superficial fibres as continuous at the lower mandibular border, with medial pterygoid fibres. For more complex accounts of lamination consult Schumacher (1961) and Yoshikawa & Suzuki (1969).



Relations: *superficial* are skin, platysma, risorius, zygomaticus major and parotid gland; the parotid duct, facial nerve and transverse facial vessels cross the muscle; *medial* are temporalis and the mandibular ramus. Fat separates it anteriorly from buccinator and the buccal nerve. The masseteric nerve and artery reach its deep surface via the mandibular incisure. The *posterior margin* is overlapped by the parotid gland; the *anterior margin* projects over buccinator and is crossed below by the facial vein.

Nerve supply: a branch of the anterior trunk of the mandibular nerve.

Actions: occlusion of teeth in mastication. Electrical activity with the mandible at rest is minimal. Masseter has a small effect in side-to-side movements, protraction and retraction. An analysis of its fibre numbers, diameters and distribution has been made by Rinqvist (1974).

The temporal fascia, covering temporalis, is a strong aponeurosis, overlapped by auriculares anterior and superior, epicranial aponeurosis and part of orbicularis oculi. Superficial temporal vessels and the auriculotemporal nerve ascend over it. Above, it is single and attached to the whole superior temporal line; below, it has two layers attached to the lateral and medial margins of the upper border of the zygomatic arch. Some fat, the zygomatic branch of the superficial temporal artery and zygomaticotemporal branch of the maxillary nerve are between them. To its deep surface superficial fibres of temporalis are attached.

The temporalis (5.27) extends like a fan from most of the temporal fossa (except its zygomatic part), and from the deep surface of the temporal fascia. Its fibres converge and descend into a tendon that passes between the zygomatic arch and cranial wall and is then attached to the medial surface, apex, anterior and posterior borders of the coronoid process, and anterior border of the mandibular ramus almost to the third molar tooth. The anterior fibres of temporalis descend vertically; traced posteriorly the

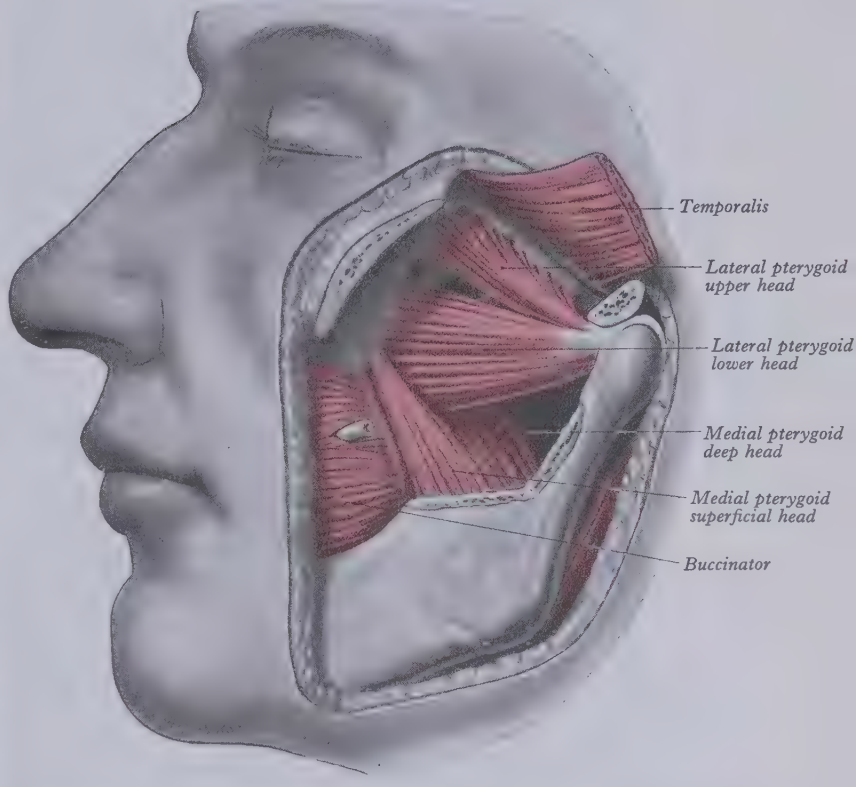
5.27 Left temporalis: the zygomatic arch and masseter have been removed. Note the changing obliquity of muscle fibres vertical anteriorly, horizontal posteriorly.

fibres are increasingly oblique, while the most posterior fibres are almost horizontal.

Relations: *superficial* are skin, auriculares anterior and superior, temporal fascia, superficial temporal vessels, auriculotemporal nerve, temporal branches of facial nerve, zygomaticotemporal nerve, epicranial aponeurosis, zygomatic arch, and masseter; *medial* are the temporal fossa, lateral pterygoid, superficial head of medial pterygoid, a small part of buccinator, the maxillary artery and its deep temporal branches, deep temporal nerves and buccal nerve and vessels. *Behind* the tendon masseteric vessels and nerve traverse the mandibular incisure. Fat separates its *anterior border* from the zygomatic bone.

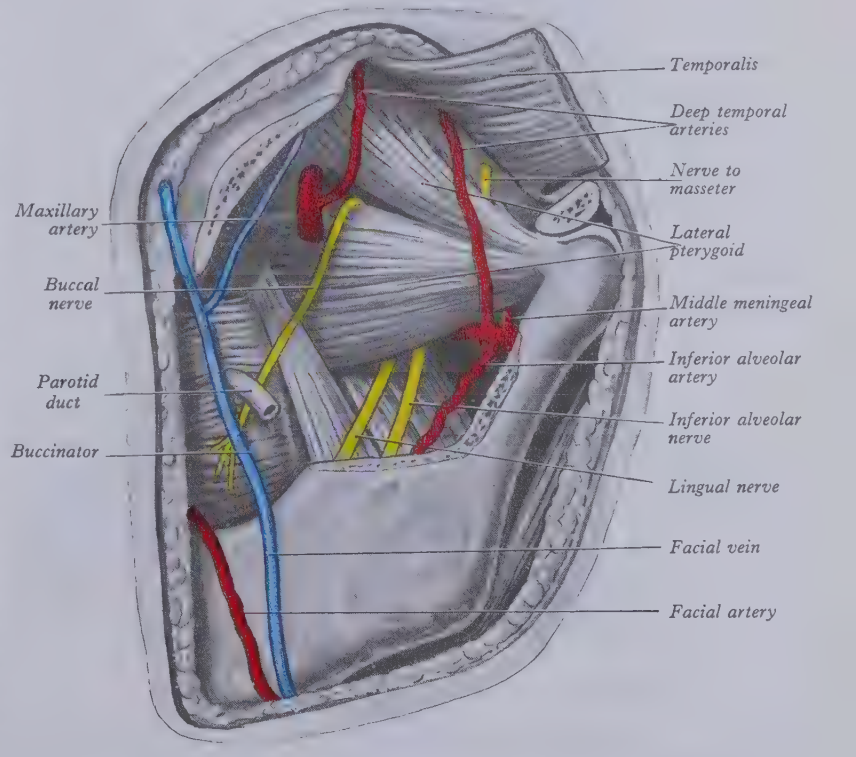
Nerve supply: deep temporal branches of the anterior trunk of the mandibular nerve.

Actions: elevation of mandible to close the mouth and approximate the teeth. This requires elevation by anterior fibres and retraction by posterior fibres, since the mandibular condylar head is on the articular eminence when the mouth is open. Posterior fibres retract the mandible from protrusion. The muscle is concerned in lateral grinding movements. Despite much electromyography, little can be added in further analysis; much unresolved disagreement exists between observers. Vitti & Basmajian (1977) suggest that temporalis is active in forcible elevation but not in slow elevation without occlusion: otherwise they confirm the above description. The contracting muscle is easily palpable despite the temporal fascia.



The lateral pterygoid (5.28) is a short, thick muscle with an upper *head* from the infratemporal surface and crest of the greater wing of the sphenoid, and a *lower head* from the lateral surface of the lateral pterygoid plate. It passes posterolaterally to a depression on the anterior aspect of the mandibular neck and to the articular capsule and disc of the temporomandibular joint.

Early in the third month in utero the muscle is attached to mesenchyme condensing round the developing mandibular condyle; part of its tendon sweeps back above the condyle to the part of Meckel's cartilage forming the head of the malleus (Harpman & Woollard 1938). This part of the tendon is absorbed into the articular disc; attachment to the malleus is lost (Rees 1954).



Relations: *superficial* are the mandibular ramus, the maxillary artery crossing deep or superficial to the muscle, the tendon of temporalis and masseter; medial are the upper part of the medial pterygoid, sphenomandibular ligament, middle meningeal artery and mandibular nerve. The *upper border* is related to the temporal and masseteric branches of the mandibular nerve; the *lower border* to the lingual and inferior alveolar nerves. The buccal nerve and maxillary artery are between the muscle's two parts (5.29).

Nerve supply is from the mandibular nerve's anterior trunk.

Action. The muscle aids opening the mouth by protracting the mandibular condyle and articular disc while the mandibular head rotates on the disc (Posselt 1952). In closure backward gliding of the disc and condyle is controlled by slow elongation of the lateral

5.28 Left pterygoid muscles: the zygomatic arch and part of the ramus of the mandible have been removed.

5.29 Structures related to the left pterygoid muscles.

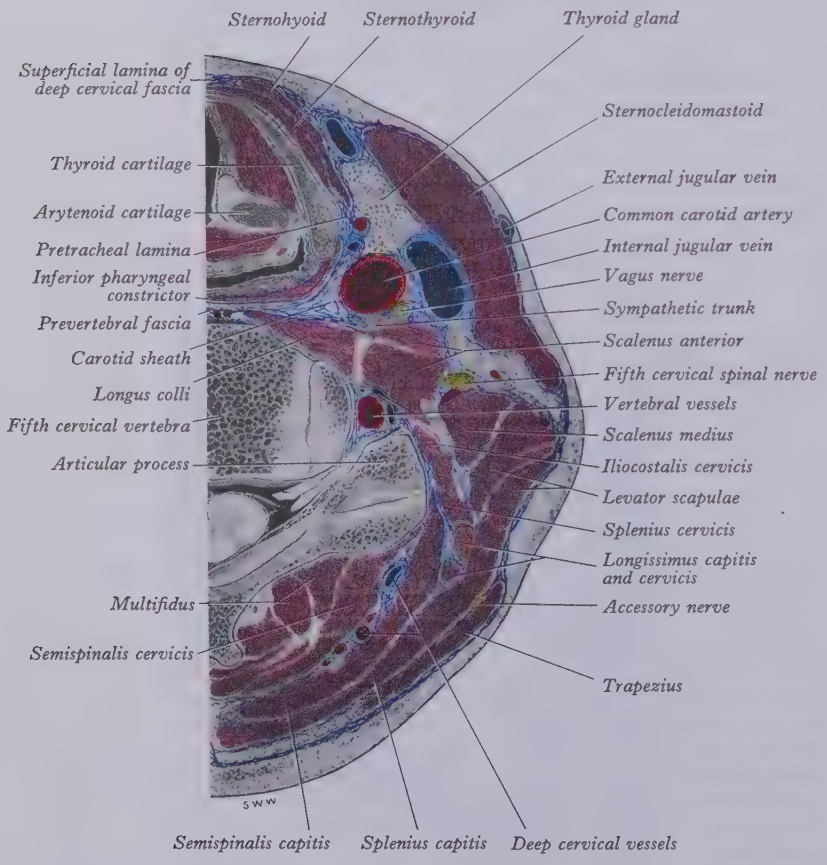
pterygoid and by masseter and temporalis, restoring the teeth to occlusion. Acting with the ipsilateral medial pterygoid the lateral advances its condyle, the mandible rotating on a vertical axis through the opposite condyle. Both medial and lateral pterygoids together protrude the mandible. Different actions have been ascribed to the two parts of the lateral pterygoid, the superior head being involved in chewing, the inferior in protrusion. Electromyographic records in rhesus monkeys (Macnamara 1972) support this. For a review consult Grant (1973).

The medial pterygoid (5.28), a thick quadrilateral muscle, is attached *deeply* to the medial aspect of the lateral pterygoid plate and grooved surface of the palatine's pyramidal process and, more *superficially*, to the lateral surfaces of the maxillary pyramidal process and the maxillary tuberosity. It descends posterolaterally to a strong tendinous lamina attached postero-inferiorly to the medial surfaces of the mandibular ramus and angle, as far as the mandibular foramen and almost to the mylohyoid groove (3.81). This area is rugged, due to tendinous fasciculi in the attachment.

Relations. *Lateral* is the mandibular ramus, from which the muscle is separated by the lateral pterygoid, sphenomandibular ligament, maxillary artery, inferior alveolar vessels and nerve, lingual nerve and a process of the parotid gland. The *medial surface* is related to tensor veli palatini, and separated from the superior constrictor by styloglossus, stylopharyngeus and areolar tissue.

Nerve supply is from the mandibular nerve. Schumacher et al (1976) have investigated nerves of masticatory muscles in detail. They observed a similar mode of branching in all of them.

Actions. The medial pterygoids assist in elevating the mandible; with the lateral pterygoids they protrude it. The pterygoid muscles of one side together rotate the mandible forwards and to the opposite side, with the opposite mandibular head as a vertical axis (p. 487); alternation of both sets of muscles, in side-to-side movements, are used to triturate food. For further analysis see pp. 487–488.



The pterygospinous ligament, sometimes partially muscular, stretches between the sphenoidal spine and posterior border of the lateral pterygoid plate near its superior end. Sometimes ossified, it then completes a foramen for branches of the mandibular nerve to the temporalis, masseter and lateral pterygoid.

ANTEROLATERAL MUSCLES AND FASCIAE OF THE NECK

Anterolateral muscles of the neck may be grouped as follows:

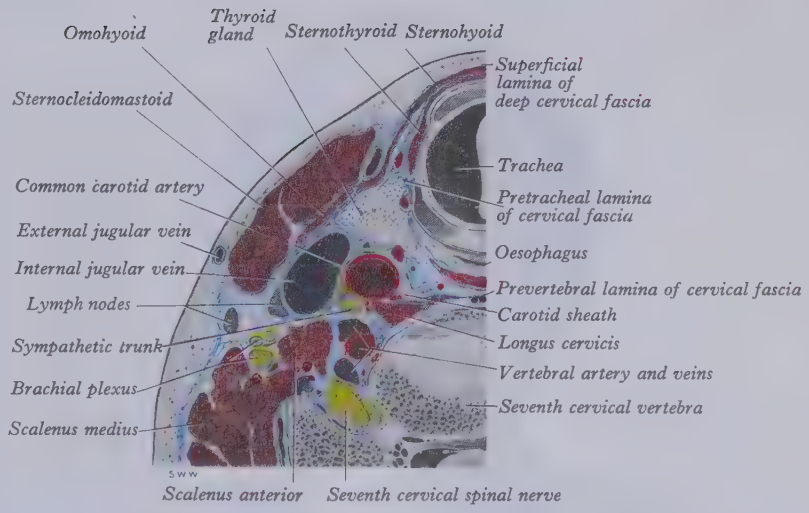
1. Superficial and lateral cervical. 3. Anterior vertebral.
2. Suprahyoid and infrahyoid. 4. Lateral vertebral.

Superficial cervical fascia, usually a thin lamina covering platysma and scarcely a separate layer, may contain considerable adipose tissue, usually more so in females. Like all superficial fascia it is not a separate stratum but a zone of loose connective tissue between the dermis and deep fascia, continuous with both.

5.30 Transverse section through the left half of the neck to show the arrangement of the deep cervical fascia. (Specimen provided by Professor R E M Bowden, Royal Free Hospital School of Medicine.)

Deep cervical fascia (5.30), internal to platysma and investing the nuchal muscles, is fibro-areolar tissue between muscles, viscera, vessels, etc. It forms certain well-defined fibrous sheets; elsewhere it is loosely arranged but condensed around blood vessels as fibrous sheaths which here, as elsewhere, enclose arteries and accompanying veins. Its *superficial (investing) lamina* is continuous with the ligamentum nuchae and periosteum of the seventh cervical spine. It thinly covers trapezius and continues from its anterior border as a loose areolar layer over the posterior triangle to the posterior border of sternocleidomastoid, where it becomes denser. It encloses this muscle and at its anterior margin unites as a single lamina over the anterior triangle to the midline and so to the opposite side; it adheres to the symphysis menti and the body of the hyoid bone.

Deep fascia is fused with periosteum along the superior nuchal line, the mastoid process and the whole mandibular base. Between the mandibular angle and anterior edge of the sternocleidomastoid it is very dense. Between the mandible and mastoid process it ensheathes the parotid gland; superficial to the gland it ascends as *parotid fascia* to the zygomatic arch; from the deep parotid layer a strong *stylomandibular ligament* (p. 486) ascends to the styloid process. Inferiorly, deep fascia is attached to the acromion, clavicle and manubrium sterni, fusing with their periostea. A little above the manubrium it splits into superficial and deep layers attached to the anterior and posterior manubrial borders and the interclavicular ligament. The slit-like *suprasternal 'space'* between the layers contain areolar tissue, lower parts of anterior jugular veins and the jugular venous arch, the sternal heads of the sternocleidomastoid muscles and sometimes a lymph node. Over the posterior triangle, inferiorly between trapezius and sternocleidomastoid, the deep fascia also has superficial and deep layers, the former attached to the superior clavicular border, the deep layer surrounding the inferior belly of omohyoid and, deep to the sternocleidomastoid, its intermediate tendon, finally blending with fascia around subclavius and the periosteum on the posterior aspect of both the clavicle and anterior end of the first rib.



The *carotid sheath*, a condensation of cervical fascia, encloses the common and internal carotid arteries, internal jugular vein, vagus nerve and constituents of the ansa cervicalis. Thicker around the arteries, it is peripherally continuous with adjacent loose areolar tissue (5.31).

The *prevertebral lamina* covers the anterior vertebral muscles, extending laterally on scaleni anterior and medius and levator scapulae as a fascial floor of the posterior triangle. The subclavian artery and brachial nerves, emerging from *behind* scalenus anterior, carry prevertebral fascia inferolaterally behind the clavicle as

the *axillary sheath*. Laterally, the lamina is thin and areolar, ceasing to be a definite layer under trapezius. Superiorly it is attached to the cranial base and inferiorly descends in front of longus colli into the superior mediastinum, blending with the anterior longitudinal ligament. Anteriorly the prevertebral lamina is separated from the pharynx and buccopharyngeal fascia by an areolar zone, the so-called *retropharyngeal space*; laterally this tissue connects the lamina to the carotid sheath and fascia on the deep aspect of sternocleidomastoid. Ventral rami of cervical spinal nerves are at first behind the prevertebral lamina; nerves to the rhomboids and serratus anterior and phrenic nerve retain this position in the neck but the accessory nerve is superficial (p. 1119).

The *pretracheal lamina* is very thin but ensheathes the thyroid gland, is attached to the arch of the cricoid cartilage and continues into the superior mediastinum with the inferior thyroid veins.

Applied Anatomy. The superficial lamina of deep cervical fascia opposes the superficial extension of abscesses, and pus tends to extend laterally. In the anterior triangle it may reach the mediastinum, anterior to the pretracheal lamina; but due to the thinness of the fascia here it more often 'points' above the sternum. Pus behind the prevertebral lamina may extend laterally into the posterior triangle or may perforate the lamina and buccopharyngeal fascia, bulging into the pharynx as a retro-pharyngeal abscess.

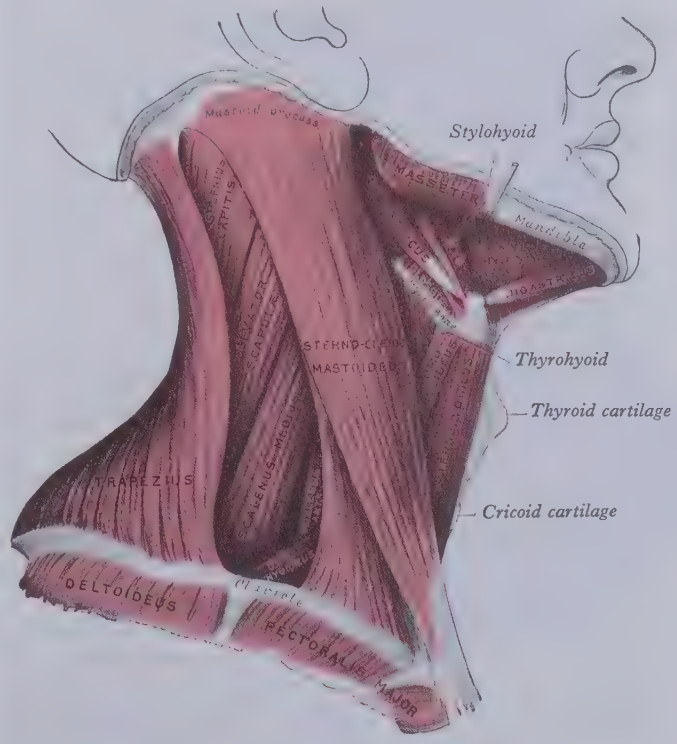
5.31 Part of a transverse section through the lower part of the neck at the level of the seventh cervical vertebra to show the arrangement of the deep cervical fascia. (Specimen provided by R E M Bowden.)

1. SUPERFICIAL AND LATERAL CERVICAL MUSCLES

These include platysma, trapezius and sternocleidomastoid.

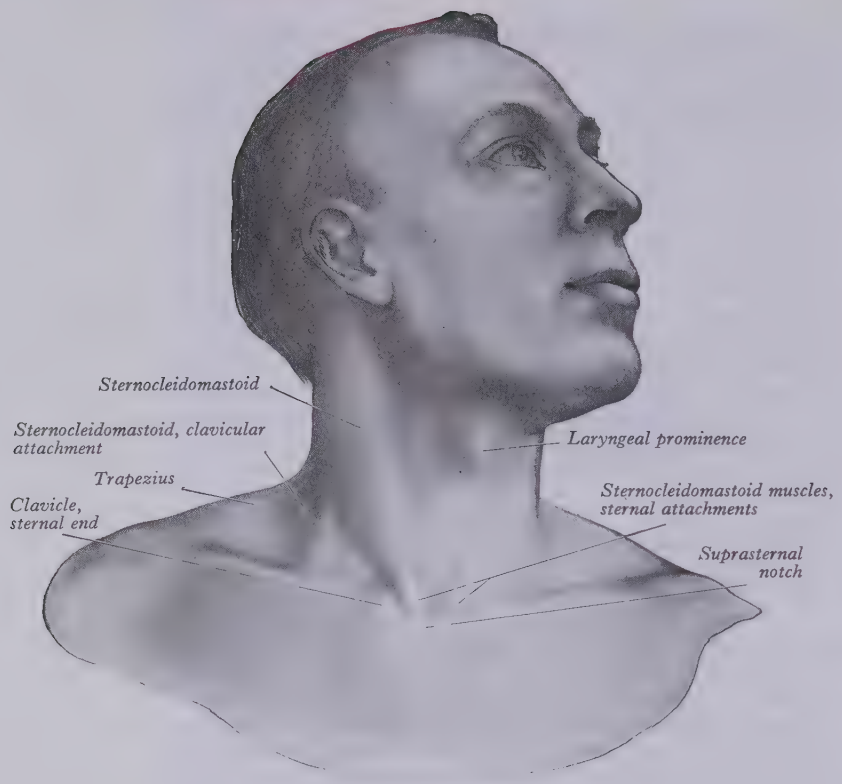
Platysma (5.21) is a broad sheet spreading from its fascial attachments over the upper parts of pectoralis major and deltoid and ascending medially across the clavicle to the side of the neck. Anterior fibres interlace across the midline inferoposterior to symphysis menti. Intermediate fibres are attached to the lower border of the mandibular body or pass upwards and medially deep to depressor anguli oris to their attachments in the lateral half of the lower lip (*pars labialis*, see p. 577). The posterior fibres cross the mandible and anterolateral part of the masseter to the skin and subcutaneous tissue in the lower face, blending with muscles at the modiolus near the buccal angle. Deep to the platysma the external jugular vein descends from the mandibular angle to the mid-clavicular point. The muscle varies much in extent and may even be absent. Slips from the mastoid process, occipital bone or fascia over the upper trapezius may join it (occipitalis minor).

Nerve supply is from the cervical branch of the facial nerve.



Actions. Platysma wrinkles the nuchal skin obliquely, diminishing the concavity between jaw and neck. Its anterior, thickest part may assist mandibular depressors. By drawing down the lower lip and buccal angle it helps to express horror and surprise. It is electromyographically active in sudden deep inspiration (de Sousa 1964) and often very much contracted in sudden, violent efforts.

Trapezius is described on p. 608 with scapular musculature.



The sternocleidomastoid (5.32) descends obliquely across the neck (5.33), and is a prominent landmark when contracted. It is thick and narrow centrally and broader and thinner at each end; inferiorly it has two 'heads'. The *medial (sternal) head*, a rounded tendinous fasciculus, is attached to the upper anterior surface of manubrium sterni and ascends posterolaterally. The *lateral (clavicular) head*, variable in width and composed of muscular and fibrous fasciculi, ascends almost vertically from the medial third of the clavicle's superior surface. The two parts are separated near their attachment by a triangular interval which corresponds to a surface depression, the *lesser supraclavicular fossa*. As they ascend the clavicular part spirals behind the sternal, soon blending with its deep surface to form a thick, rounded mass. Superiorly this is attached by a strong tendon to the mastoid process's lateral aspect, from its apex to its superior border, and by a thin aponeurosis to the lateral half of the superior nuchal line. Clavicular fibres mainly reach the mastoid process; sternal fibres are more oblique, superficial and reach the occiput. Traction by the two heads therefore differs; the muscle is 'cruciate' and slightly 'spiralized' (p. 566).

This muscle divides the anterolateral aspect of the neck into principal *anterior* and *posterior triangles*. Boundaries of the *anterior cervical triangle* are the median ventral line, the base of the mandible and a line from its angle to the mastoid process and the anterior sternocleidomastoid border; its apex is at the superior sternal border. Boundaries of the *posterior cervical triangle* are the posterior border of sternocleidomastoid, the middle third of the clavicle's superior surface and the anterior margin of trapezius; its apex is where sternocleidomastoid and trapezius approach or meet at the occiput. The subdivisions and contents of these major triangles are described on pp. 741–743.

Relations. *Superficial* are skin and platysma and deep to these the external jugular vein, great auricular and transverse cervical nerves and superficial lamina of the deep cervical fascia. The muscle is overlapped by a small part of the parotid gland. *Deep* are the sternoclavicular joint, sternohyoid, sternothyroid, omohyoid and anterior jugular vein crossing superficial to the infrahyoid

5.32 Muscles of the neck: right lateral aspect.

5.33 Surface landmarks of the neck.

muscles and with the carotid sheath and subclavian artery deep to them. Between the omohyoid and the posterior belly of the digastric sternocleidomastoid is superfical to the common, internal and external carotid arteries, the internal jugular, facial and lingual veins, the deep cervical lymph nodes, vagus nerve and rami of ansa cervicalis. The sternocleidomastoid branch of the superior thyroid artery crosses deep to the muscle at the upper border of omohyoid. The posterior part of the sternocleidomastoid is related internally to splenius, levator scapulae and the scaleni, the cervical plexus, upper part of brachial plexus, phrenic nerve, and transverse cervical and suprascapular arteries. The occipital artery crosses deep to the muscle near the lower border of the digastric, where the accessory nerve, piercing the muscle, descends laterally deep to it. Superiorly, the muscle is superficial to the mastoid process, splenius, longissimus capitis and the posterior belly of digastric.

Nerve supply is the accessory nerve, which usually traverses the muscle and branches of ventral rami of the second, third and sometimes fourth cervical spinal nerves; although these cervical rami were long considered solely proprioceptive, clinical evidence suggests that some of these cervical fibres are motor (see Fitzgerald et al 1982).

Actions. Acting alone, the muscle tilts the head towards the ipsilateral shoulder, turning the face to the opposite side, as in an upward, sideways glance. But level rotation, a much commoner visual movement, is probably the most frequent use of the sternocleidomastoids. Together they also project the head forwards, assisting the longi colli in cervical flexion, a common movement in feeding. They also raise the head from the supine position. With the head fixed, they aid thoracic elevation in inspiration. Electromyography (e.g. de Sousa 1973) suggests that sternal fibres are more active in contralateral rotation but that both parts are involved in all the above movements; the muscle may also, apparently, be involved in cervical *extension*.

Applied Anatomy. *Torticollis* is due to permanent contracture of sternocleidomastoid. Spasmodic torticollis, in adults, begins with tonic or clonic spasm of one muscle, followed by spasm of trapezius. Such abnormal conditions illustrate the isolated muscle's action, but this is a caricature of its ordinary activities; these are invariably modified by synergists and antagonists, such as splenius capitis (p. 587) and others.

2 (A). THE SUPRAHYOID MUSCLES

The *suprahyoid* group include digastric, stylohyoid, mylohyoid and geniohyoid muscles.

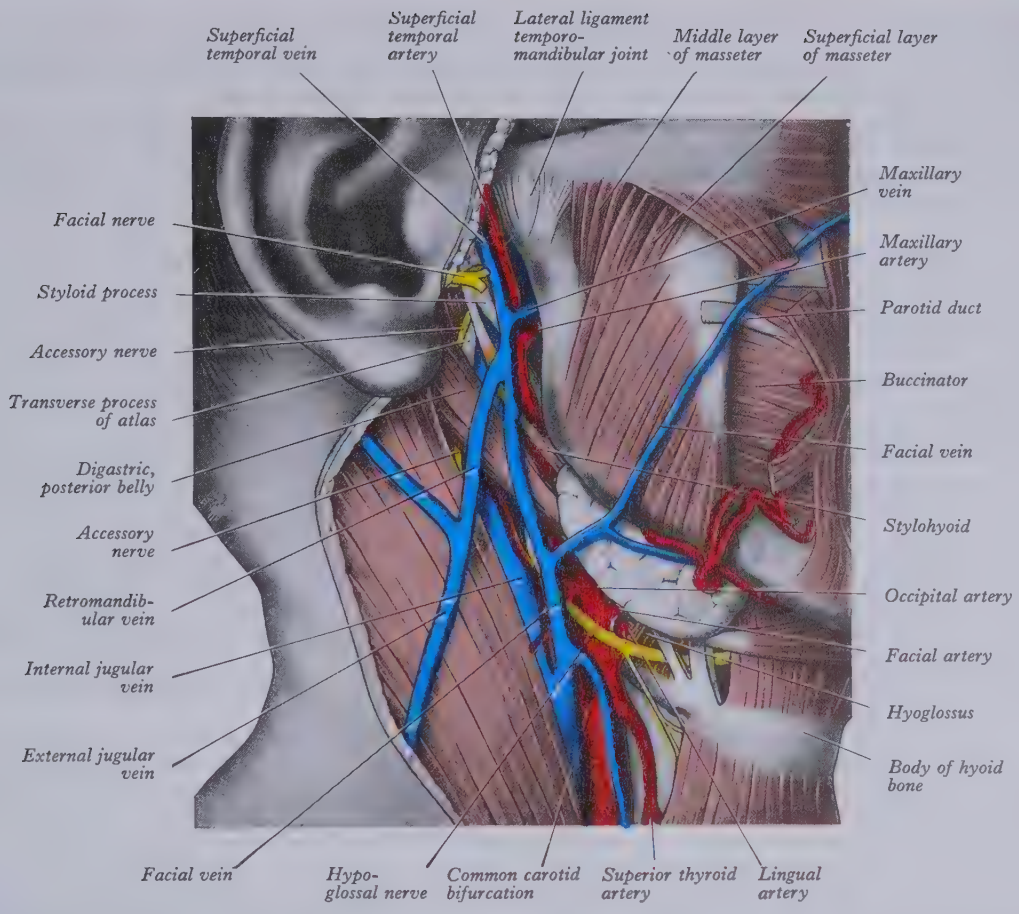
Digastric (5.32,34,35) has two bellies and an intermediate tendon. Inferior to the mandible, it angles from the mastoid process to the chin. Its longer, *posterior belly* is attached in the temporal mastoid notch and slopes down and forwards; the *anterior belly* is attached to the mandible's digastric fossa near the midline and inclines backwards. The two parts meet in a rounded tendon, perforating the stylohyoid and held to the hyoid's body and greater cornu by a fibrous loop, sometimes lined by a synovial sheath. An aponeurosis extends from the tendon to the hyoid body and greater cornu. The tendon may be absent and the muscle is then attached midway along the mandibular body. Its posterior belly may be augmented by a slip from the styloid process or be wholly attached to it. The anterior belly may partly cross the midline and is sometimes partially fused with mylohyoid.

Relations. *Superficial* yoidare platysma, sternocleidomastoid, part of splenius, longissimus capitis, the mastoid process, stylohyoid, retromandibular vein and parotid and submandibular salivary glands. *Medial* to the anterior belly is mylohyoid; medial to the posterior belly are superior oblique, rectus capitis lateralis, the transverse process of atlas, accessory nerve, internal jugular vein, occipital artery, hypoglossal nerve, internal and external carotid, facial and lingual arteries and hyoglossus (5.34).

Nerve supply: the anterior belly by the mylohyoid branch of the inferior alveolar nerve; posterior belly by the facial nerve. These supplies accord with derivations from the mesenchyme of the first and second brachial arch (p. 172). Lennartsson (1979) has described proprioceptors.

Actions: mandibular depression and hyoid elevation. Electromyography indicates that the muscles always act together and are secondary to the lateral pterygoids in mandibular depression, assisting maximal depression (Moyers 1950); the posterior bellies are active in swallowing and chewing.

Stylohyoid (5.34,35) is attached by a tendon to the posterior aspect of the styloid process near its base, descending forwards to the hyoid body at its junction with the greater cornu, above the omohyoid, where it is perforated by the digastric tendon. Occasionally the muscle is absent or double; it is medial to the external carotid artery; it may end in digastric or in supra- or infrahyoid muscles.



Nerve supply: a branch of the facial nerve.

Actions. Stylohyoid elevates and retracts the hyoid bone, elongating the buccal floor. With other hyoid muscles it fixes the hyoid bone, the basis for lingual muscles attached to it. Its roles in masticatory and vocal movements have not been adequately analysed (p. 1273).

The stylohyoid ligament, a fibrous cord, extends from the tip of the styloid process to the lesser hyoid cornu. The highest fibres of the middle pharyngeal constrictor are attached to it. It is intimately related to oropharynx (5.25). Below, it is overlapped by hyoglossus. Derived from the cartilage of the second branchial arch (p. 171), it may be partially ossified; in many mammals it is a distinct *epihyal* bone.

The mylohyoid (5.32,35), superior to the anterior digastric belly, forms with its fellow a muscular floor for the oral cavity. It is flat, triangular and attached along the mandible's whole mylohyoid line. Posterior fibres pass medially and slightly down to the hyoid body's front, near its lower border. Middle and anterior fibres from each side decussate in a median fibrous raphe stretching from symphysis menti to the hyoid bone; but this may be absent, the muscles then being a continuous sheet. Sometimes mylohyoid is fused with the anterior belly of digastric.

Relations. The *inferior (superficial) surface* is related to the platysma, anterior digastric belly, superficial part of the submandibular gland, facial and submental vessels, mylohyoid vessels and nerve. The *superior (internal) surface* is related to the geniohyoid, part of hyoglossus, styloglossus, hypoglossal and lingual nerves, the submandibular ganglion, sublingual gland, the deep part of the submandibular gland and duct, lingual and

5.34 Relations of many faciocervical structures, exposed by the removal of only skin, fasciae, parotid glands and cutaneous branches of the cervical plexus. Focal regions to be noted are the carotid triangle and some of its principal contents and the styloid process in the floor of the mandibulo-mastoid gap. The labial modiolus is omitted and details of labial musculature simplified.

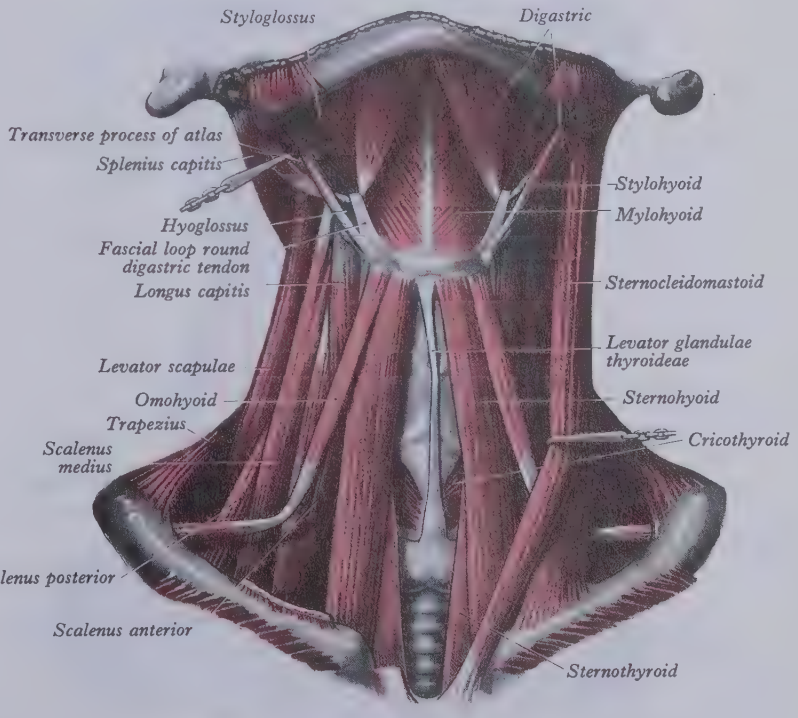
sublingual vessels and, posteriorly, the oral mucous membrane. A hiatus in the muscle, through which a process of sublingual gland protrudes, was noted in one-third of cases by Gaughran (1963).

Nerve supply: mylohyoid branch of the inferior alveolar nerve.

Actions: elevation of the oral floor in the first stage of deglutition (Whillis 1946). It may also elevate the hyoid bone or depress the mandible.

The geniohyoid (5.35), a narrow muscle above the medial part of mylohyoid, extends from the inferior mental spine behind symphysis menti to the anterior aspect of the hyoid body; it adjoins its fellow and may fuse with it or genioglossus.

Nerve supply: the first cervical spinal nerve, through the hypoglossal nerve (p. 1119).



Actions. Geniohyoid elevates the hyoid bone and draws it forwards as a partial antagonist to stylohyoid. When the hyoid is fixed, it depresses the mandible.

2 (B). THE INFRAHYOID MUSCLES

The *infrahyoid* group includes sternohyoid, sternothyroid, thyrohyoid and omohyoid muscles. As antagonists to the suprahyoid group they depress the hyoid bone but may act as fixators or co-operate in cyclic hyoid movements.

Sternohyoid (5.32,35), a thin, narrow strap, extends from the posterior aspect of the clavicle's medial end, the posterior sternoclavicular ligament and the upper posterior aspect of manubrium sterni, ascending medially to the inferior border of the hyoid body. Below, it is separated from its fellow but the two usually meet at midpoint and are contiguous above this. The muscle may be absent, double, augmented by a clavicular slip (*cleidohyoid*) or interrupted by a tendon.

Nerve supply: ansa cervicalis (c.1,2,3).

5.35 Muscle of the front of the neck. On the right side the sternocleidomastoid has been removed. In this subject, the origin of the scalenus medius extended up to the transverse process of the atlas.

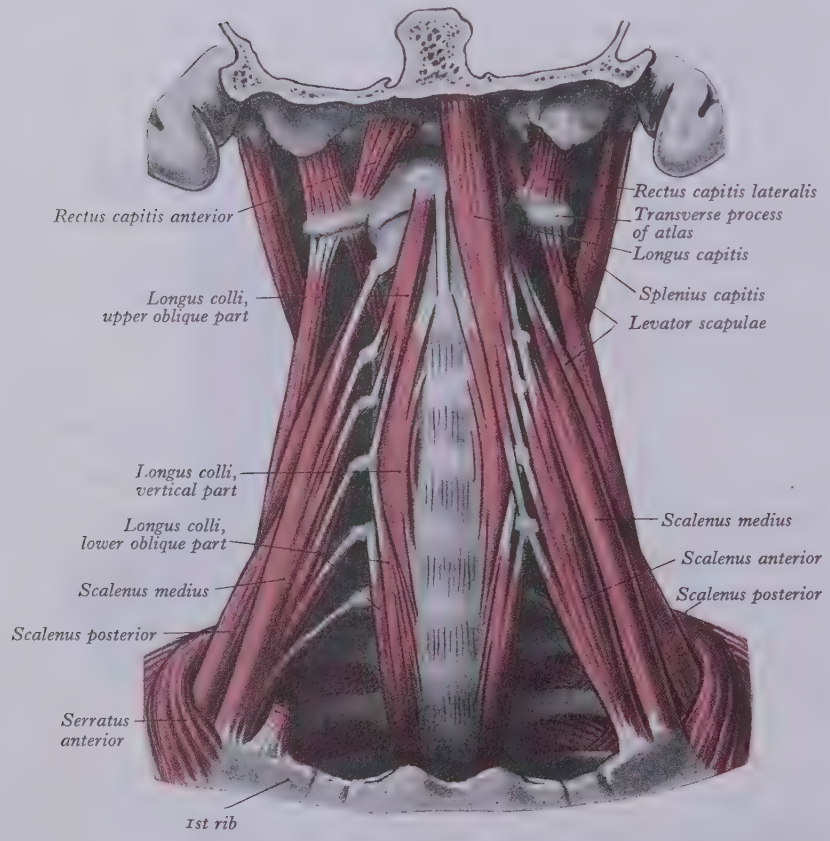
Actions: hyoid depression after elevation in deglutition, speech and mastication.

Sternothyroid (5.32,35), shorter and wider than sternohyoid, is deep and partly medial to it. It is attached below to the posterior manubrial surface inferior to the sternohyoid and to the posterior edge of the first costal cartilage; and above to the oblique line on the thyroid lamina. Inferiorly it is in contact with its fellow but diverges as it ascends. It is anterolateral to the thyroid gland.

Nerve supply: from ansa cervicalis (c.1,2,3).

Actions: depression of the elevated larynx after swallowing or in vocal movements.

Thyrohyoid, a small quadrilateral muscle, appears as an upward continuation of the sternothyroid. From the thyroid lamina's oblique line it ascends to lower border of the greater cornu and adjacent hyoid body.



Nerve supply: a branch of the hypoglossal nerve. Like the branch to geniohyoid this contains fibres from the first cervical spinal nerve, which supply the muscle.

Actions: hyoid depression or elevation of the larynx, or varying mixtures of both.

Omohyoid (5.32,35) has two bellies united at an angle by an intermediate tendon. Its inferior belly, a flat narrow band, extends from the upper scapular border, near the scapular notch, and occasionally the superior transverse scapular ligament (p. 501), inclining forwards and slightly up across the lower neck to pass deep to the sternocleidomastoid as the intermediate tendon. It divides the posterior triangle into upper and lower parts (p. 742). The *superior belly* ascends almost vertically from this tendon, near the lateral border of sternohyoid to the lower border of the hyoid body, lateral to sternohyoid's attachment. The variable intermediate tendon is usually near the internal jugular vein, opposite the cricoid arch. It is ensheathed by a band of deep cervical fascia that descends to the clavicle and first rib, maintains the angulation between its bellies and may contain some striated muscle. Either belly may be absent or double; the inferior may be attached to the clavicle; the superior is sometimes fused with the sternohyoid (Buntine 1970).

Nerve supply. Superior and inferior bellies are supplied respectively by branches from the superior ramus of the ansa cervicalis (c.1) and the ansa itself (c.2,3).

Actions: hyoid depression in prolonged inspiratory efforts; omohyoid may also tense the lower deep cervical fascia, lessening the inward suction of soft parts. Electromyographic data for hyoid musculature are sparse.

5.36 The anterior and lateral vertebral muscles. On the right side the scalenus anterior and the longus capitis have been removed.

3. THE ANTERIOR VERTEBRAL MUSCLES

This group includes longi colli and capitis and recti capitis anterior and lateralis, all partly flexors of head and neck (5.36).

M. longus colli, placed anterior to the vertebral column, extends between the atlas and the third thoracic vertebra. Divisible into inferior oblique, superior oblique and vertical parts, all are attached by tendinous slips. The *inferior oblique part* is smallest and ascends laterally from the fronts of the first two or three thoracic vertebral bodies to the anterior tubercles of the fifth and sixth cervical transverse processes. The *superior oblique part* ascends medially from the anterior tubercles of third to fifth cervical transverse processes to a narrow tendon attached to the anterolateral surface of the atlantal anterior tubercle. The *vertical*, intermediate part ascends from anterior aspects of the upper three thoracic and lower three cervical vertebral bodies to those of the second to fourth cervical.

Nerve supply: ventral rami of second to sixth cervical vertebrae spinal nerves.

Actions: forward flexion of the neck acting as a whole; additionally the oblique parts flex it laterally and the inferior oblique rotates it to the opposite side. Electromyography (Fountain et al 1966) largely confirms the above, except for lateral flexion. The main antagonist is longissimus cervicis.

M. longus capitis is broad and thick above, narrow below, where tendinous slips are attached to the *transverse processes* of the third to sixth cervical vertebrae at their anterior tubercles, extending above to the inferior surface of the basilar occipital bone.

Nerve supply: ventral rami of the first to third cervical spinal nerves.

Action: flexion of the head.

Anterior vertebral muscles vary chiefly in numbers of vertebral slips.

M. rectus capitis anterior, a short, flat muscle behind the upper part of longus capitis, ascends from the anterior surface of the lateral atlantal mass and root of its transverse process almost vertically to the inferior surface of the basilar occipital bone immediately anterior to its occipital condyle.

Nerve supply: the loop between the ventral rami of the first and second cervical spinal nerves.

Action: flexion of the head at the atlanto-occipital joints.

M. rectus capitis lateralis is a short, flat muscle extending from the upper surface of the atlantal transverse process to the inferior surface of the occipital jugular process. From these attachments and its relation to the ventral ramus of the first spinal nerve, the muscle is homologized with posterior intertransverse muscles.

Nerve supply: the loop between the ventral rami of the first and second cervical spinal nerves.

Action: lateral flexion of the head.

The actions of these deep-seated muscles can only be deduced; their precise roles in natural activities await adequate technical demonstration.

4. THE LATERAL VERTEBRAL MUSCLES

The scaleni, anterior, medius and posterior, extend obliquely like *scaling* ladders between the upper two ribs and cervical vertebral transverse processes (5.36).

Scalenus anterior is situated deep (posteromedial) to the sternocleidomastoid. From the third to sixth cervical anterior tubercles musculotendinous fascicles converge, blend and then descend almost vertically to a narrow, flat tendon attached to the scalene tubercle on the first rib's inner border and a ridge anterior to the subclavian arterial groove.

Relations. *Anterior* are the clavicle, subclavius, sternocleidomastoid, omohyoid, the lateral part of the carotid sheath, transverse cervical, suprascapular and ascending cervical arteries, subclavian vein, prevertebral fascia and phrenic nerve. *Posterior* are the suprapleural membrane (p. 1269), pleura, roots of the brachial plexus, and subclavian artery; the latter two separate it from scalenus medius. *Below* its attachment to the sixth cervical vertebra, the medial border of the muscle is separated from longus colli by an *angular interval* (5.36) in which vertebral artery and vein ascend to the sixth foramen transversarium. The inferior thyroid artery crosses the interval near its apex and the sympathetic trunk and its cervicothoracic ganglion are here close to the posteromedial side of the vertebral artery (6.63). The thoracic duct crosses the left triangular interval level with the seventh cervical vertebra and usually contacts the medial edge of scalenus anterior. The musculotendinous attachments of scalenus anterior to anterior tubercles are separated from those of longus capitis by the ascending cervical branch of the inferior thyroid artery.

Nerve supply: ventral rami of the fourth to sixth cervical spinal nerves.

Actions. Acting from below, scalenus anterior bends the neck anterolaterally and rotates it contralaterally; from above it helps to elevate the first rib.

Scalenus medius, largest and longest of the scaleni, runs from the transverse process of the axis (and sometimes atlas) and lower five cervical posterior tubercles (5.35) to the first rib's upper surface, between its tubercle and the groove for the subclavian artery.

Relations. Its *anterolateral surface* is related to sternocleidomastoid; it is crossed by the clavicle and omohyoid; *anteriorly*, it is separated from scalenus anterior by the subclavian artery and ventral rami of the cervical spinal nerves. Levator scapulae and scalenus posterior are posterolateral. The upper two roots of the nerve to serratus anterior and the dorsal scapular nerve (to the rhomboids) pierce the muscle and appear on its lateral surface.

Nerve supply: third to eighth cervical spinal ventral rami.

Actions. From below, scalenus medius bends the neck ipsilaterally; from above it helps to raise the first rib. Scalene muscles, particularly the medius, are active during inspiration, even quiet breathing in the erect attitude (Campbell 1955).

Scalenus posterior, the smallest and most deeply situated, extends from the fourth, fifth and sixth cervical posterior tubercles to a thin tendon attached to the second rib's external border and its surface behind serratus anterior. It is occasionally blended with scalenus medius.

Scalene muscles vary in the number of their attachments, degree of separation and segmental innervation.

Nerve supply: lower three cervical spinal ventral rami.

Actions: ipsilateral flexion of the lower cervical vertebral column with the second rib fixed; from above, elevation of the second rib.

The scalenus minimus pleuralis is associated with the suprapleural membrane and cervical pleura (see p. 1269).

FASCIAE AND MUSCLES OF THE TRUNK

Muscles of the trunk may be grouped as follows:

1. Deep muscles of the back.
2. Suboccipital muscles.
3. Muscles of the thorax.
4. Muscles of the abdomen.
5. Muscles of the pelvis.
6. Muscles of the perineum.

1. Deep Muscles of the Back

The deep (intrinsic) dorsal muscles are a complex extending from pelvis to skull, including extensors and rotators of the head and neck (splenius capitis and cervicis), short segmental muscles (interspinales and intertransversarii), and spinal extensors and rotators (erector spinae and transversospinalis, the latter comprising semispinales, rotatores, and multifidus). Collectively these muscles control the vertebral column (5.37), acting in concert with numerous other muscles.

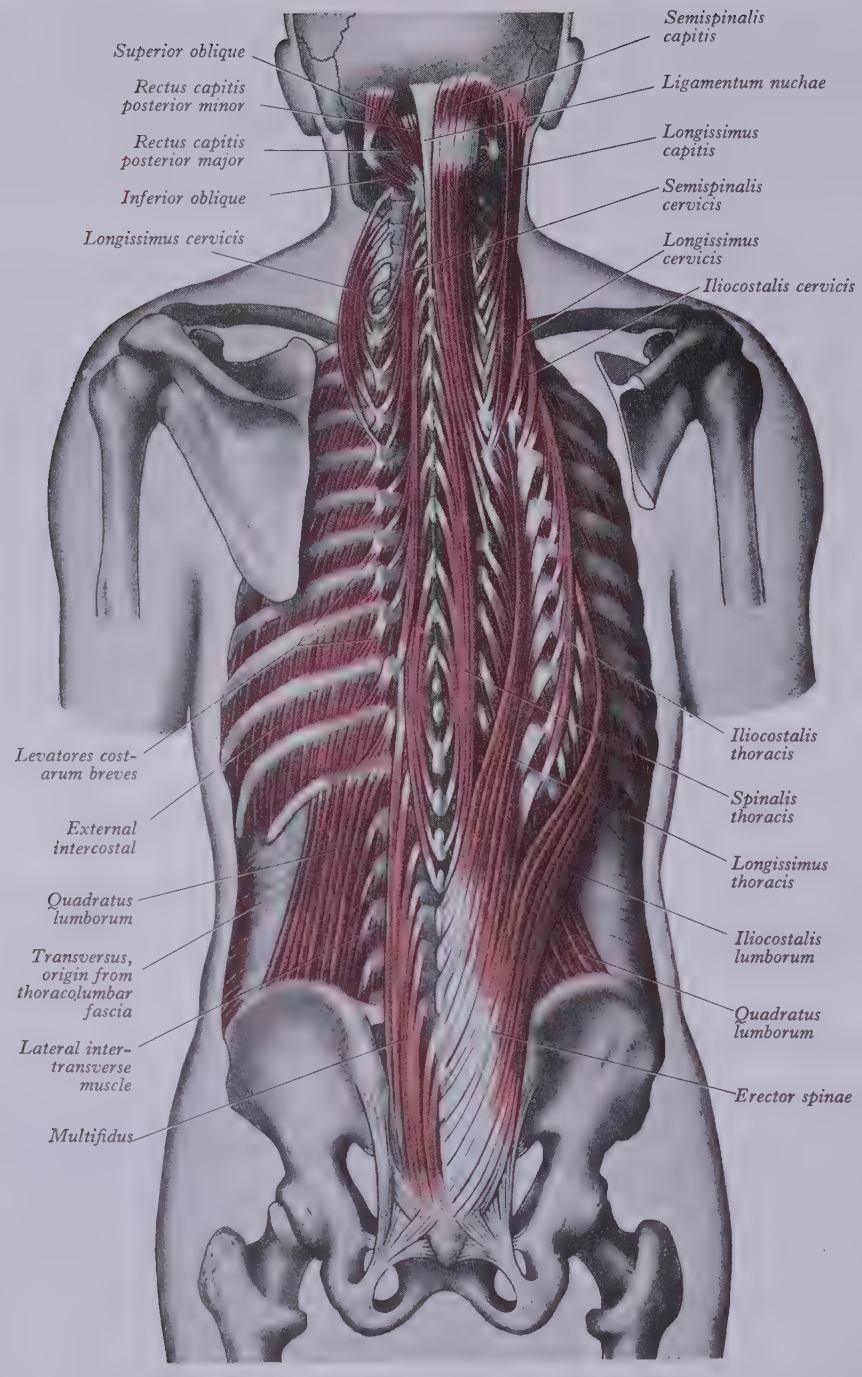
Superficial and *deep fasciae* of the neck are described on p. 608.

The thoracolumbar (lumbar) fascia covers these deep muscles. *Above*, it is anterior to serratus posterior superior and continuous with the superficial lamina of deep posterior cervical fascia. At *thoracic levels* it is a thin covering for vertebral extensors, separating them from the muscles connecting the vertebral column to the upper extremity. It is attached *medially* to the thoracic spines, *laterally* to the costal angles. At *lumbar levels* it is trilaminar (5.38); its posterior layer is attached to the lumbar and sacral spines and supraspinous ligaments, the middle *medially* to tips of lumbar transverse processes and intertransverse ligaments, *below* to the iliac crest and *above* to the twelfth rib's lower border and lumbocostal ligament (p. 497). The anterior layer covers quadratus lumborum and is attached *medially* to the anterior aspects of the lumbar transverse processes behind psoas major, *below* to the iliolumbar ligament and adjoining iliac crest; *above* it forms the lateral arcuate ligament (p. 592). Posterior and middle layers unite at the lateral margin of erector spinae and at the lateral margin those of quadratus lumborum are joined by the anterior layer, together forming a posterior aponeurosis for transversus abdominis. Bogdule & Macintosh (1984) describe the posterior lamina as being itself bilaminar; they have developed interesting concepts of the fascia's functions.

Splenius capitis (5.58) is attached below to the dorsal edge of the lower half of ligamentum nuchae, the spines of the seventh cervical and upper three or four thoracic vertebrae and their supraspinous ligaments (deep to rhomboids and trapezius). The muscle ascends laterally deep to sternocleidomastoid, reaching the mastoid process and rough surface below the lateral third of the superior nuchal line. It partly floors the posterior triangle, above and behind levator scapulae.

Nerve supply: dorsal rami of the middle cervical spinal nerves.

Splenius cervicis ascends from the third to the sixth thoracic spines to the upper two or three cervical posterior transverse tubercles, anterior to the attachments of levator scapulae. It may be absent, variable in attachments or possess accessory slips.



Nerve supply: dorsal rami of the lower cervical spinal nerves.

Actions. Together the splenii retract the head; separately, they draw it to one side, with slight rotation to turn the face to the same side, in synergy with the contralateral sternocleidomastoid.

THE ERECTOR SPINAE (SACROSPINALIS)

This muscle and its prolongations to thoracic and cervical levels are in a groove flanking the vertebral column (5.37), covered in the lumbar and thoracic regions by thoracolumbar fascia, serratus posterior inferior below and rhomboid and splenial muscles above. It is a large musculotendinous mass, varying in size and composition at different levels. In the sacral region it is relatively narrow and U-shaped but its attachments are chiefly tendinous and of great strength. In the lumbar region it expands into a thick *fleshy* mass, readily palpable, its lateral border flanked by a visible surface groove (5.39). As it ascends across the thorax, the groove follows the costal angles, first inclining laterally, then vertically, finally inclining medially until it is obscured by the scapula. (Parts of this muscular mass have been subjected to an interesting investigation of patterns of types of muscle fibres by Surca & Kostere 1985.)

Erector spinae springs from the anterior surface of a broad, thick tendon attached (medial limb of the U) to the median sacral crest, lumbar and eleventh and twelfth thoracic spines, their supraspinous ligaments and (lateral limb of the U) to the medial aspect of the dorsal part of iliac (p. 424) and lateral sacral crests (p. 325), where it blends with the sacrotuberous and dorsal

5.37 The deep muscles of the back. On the left side the erector spinae and its upward continuations (with the exception of the longissimus cervicis, which has been displaced laterally) and the semispinalis capitis have been removed.

sacro-iliac ligaments. Some fibres are continuous with glutéus maximus and many, centrally placed, with multifidus. From all aspects of the tendon muscle fibres arise and form a large mass which divides in the upper lumbar region into three columnar muscles: *iliocostocervicalis* (lateral), *longissimus* (intermediate) and *spinalis* (medial); each is regionally subdivided as follows:

Iliocostocervicalis

Iliocostalis lumborum has flat tendons which reach the inferior borders of the lower six or seven costal angles.

Iliocostalis thoracis starts from the upper borders of the lower costal angles, *medial* to the above; it ascends to the superior borders of the upper costal angles and the back of the seventh cervical transverse process.

Iliocostalis cervicis ascends from the third to sixth costal angles, *medial* to the tendons of iliocostalis thoracis and to the posterior tubercles of the fourth to sixth cervical transverse processes.

Nerve supply: dorsal rami of the cervical, thoracic and upper lumbar spinal nerves.

Actions: extension and lateral flexion of the vertebral column (p. 590).

Longissimus

Longissimus thoracis is the largest part of erector spinae. In the lumbar region, already separate from iliocostalis lumborum, it is partly attached to the entire posterior surfaces of the lumbar transverse and accessory processes and to the middle layer of thoracolumbar fascia. Its rounded tendons reach the tips of all thoracic transverse processes and the lower nine or ten ribs between their tubercles and angles.

Longissimus cervicis, medial to l.thoracis, extends from the

long tendons attached to the upper four or five *thoracic* transverse processes to again form tendons attached to the second to sixth *cervical* transverse process posterior tubercles.

Longissimus capitis, between l.cervicis and semispinalis capitis, is attached by tendons to the upper four or five thoracic transverse and lower three or four cervical articular processes; it reaches the posterior margin of the mastoid process, deep to splenius capitis and sternocleidomastoid. It usually has a tendinous intersection near its upper end.

Nerve supply: dorsal rami of the lower cervical, thoracic and lumbar spinal nerves.

Actions. The longissimi thoracis and cervicis bend the vertebral column back and laterally; longissimus capitis extends the head, turning the face to the same side.

Spinalis

Spinalis thoracis, the medial part of erector spinae, is scarcely a separate muscle, lying medial to longissimus thoracis and blended with it. It springs by three or four tendons from the eleventh thoracic to the second lumbar spines which unite to form a small muscle attached by separate tendons to the upper thoracic spines, varying from four to eight. It blends with semispinalis thoracis which lies anterior to it.

Spinalis cervicis, an inconstant muscle, ascends from the lower ligamentum nuchae, the seventh cervical spine (and sometimes first and second thoracic) to reach the spine of the axis (occasionally the two below it). It is often absent.

Spinalis capitis is variably blended with semispinalis capitis.

Nerve supply: dorsal rami of the lower cervical and the thoracic spinal nerves.

Actions. The spinales are extensors of the vertebral column.

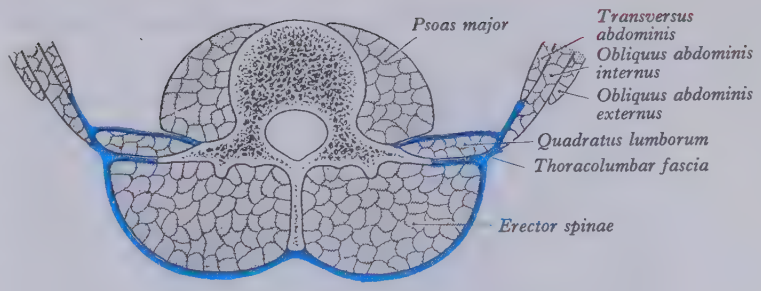
TRANSVERSOSPINALIS

This muscular group consists of the following:

Semispinalis thoracis.	Multifidus.	Rotatores thoracis.
Semispinalis cervicis.		Rotatores cervicis.
Semispinalis capitis.		Rotatores lumborum.

These muscles ascend obliquely and medially from the transverse processes to adjacent but sometimes more distant vertebral spines.

Semispinalis thoracis consists of thin fasciculi between long tendons extending from the lower attachments to the sixth to tenth thoracic transverse processes, thence to the upper four thoracic and lower two cervical spines.

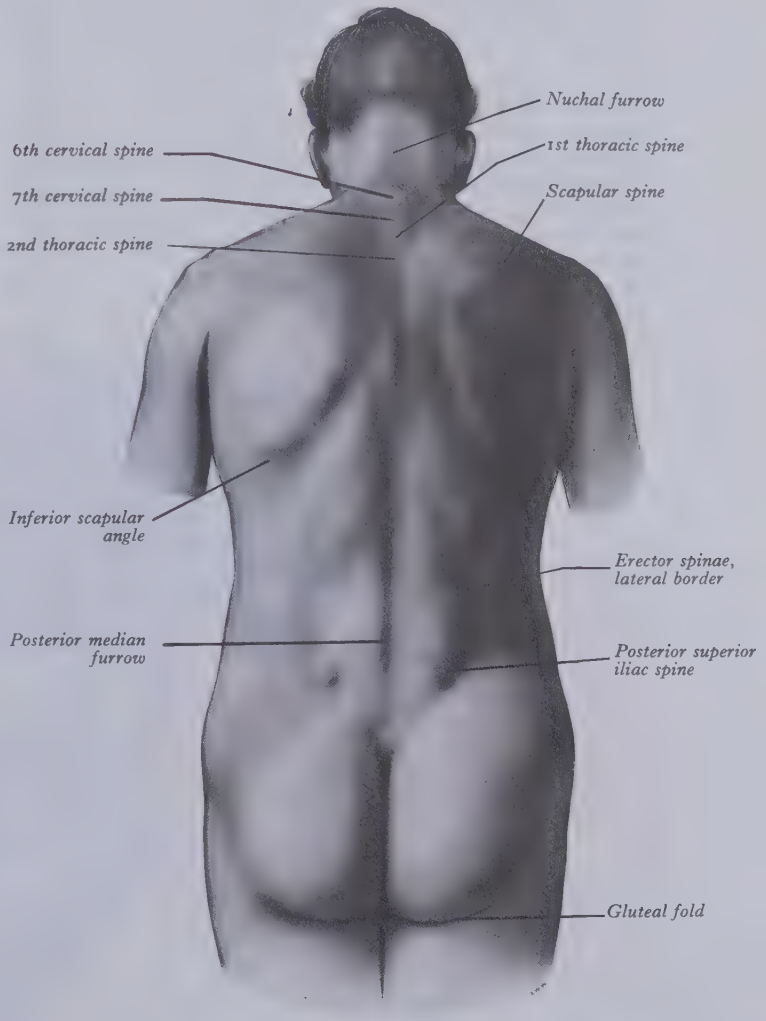


Semispinalis cervicis, a thicker muscle, is attached inferiorly by tendinous and fleshy fibres to the upper five or six thoracic transverse processes, extending superiorly to the fifth to second (axis) cervical spines. The axial fasciculus is the largest and mainly muscular.

Semispinalis capitis (5.37) is deep to splenius and medial to longissimi cervicis and capitis. It springs inferiorly by tendons attached to tips of the upper six or seven thoracic and seventh cervical transverse processes, the fourth to sixth cervical articular processes and, occasionally, the seventh cervical or first thoracic spine. Tendons are succeeded by a broad muscle, ascending to the medial area between the superior and inferior nuchal lines. Its medial part, more or less distinct, is the *spinalis capitis*, sometimes called the *biventer cervicis*, having an incomplete intermediate tendon or intersection.

Nerve supply: dorsal rami of the cervical and thoracic spinal nerves.

Actions. Semispinales thoracis and cervicis extend the thoracic and cervical vertebral regions, rotating them contralaterally; semispinalis capitis extends the head, also minimally turning the face likewise.



Multifidus, a mixture of muscular and tendinous fasciculi, is deep to the foregoing muscles, in the groove lateral to the vertebral spines from sacrum to axis. Its caudal fasciculi are attached to the sacral dorsum as low as its fourth foramen, to the aponeurosis of erector spinae, the posterior superior iliac spine and dorsal sacroiliac ligaments and to all lumbar mamillary processes, all thoracic transverse processes and the lower four cervical articular processes. Each fasciculus ascends medially to the whole length of the spine of a vertebra above; fasciculi, however, vary in length, the most superficial passing from one vertebra to the third or fourth above, deeper ones from a vertebra to the second or third above, the deepest connecting adjacent vertebrae.

5.38 Transverse section through the posterior abdominal wall, showing disposition of the thoracolumbar fascia. Note that all other connective tissue strata have been omitted.

Nerve supply: dorsal rami of the spinal nerves.

Rotatores thoracis are deep to multifidus and are the only fully developed rotatores; there are eleven pairs. Small and quadrilateral, they connect the upper posterior part of a transverse process to the lower border and lateral surface of the lamina immediately above. The first is between the first and second thoracic vertebrae, the last between the eleventh and twelfth. One or more may be absent from the upper or lower ends of the series.

5.39 Dorsal aspect of the trunk, showing principal surface landmarks.

Rotatores cervicis et lumborum are irregular, variable muscles with similar attachments.

Nerve supply: dorsal rami of the spinal nerves.

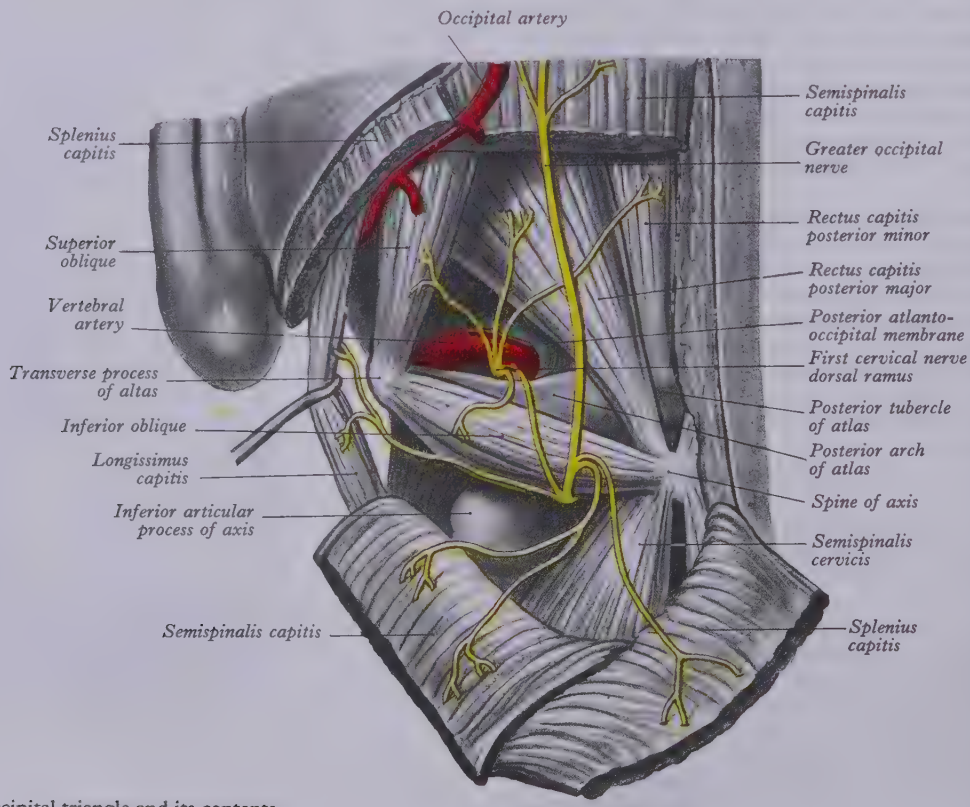
Interspinales are short paired fasciculi between adjacent vertebral spines, flanking the interspinous ligament. Six *cervical* pairs occur between the axis and the first thoracic vertebra. They are small bundles, attached between apices of spines. *Thoracic pairs* occur between the first and second spines, sometimes the second and third and the eleventh and twelfth. Four *lumbar* pairs exist between the five lumbar spines. Occasionally pairs occur at thoracico-lumbar and lumbosacral junctions. Sometimes cervical interspinales span more than two vertebrae.

Nerve supply: dorsal rami of the spinal nerves.

Intertransversarii, small muscles between transverse processes, are best developed at *cervical level*, consisting of anterior and posterior slips, separated by ventral rami of the spinal nerves. *Posterior intertransverse muscles* are divisible into medial and lateral slips, respectively supplied by dorsal and ventral rami. Each *medial*, 'proper' intertransverse muscle is often divided into medial and lateral parts by the passage of a dorsal ramus. The *anterior intertransverse muscles* and *lateral* parts of the posterior connect the costal processes of contiguous vertebrae; *medial* parts of the posterior muscles connect true transverse processes. Seven pairs of intertransversarii exist, from the atlas to the first thoracic vertebra; but the pair between atlas and axis is often absent. At *thoracic levels* they are single muscles between the last three thoracic and first lumbar transverse processes. At *lumbar level* there are *intertransversarii mediales*, connecting accessory processes of one vertebra to the mamillary processes of the next, and *intertransversarii laterales*, divisible into ventral and dorsal parts (Cave 1937, Morison 1954); ventral parts connect lumbar transverse processes (costal elements); dorsal parts connect accessory processes to the transverse processes of succeeding vertebrae. Thoracic intertransverse muscles and ligaments are homologous with the medial slips of cervical 'proper' posterior intertransverse muscles; *levatores costarum* are homologous with their lateral moieties. The lateral branch of a dorsal spinal ramus separates thoracic intertransverse from levator costae muscles. The lumbar levatores are medial intertransverse muscles, lateral intertransverse being homologous with intercostal muscles. For other views on such homologies consult Sato (1973).

Nerve supply: lumbar intertransversarii mediales, thoracic intertransversarii and medial parts of cervical posterior intertransversarii are supplied by the dorsal rami, the others by ventral rami of the spinal nerves.

Actions. Shorter dorsal muscles are probably postural. The vertebral column is, in effect, a series of short jointed levers, unstable to compression and tending to buckle unless movements at individual joints are controlled. The short muscles may steady adjoining vertebrae and control them during motion of the whole vertebral column, ensuring effective action in the long muscles. Theoretically, short muscles may produce extension (multifidus, spinales), lateral flexion (multifidus, intertransversarii) and rotation (multifidus and rotatores) but details are obscure. Deep muscles are certainly involved in the control of posture, contracting intermittently during swaying movements from an upright position. The erectores spinae extend the trunk, control of extension depending largely on the recti abdominis. Conversely, flexion is initiated by the recti; but as the relevant centre of gravity moves forwards control is transferred to the erectores spinae. Lateral flexion is controlled by the contralateral erector spinae. However, in full flexion the erectores spinae are electromyographically quiet; flexion may be then limited by the spinal ligaments and compression of the intervertebral discs (Floyd & Silver 1955, Joseph 1960). Electromyographic activity in dorsal muscles is greater during work carried out on low surfaces from standing positions (Jonsson 1974), as would be expected.



2. Suboccipital Muscles

These small muscles (5.40) extend the head at atlanto-occipital joints (recti capitis posteriores major and minor) and rotate it with the atlas on axis (obliqui capitis superior and inferior).

Rectus capitis posterior major starts as a pointed tendon from the axial spine and broadens as it ascends laterally to the inferior nuchal line and occipital bone below it. The two diverging muscles leave a triangular space, revealing parts of recti capitis posteriores minores.

Actions: extension and ipsilateral rotation of the head.

Rectus capitis posterior minor, attached by a pointed tendon to the posterior atlantal tubercle, widens as it ascends to the

5.40 The left suboccipital triangle and its contents.

medial part of the inferior nuchal line and occipital bone between this and the foramen magnum (p. 373). It may be doubled.

Action: extension of the head.

Obliquus capitis inferior, the larger oblique, ascends laterally from the lateral aspect of the spine and adjacent lamina of the axis to the inferoposterior aspect of the atlantal transverse process.

Action: ipsilateral rotation of the head, occurring at a mechanical advantage due to the width of the atlas.

Obliquus capitis superior, attached by tendinous fibres to the upper surface of the atlantal transverse process, ascends dorsally, expanding to the occipital bone between the superior and inferior nuchal lines, lateral to semispinalis capitis and overlapping rectus capitis posterior major.

Actions: posterolateral flexion of the head. The muscle and its neighbours are probably postural rather than prime movers but observation is difficult.

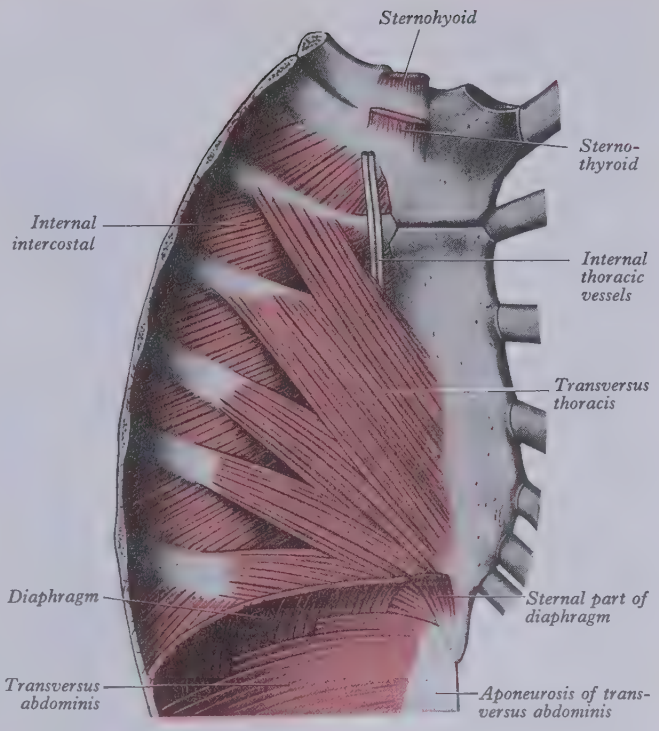
Nerve supply of all suboccipital muscles is from the dorsal ramus of the first cervical spinal nerve.

The Suboccipital Triangle

This region is bounded superomedially by rectus capitis posterior major, superolaterally by obliquus capitis superior, inferolaterally by obliquus capitis inferior. Medially it is covered by dense adipose tissue, deep to semispinalis capitis, laterally by longissimus capitis and sometimes splenius capitis, overlapping obliquus capitis superior. The 'floor' is the posterior atlantooccipital membrane and the posterior atlantal arch; the vertebral artery and dorsal ramus of the first cervical spinal nerve (5.40) are in a groove on the arch's upper aspect.

3. Muscles of the Thorax

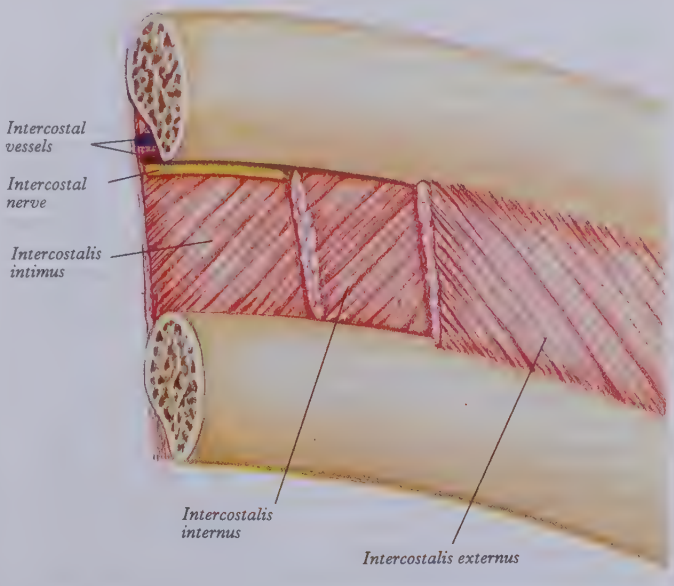
These comprise (5.41,42,43) muscles connecting adjacent ribs (intercostales), spanning several ribs (subcostales), connecting the ribs to the sternum (transversus thoracis) or to vertebrae (levatores costarum, serratus posterior superior et inferior) and the diaphragm. All are concerned in costal movements and hence, potentially, respiration.



Intercostales

The intercostales (5.42) are thin musculotendinous layers occupying intercostal spaces, named from their spatial relations: intercostales externi, interni and intimi.

Intercostales externi, in eleven pairs, extend from the costal tubercles, where they blend with the posterior fibres of the superior costotransverse ligaments almost to the costal cartilages, where each continues as an aponeurotic *external intercostal membrane* which reaches the sternum. Each muscle connects the adjacent borders of two ribs. In the lower two spaces they reach the free ends of costal cartilages but in the upper two or three do not reach the ends of the ribs. They are thicker than intercostales interni; their fibres ascend medially at the back of the thorax, laterally at the front.



Intercostales interni, in eleven pairs, have attachments commencing at the sternum between the cartilages of true ribs and at anterior extremities of cartilages of 'false' ribs, extending back to the posterior costal angles, where each becomes an aponeurotic *internal intercostal membrane*, continuous posteriorly with the anterior fibres of a superior costotransverse ligament, anteriorly with fascia between the internal and external muscles. Each muscle descends from a costal groove and adjacent costal cartilage to the upper border of the rib below. Their fibres are also oblique and nearly at right angles to those in the external intercostal muscles.

Actions. Opinions are not unanimous; the following views have been proposed: that both groups act as costal elevators, that external intercostals are elevators and internal intercostals depressors, that intercartilaginous parts of internal intercostals act with external intercostals in inspiration, and that all intercostals are elastic supports preventing the contents of intercostal spaces from bulging in or out during respiration. Experiment shows impulses traversing the nerves to the external intercostals

5.41 The left transversus thoracis, exposed and viewed from its posterior aspect. Note that, in the interval between the sternal and costal origins of the diaphragm, the lower border of the transversus thoracis is in contact with the upper border of the transversus abdominis. Note and contrast the relatively 'high' anterior diaphragmatic attachments with the 'low' lumbar level of its posterior attachments (see 5.43).

of lower spaces (5–9) in normal inspiration and continuing into early expiration (Bronk & Ferguson 1935, Draper et al 1960). In forced inspiration contraction is obviously stronger and more sustained. Electromyography yields divergent results. Some claim that intercostals of the sixth to eighth spaces contract in the inspiratory phase of quiet breathing and relax in expiration (Campbell 1955) and that in quiet breathing intercostals of the upper four spaces show sustained, not rhythmic activity; in forced inspiration this is increased and continues at a diminished level in

5.42 Dissection of a part of the thoracic wall, showing the position of the intercostal vessels and nerve relative to the intercostal muscles.

forced expiration (Jones et al 1953). It is possible that distribution of activity in intercostals varies with the depth of respiration (p. 594). These controversies have not been resolved (Hoskiko 1962, Basmajian 1967). Intercostals are always active in speech.

Intercostales intimi were once described as the internal laminae of internal intercostal muscles, having fibres coinciding in direction. Each is attached to the internal aspects of adjoining ribs. They are insignificant, sometimes absent, at higher thoracic levels but increase below, extending through the middle two quarters of the lower spaces. Walmsley (1915) considered them in the plane of transversus abdominis and suggested the term musculi intracostales, supported by Davies et al (1931). Posteriorly, in spaces where they appear, they may blend with corresponding subcostales, which Davies et al regarded as a fourth layer; general opinion favours Walmsley's three-layered arrangement. The intercostales intimi are related to endothoracic fascia and the parietal pleura, and externally to the intercostal nerves and vessels.

Actions. Without real information these muscles are presumed to act with intercostales interni (vide supra).

Subcostales are musculo-aponeurotic fasciculi, usually well developed only in the lower thorax; each descends, parallel with intercostales interni, from the internal surface of one rib, near its angle, to that of the second or third below it. Like intercostales intimi they separate intercostal vessels and nerves from pleura. Their incidence and distribution have been recorded by Satoh (1974).

Actions: probably costal depression.

Transversus thoracis (sternocostalis), a bilateral muscle, is spread internally on the anterior thoracic wall (5.41). It extends from the lower third of the posterior sternal surface, the xiphoid process and costal cartilages of the lower three or four sternal ribs near the sternum. Its fibres diverge and ascend laterally as slips attached to the lower borders and inner surfaces of the second to sixth costal cartilages. The lowest fibres are horizontal and adjoin the highest ones of transversus abdominis; the intermediate fibres are oblique, the highest almost vertical. Attachments vary even on opposite sides in one individual. Like intercostales intimi and subcostales, the muscle separates intercostal nerves from pleura.

Actions: depression of the costal cartilages.

Nerve supply: adjacent intercostal nerves.

Levatores costarum (5.37) are 12 paired, strong bundles attached to the tips of the seventh cervical to the eleventh thoracic transverse processes, descending laterally, parallel with the posterior borders of the external intercostals, to reach the upper edge and external surface of the rib below, between its tubercle and angle (*levatores costarum breves*). The four lower muscles divide into two fasciculi, one attached as described, the other descending to the *second* rib below (*levatores costarum longi*).

Nerve supply: lateral branches of the dorsal rami of corresponding thoracic spinal nerves (Morison 1954).

Actions: costal elevation, but a role in respiration is disputed (Primrose 1952); possibly vertebral rotation and lateral flexion.

Serratus posterior superior, a thin, quadrilateral muscle external to the upper posterior aspect of the thorax, is attached by a thin aponeurosis to the lower part of the ligamentum nuchae, the seventh cervical and upper two or three thoracic spines and their supraspinous ligaments. It descends laterally, ending as four digitations attached to the upper borders and external surfaces of the second to fifth ribs, lateral to their angles. It is superficial to the thoracolumbar fascia and deep to the rhomboid muscles. Digitations vary from three to six; the muscle may be absent.

Nerve supply: second to fifth intercostal nerves.

Actions. It obviously elevates the ribs but experiments in dogs show no respiratory function (Ogawa et al 1960); its human role is uncertain.

Serratus posterior inferior (5.58) is a thin, irregularly quadrilateral muscle attached by a thin aponeurosis to the lower two thoracic and upper two or three lumbar spines and their supraspinous ligaments; the aponeurosis also blends with the thoracolumbar fascia. Ascending laterally, the muscle's four digitations reach the inferior borders and outer surfaces of the lower four ribs, anterolateral to their angles; their number may be reduced; the whole muscle may be absent.

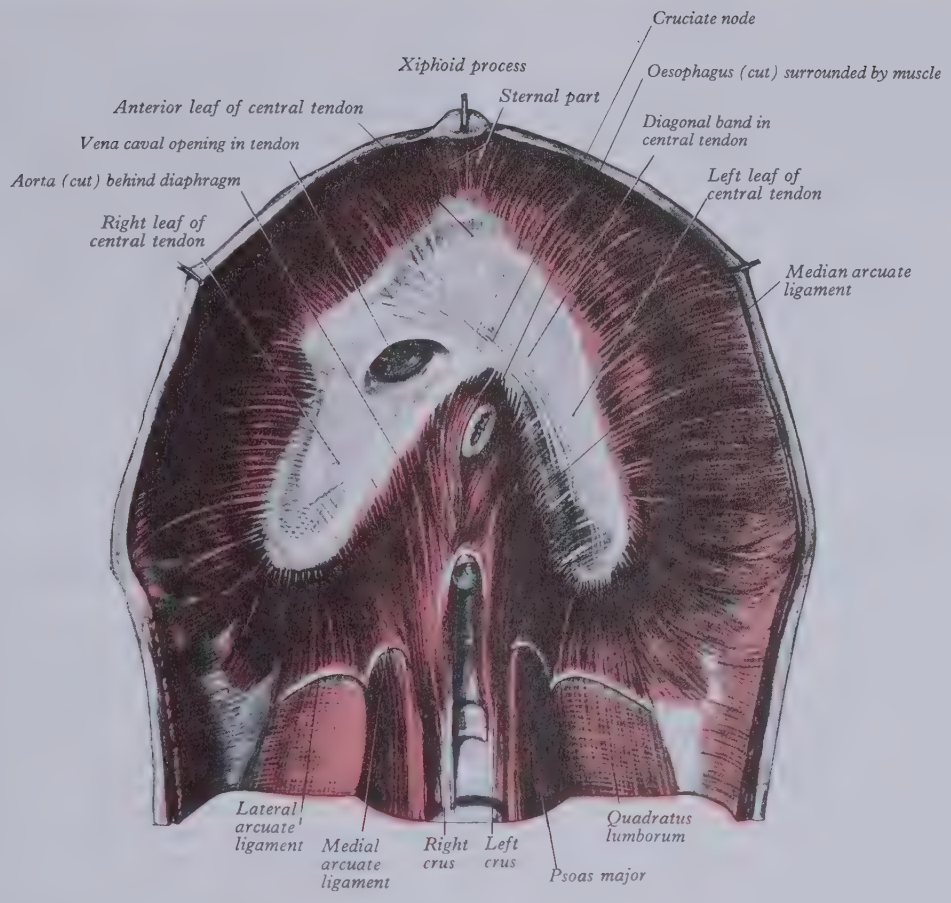
Nerve supply: ventral rami of the ninth to twelfth thoracic spinal nerves.

Actions. The muscle draws the lower ribs down and backwards, but perhaps not in respiration.

THE DIAPHRAGM

The diaphragm (5.43) is a modified half-dome of musculofibrous tissue between thorax and abdomen, its mainly convex posterosuperior aspect facing the former and concave antero-inferior surface the latter. Its muscular periphery is attached to (and posteriorly beyond) the highly oblique circumference of the thoracic outlet, whence it converges to a central tendon. Its muscular fibres form sternal, costal and lumbar groups, which are, however, particular dispositions in an otherwise continuous sheet.

Diaphragmatic shape. It is common to designate this partition as a dome; this is misleading, particularly when viscera, serous membranes and apertures are considered in terms of relations, vertebral levels and surface anatomy. The term, modified *half-dome*, is a useful simplification for the overall shape, but needs some amplification. Considering the skeletal thoracic outlet (p. 326) and upper three lumbar vertebrae, its attachments include, serially: the xiphoid process and symphysis, ventral rib ends and costal cartilages of the (vertebrosternal) seventh, (vertebrochondral) eighth to tenth and (vertebral, 'free' or floating) eleventh and twelfth ribs; the relative positions of the twelfth rib, first lumbar transverse process, the upper lumbar vertebral bodies and associated symphyses. From these the levels of lumbar, costal and sternal attachments can be assessed and the relative lengths, curvatures and planes of its muscular sectors are more easily understood; also the comparative vertebral levels of the aortic, oesophageal and vena caval orifices (vide infra). Thus the attachments are low (lumbar *levels*) posteriorly and laterally but anteriorly they rapidly ascend medially to the xiphoid levels. The superior surface is centrally almost flat where it is related to the pericardium covering most of the diaphragmatic surface of the heart. On each side of this *cardiac plateau* is raised a smooth dome or *cupola* (higher on the right), each reflecting the shape of superjacent lung and pleura and subjacent viscera (listed below).



Diaphragmatic attachments. The *sternal part* is attached by two slips to the back of the xiphoid process: the *costal part* to the internal surfaces of the lower six costal cartilages and their adjoining ribs, interdigitating with transversi abdominis (5.41); the *lumbar part* attaching to the aponeurotic medial and lateral arcuate ligaments (lumbocostal arches) and to some lumbar vertebrae by *crura*. The xiphoid slips are sometimes absent.

The *lateral arcuate ligament*, a thickened band in the fascia on quadratus lumborum, arches across this muscle and attaches medially to the front of the first lumbar transverse process, laterally to the inferior margin of the twelfth rib near its midpoint.

The *medial arcuate ligament* is a tendinous arch in the fascia covering psoas major; medially it blends with the lateral tendinous margin of the corresponding crus and is thus attached to the side of the first or second lumbar vertebral body; laterally it is attached to the front of the first lumbar transverse process.

The *crura* are tendinous at their attachments, blending with the anterior longitudinal vertebral ligament. The *right crus*, broader and longer, springs from anterolateral aspects of the bodies and intervertebral discs of the upper *three* lumbar vertebrae, the *left crus* from corresponding parts of the upper *two*. Their medial tendinous margins converge in a median arch across the aorta at the level of the thoracolumbar disc; this *median arcuate ligament* is often poorly defined.

From this circumferential attachment fibres converge to a central tendon; those from the xiphoid process are short, with only a slight inclination, and sometimes aponeurotic; those from arcuate ligaments, and especially from ribs and cartilages, are longer, initially almost vertical, then progressively curved as they ascend to their central attachment. Fibres from crura diverge, the most lateral continue ascending laterally to reach the central tendon. Medial right crural fibres ascend *left* of the oesophageal opening; sometimes a muscular fasciculus from the medial side of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the vena caval opening but does

5.43 Abdominal aspect of the diaphragm. Contrast the relatively 'high' anterior sternocostal attachment descending steep and obliquely to its complex 'low' lumbar posterior attachment (see 5.41).

not approach the oesophageal opening (Low 1907). The latter's right margin is covered by deeper medial *right* crural fibres.

The *central tendon* is a thin, strong aponeurosis of interwoven collagen fibres, with part of its margin nearer the front of the diaphragm, so that the posterior muscular fibres are longer. Its central area is beneath the pericardium and partly blended with it. The whole is trifoliate; its three leaves are partly separated by slight indentations. The middle leaf is an equilateral triangle, its apex towards the xiphoid process. Right and left leaves are long and linguiform, curving posterolaterally, the left being narrower. The central area shows four *diagonal bands* expanding from a thick *node* where decussation of compressed tendinous strands occurs in front of the oesophageal aperture and left of the vena caval opening.

The Diaphragmatic Apertures

The diaphragm is traversed by many structures; three large openings, aortic, oesophageal and vena caval (5.43) and a number of smaller avenues exist.

The *aortic aperture*, lowest and most posterior, is level with the caudal border of the twelfth thoracic vertebra and the thoracolumbar intervertebral disc, slightly left of midline. It is actually a vertical osseo-aponeurotic and symphysio-aponeurotic channel, between the crura laterally, the vertebral column posteriorly and the diaphragm anteriorly. It is thus *behind* the diaphragm or its median arcuate ligament when present. Occasional tendinous crural fibres pass *behind* the aorta, forming a fibrous ring. The opening transmits the aorta, thoracic duct and sometimes azygos and hemiazygos veins (p. 808); lymphatic trunks also *descend* through it from the lower posterior thoracic wall.

The *oesophageal aperture* is surrounded by diaphragmatic *muscle* and is sited at an intermediate level, opposite the tenth thoracic vertebra; it is elliptical (long axis slightly oblique, ascending to the left of the midline) and between the medial fibres derived from the right crus (Low 1907), which have now crossed the midline. It is above, in front and slightly left of the aortic opening. (Strictly, because of the obliquity of this elliptical aperture, its lower end is almost directly anterosuperior to the aortic orifice, whereas its upper end is further anterosuperior and a few centimetres to the left.) It transmits oesophagus, gastric nerves, oesophageal branches of left gastric vessels and lymphatic vessels. Muscle of the oesophageal wall and that of the opening remain separate. Inferior diaphragmatic fascia, continuous with transversalis fascia (p. 603) and rich in elastic fibres, ascends the opening like a flattened cone to blend with the oesophageal wall about 2 cm above the gastro-oesophageal junction; some elastic fibres penetrate to the submucosa. This fascial expansion, the *phrenoesophageal ligament*, flexibly connects oesophagus and diaphragm, permitting some freedom during swallowing and respiration (Allison 1951, Hayward 1961).

The *vena caval aperture*, highest of the three and about level with the disc between the eighth and ninth thoracic vertebrae, is quadrilateral and sited *within* the central tendon, at the junction of its right leaf with the central area, so that its margin is aponeurotic. The inferior vena cava is adherent to the margin as it traverses the opening and is accompanied by branches of the right phrenic nerve.

Two lesser apertures in each crus transmit the greater and lesser splanchnic nerves. The ganglionated sympathetic trunks are usually behind the medial arcuate ligaments. Openings for small veins are frequent in the central tendon.

In two small bilateral areas muscular tissue is replaced by areolar tissue. One, between sternal and costal parts, contains the superior epigastric artery and lymph vessels from the abdominal wall and liver; the other, between the costal part and fibres from

the lateral arcuate ligament, is less constant; when it exists, the kidney (posterosuperior aspect) is separated from the pleura only by areolar tissue.

Relations. *Superiorly* are three serous membranes: on each side pleura separates it from a pulmonary base, between them pericardium over the middle folium (and apically some diaphragmatic muscle) separates it from heart. The central area (*cardiac plateau*) is slightly *lower*, flatter and more horizontal than the smooth convex summits (*cupolae*) of the lateral regions. Thus in anteroposterior view the superior profile of the diaphragm consists of a high smooth convex right cupola, a flat low cardiac plateau that extends more to the left than right and also inclines gently ventrally and towards its left limit, finally a less high, slightly narrower, but smooth convex left cupola. (For variations in levels see below.) The inferior surface is mostly covered by peritoneum, that of the *right cupola* being in contact with the convex surface of the right hepatic lobe, right kidney and suprarenal gland; the peritoneum of the *left cupola* is in contact with the left hepatic lobe, gastric fundus, spleen, left kidney and suprarenal gland. (As mentioned, the right cupola is higher and less mobile than the left; also their abdominothoracic visceral relations differ. Clinically, therefore, the profile of a cupola should be specified, right or left. Unqualified terms, e.g. *the* dome, or cupola *of the diaphragm*, should be abandoned.)

Nerve supply. Motor fibres travel in the phrenic nerves. The lower six or seven intercostal nerves distribute sensory fibres to the peripheral diaphragm. A controversy concerning the crural motor supply suggested an intercostal innervation but Collis et al (1954) indicated the phrenic nerves as sources; this was confirmed by Shehata (1966). Both state that all crural fibres (irrespective of origin) right or left *of the oesophageal opening* are supplied by the ipsilateral phrenic nerve.

Actions. The diaphragm is the essential respiratory muscle. Its general concavity towards the abdomen is flatter and centrally attached above; its periphery is muscular. During inspiration the lowest ribs are at first fixed; from these and the crura, muscular fibres draw down the central tendon with its attached pericardium. The curvature is scarcely altered, the cupolae also moving down and a little forwards almost parallel to their original positions, displacing the abdominal viscera, the descent of which is permitted by stretching of the abdominal wall; the limit of this is soon reached, the central tendon becoming fixed for diaphragmatic contraction, which elevates the lower ribs and through them pushes forwards the sternum and upper ribs. The right cupola, above the liver, has greater resistance to overcome but right crus and cupola are more substantial than the left. The balance between descent of the diaphragm and protrusion of the abdominal wall ('abdominal' breathing) and elevation of the ribs ('thoracic' breathing) varies in individuals and with the depth of respiration. Thoracic breathing is usually more marked in females and, of course, in deep inspiration.

In all expulsive acts the diaphragm adds power to such effort. Thus, before sneezing, coughing, laughing, crying, vomiting, urination, defaecation, and during expulsion at birth, a deep inspiration helps. Deep inspiration, followed by closure of the glottis, is also a preliminary to powerful action of the trunk muscles, as in lifting heavy weights.

The right crus has been said to act as a sphincter of the human oesophagus. Expiration immediately after swallowing relaxes these fibres, allowing the oesophageal contents to enter the stomach (Whillis 1931, p.1318). Less emphasis is now placed on this supposed action of the right crus; the intrinsic muscle of the lower oesophagus, below the attachment of the phrenoesophageal ligament, is considered an effective sphincter (p. 1333).

The level of the diaphragm varies continuously during respiration; it is also affected by distension of the stomach and intestines and the size of the liver. After forced expiration the right cupola is level anteriorly with the fourth costal cartilage, laterally with the fifth to seventh ribs, posteriorly with the eighth; the left cupola is a little lower. Diaphragmatic excursion is about 1.5 cm in quiet breathing; in deep respiration maximal ranges are 6–10 cm (Campbell 1958).

Radiographs show that diaphragmatic level also varies with posture, its profile being *highest* in the supine body, in which respiratory excursions are greatest in normal breathing. With the body erect, the diaphragm is lower, its respiratory movements smaller. The diaphragmatic profile is even lower in sitting and respiratory excursions smallest. With the body horizontal and on one side, the halves of the diaphragm do not behave similarly and they achieve *extreme positions and ranges*; the uppermost sinks lower even than in sitting and moves little with respiration; the lower half rises higher even than in the supine position and respiratory excursions are much increased.

Position of the diaphragm in the thorax apparently depends on: (1) elastic retraction of lung tissue, tending to pull it up; (2) visceral pressure from below (negative in sitting or standing, positive in recumbency), (3) intra-abdominal pressure due to abdominal muscles (contracting in standing but not in sitting), the diaphragm being pushed up higher in the former.

Applied Anatomy. Abdominal organs, usually the stomach, may herniate into the thorax, either alongside the oesophagus or between the lateral arcuate and costal fibres.

The Movements of Respiration

Rhythmic respiratory movements alter thoracic capacity, causing inflow and outflow of air to ventilate pulmonary alveoli, where gaseous exchanges between blood and alveolar air occur. Capacity can be increased in transverse, antero-posterior and vertical dimensions, together or separately.

Transverse and anteroposterior dimensions are increased by costal movement. When elevated, the anterior ends of the vertebrosternal ribs thrust forwards and upwards and this is transmitted to the sternal body, with slight movement at the manubriosternal symphysis (joint, angle) increasing anteroposterior diameter. The same ribs, rotating at vertebral ends (p. 498), are everted, increasing transverse diameter. Elevation of vertebrochondral ribs (4.35) splays them out and backwards, increasing transverse diameter with some widening of the infrasternal angle and enlargement of the upper abdominal cavity. Vertical dimension is increased by diaphragmatic contraction pressing on abdominal viscera, which are permitted to descend by relaxation of the abdominal wall during inspiration; at the limit of this descent abdominal viscera halt the central tendon, enabling the diaphragm to elevate the lower ribs. (Movements of the first rib and manubrium, i.e. the whole sternum, only become appreciable in deep and forced respiration; vide infra and p. 498.)

A respiratory cycle has inspiratory and expiratory phases. At rest the former lasts about one, the latter about three seconds. Increase of thoracic capacity reduces intrapleural pressure and thereby expands the lungs, decreases intrapulmonary pressure and draws air into the respiratory passages. The expiratory phase is largely passive, recoil of the thoracic wall and lungs raising intrathoracic pressure to expel air.

In *quiet respiration* about 500–750 ml of *tidal air* are inspired and expired in each cycle, about one-third occupying '*anatomical dead space*', extending from the nostrils to the terminal bronchioles, where epithelium is not respiratory and little gaseous exchange occurs. The remaining inspired air ventilates the alveoli. Inspired air is warmed, humidified and filtered in the 'dead space', especially in the nose.

In *quiet inspiration* the main and often sole active muscle is the diaphragm. In average adults the right cupola descends to the level of the disc between the tenth and eleventh thoracic vertebrae, and the left cupola is level with the disc between the eleventh and twelfth, the central tendon moving about 1.5 cm. This is responsible for almost all the tidal volume of about 500 ml. There is little or no movement of osseous boundaries of the thoracic inlet. Electromyography, however, shows a rhythmic activity of the scalene muscles (anterior and medius), which fix the upper ribs; intercostal muscles in the upper six spaces may also show activity, preventing displacement of soft tissues in these spaces by changes of intrapleural pressure. Intercostals of lower spaces may also show rhythmic contraction, increasing the transverse diameter at this level and probably also resisting pressure changes.

In *inspiration* intrapleural and intrapulmonary pressures fall below atmospheric; at its end intrapulmonary equals atmospheric. Air entering the lung is not uniformly distributed, regional differences occurring in ventilation and blood flow. Ventilation is greater in lower than in upper lobes, due to greater movement in the lower thorax. Regional differences may also be related to the varying elasticity and dimensions of air passage. Alveoli which expand earliest in inspiration may receive more air from the dead space.

In *quiet expiration* elastic recoil of the lungs and thoracic wall is balanced by a slow relaxation of inspiratory muscles; electromyography shows that the diaphragm and intercostals continue to relax into expiration. The thin film of material between alveolar air and the surface of alveolar epithelium (p. 1281) may also be a factor in recoil. With the ventilation rate below 40 litres/min intercostal and abdominal muscles are not active in expiration.

In *deep inspiration* these movements are augmented and additional muscles participate, all contracting with greater force; active motor units increase, discharges along their nerves are for longer periods and motor units are more synchronized. Intercostal muscles become active in progressively higher spaces to move the upper ribs and sternum. The first rib is elevated by the scaleni, anterior and medius, and by sternocleidomastoid indirectly through the clavicle and costoclavicular ligament and directly through its manubrial attachment. Each 1 cm increase in the circumference of the thorax increases the capacity by about 200 ml. The twelfth rib, fixed by quadratus lumborum, enables the diaphragm to press more powerfully on abdominal viscera (Boyd et al 1965); this may also provide a basis for controlled relaxation in precise adjustments of expiration for speech (Taylor 1960). The spinal erectors also diminish thoracic vertebral curvature, slightly increasing the width of the intercostal spaces and allowing the ribs a greater range of movement. Intrapulmonary pressure at the start of *deep expiration* may rise to 30 mm above atmospheric.

In *forced respiration*, breathing against resistance, further muscles act. In forced *inspiration* the diaphragm contracts maximally, the right cupola descends level with the eleventh thoracic vertebra, the left cupola reaching that of the twelfth. This corresponds to a change in level of 9–10 cm. Action of the spinal erectors is augmented and muscles connecting the upper limb to the trunk may participate. Forced *expiration* is augmented by strong contraction of the abdominal muscles, particularly the oblique and transverse, and latissimi dorsi, all contracting forcefully in such efforts as coughing and sneezing. The abdominal muscles raise intra-abdominal pressure, forcing the relaxing diaphragm up and drawing lower ribs down and medially.

The range and balance of thoracic movements exhibit striking individual variations, perhaps dependent on the form of the thoracic skeleton, habit and other factors; such variation must be allowed for when movements are analysed in any individual.

In all phases of respiration changes in nostrils, larynx, trachea and bronchial tree occur. Dilatation of nostrils is evident in forced respiration. During quiet respiration the rima glottidis (p. 1254) is widened by lateral rotation of the vocal processes, abducting the vocal folds; it is widened further in forced inspiration by increasing abduction of the folds and the arytenoid cartilages. Tracheal, bronchial and bronchiolar calibre can be changed by distension or actively by alteration of the tone of their mural muscle, mediated by para-sympathetic (vagal) and sympathetic nerve supplies, so that they dilate in inspiration and contract in expiration.

Applied Anatomy. Changes in the level of the diaphragm during alteration in posture explain why patients with severe dyspnoea are most comfortable when sitting up. In unilateral disease of pleura or lungs interference with the position or movement of the diaphragm is usually observable by X-ray examination.

4. Muscles of the Abdomen

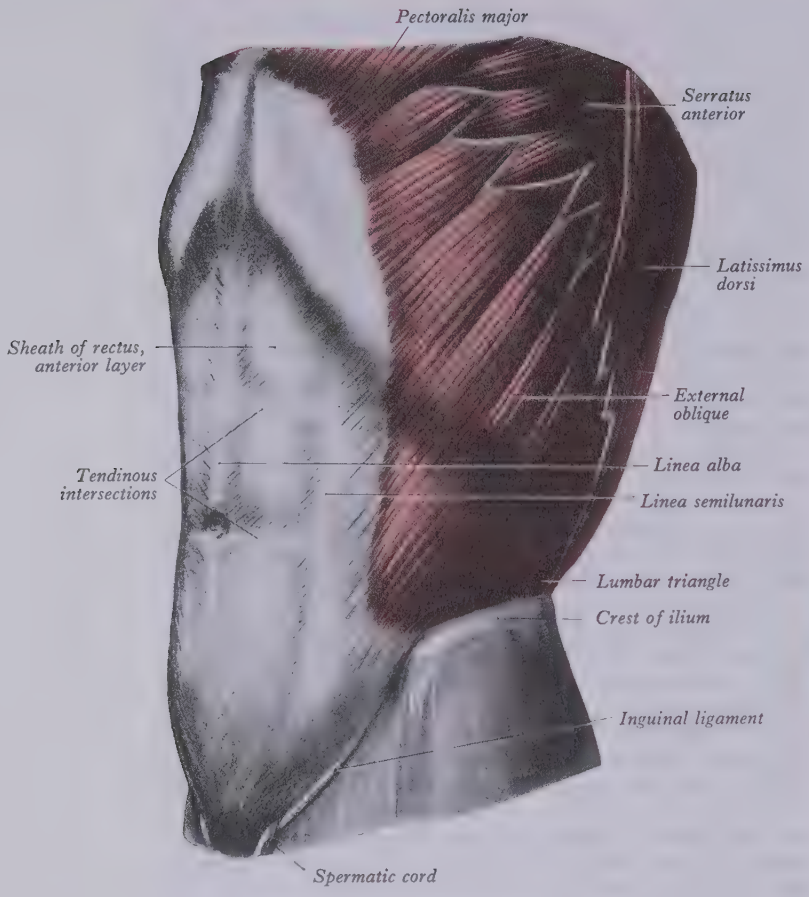
Abdominal muscles are usually considered in anterolateral and posterior groups.

ANTEROLATERAL ABDOMINAL MUSCLES

This is a group of four large flat muscular sheets forming the abdominal wall (obliqui externus and internus, transversus and rectus abdominis) and smaller elements, cremaster and pyramidalis.

Superficial fascia of the superior and central abdominal wall is a single layer containing variable fat; but inferiorly, particularly in the obese, it differentiates usually into two layers, the extent and significance of which is disputed; between them are superficial vessels, nerves and lymph nodes.

The superficial layer (or layers) is thick, areolar and contains variable fat. It passes over the inguinal ligaments into corresponding superficial fascia of the thighs; in males, however, this layer continues over the penis, spermatic cords and scrotum, where it is thin, free of fat, pale red, containing non-striated muscular fibres, the *dartos* muscle supplied by the genitofemoral nerves. Thence it continues into the remaining perineum, including in females the labia majora.



The deep layer (or layers) is more membranous, contains elastic fibres and is loosely connected by areolar tissue to the external oblique aponeuroses; but in the midline it is adherent to the linea alba and symphysis pubis and thickened, and prolonged on the dorsum penis, contributing to its *fundiform ligament* (5.45). It is continuous with superficial thoracic fascia and, over the inguinal ligaments, with a membranous superficial layer in the proximal thigh and it fuses with the subjacent fascia lata in the depths of the (ventral) *inguinal flexures* (5.45); medially, it is continued over penis and spermatic cord to the scrotum and thence to form the remainder of the membranous layer of superficial perineal fascia (p. 606), in females into the labia majora and remaining perineum.

In children the testis can often be retracted into loose areolar tissue between the external oblique and the deep layer of superficial fascia over (ventral to) the inguinal canal, the *superficial inguinal pouch* (Browne 1938).

Obliquus externus abdominis (5.44A,B,53A–E), curved anterolaterally round the abdomen, is the largest and most superficial anterolateral muscle and has eight digitations attached to the external surfaces and inferior borders of the lower eight ribs, alternating with digitations of serratus anterior and latissimus dorsi along an oblique line extending down and backwards; upper digitations are attached close to costal cartilages, the lowest to the apex of the twelfth cartilage, the middle ones to ribs some distance from their cartilages. Fibres diverge inferomedially, the posterior fibres being almost vertical and attached to the outer lip of the anterior half of the ventral segment of the iliac crest (p. 424); the middle and upper fibres are progressively less oblique and end in an aponeurosis, along a line from the ninth costal cartilage to a little below the umbilicus and then turning laterally towards the anterior superior iliac spine. Fibres rarely descend beyond a line from the anterior superior iliac spine to the umbilicus. The muscle has a free posterior border (5.58).

The muscle's *aponeurosis* was for long accepted as a single dense tendinous sheet, its fibres descending medially to end in the median *linea alba* (5.44), a raphe stretching from xiphoid process to symphysis pubis, in which right and left aponeuroses fuse and cover the abdomen. (However, this main part of the aponeurosis, together with those of obliquus internus and transversus, the sheath of rectus abdominis and the linea alba have been reinvestigated and new observations and functional implications recorded, vide infra, 5.44B, 53C–E.) Inferomedially each aponeurosis is attached to the pubic symphysis (upper border), pubic crest and tubercle. Between the anterior superior iliac spine and pubic tubercle it is a thick band, infolded to form a groove; this is the *inguinal ligament*. Expansions from its medial end are attached to the pecten pubis as the *lacunar ligament* and fibres also pass superomedially to the rectus sheath and linea alba, as a *reflected part* of the inguinal ligament (5.50).

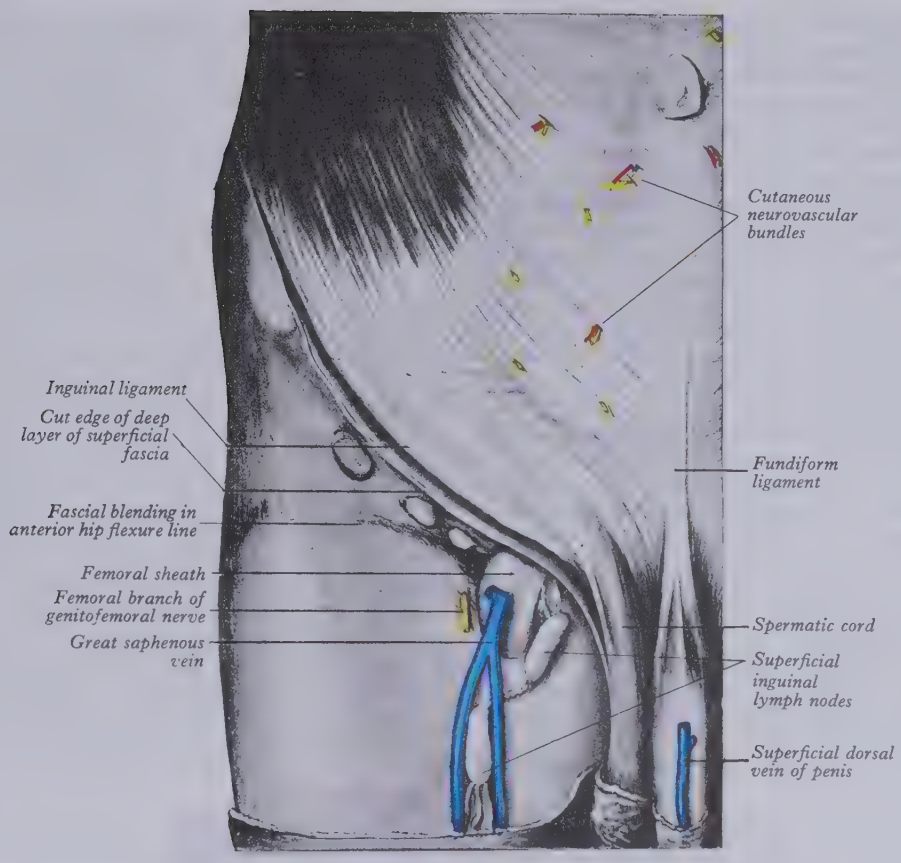
Rizk (1980) made extensive investigations into ventral abdominal musculature in 41 human specimens (male and female ranging from birth to 70 years), and in 75 specimens from many other mammalian groups. The main part of the human obliquus externus aponeurosis from costoxiphoid margin to pubis was *bilaminar*, i.e. deep and superficial layers, their fibres

5.44A The left obliquus externus abdominis.

5.44B The concept of bilaminar aponeuroses of the external oblique muscles. Note that the fibres of the superficial and deep layers are approximately at right angles; decussations occur as part of the linea alba (modified from Rizk 1980; see text for further details and reference).

approximately at right angles to each other and neither ending at the linea alba but both crossing the midline to enter the contralateral half of the abdominal wall at linear decussations. The *deep layer* fibres are direct continuations of the ipsilateral muscle's fasciculi; they pass inferomedially and at the midline, which they cross, they separate into two laminae. A considerable proportion are *directly continuous* with the aponeurotic fibres of the anterior layer of the contralateral obliquus *internus* (forming, in effect, a *bilateral digastric muscle*); the remainder form the external's superficial layer of its contralateral aponeurosis. Below the umbilicus most crossed fibres remain deep but some recurve to form the superficial intercrural fibres.

The *superficial layer* derived, as noted, from the contralateral deep fibres, largely forms a series of parallel, wide S-shaped curves, broadly downwards and laterally. Decussation of external oblique aponeurotic fibres was single and midline (30%), or triple (70%) with one midline and two near the medial margins of recti abdominis. The superficial fibres, after decussation, as indicated, passed principally *inferolaterally* (crossing the inferomedially inclined deep fibres); designated S-shaped, but rather gently sinuous, the medial three-quarters, or more, had a superolateral convexity, the lateral extremity a superolateral concavity. The investigator quoted divided the anterolateral abdominal wall into principal levels: costal margin and xiphoid down to umbilicus, from the latter to the iliac crest, from the iliac crest to the inguinal ligaments and pubes. Unfortunately, which part of the iliac crest is not specified. Nevertheless, using this terminology the superficial aponeurotic fibres of obliquus abdominis externus are as described down to umbilical level and below the iliac crest they become the intercrural fibres associated with the superficial inguinal ring. Between umbilicus and iliac crest, however, the anterior laminae of obliquus abdominis *internus* become superficial to externus, vertical lines of decussation between internus and externus occurring along the ventral centre-line of each rectus abdominis. For this limited extent, therefore, the most ventral (superficial) stratum in the medial half of the ventral wall of the rectus sheath is provided by obliquus internus.



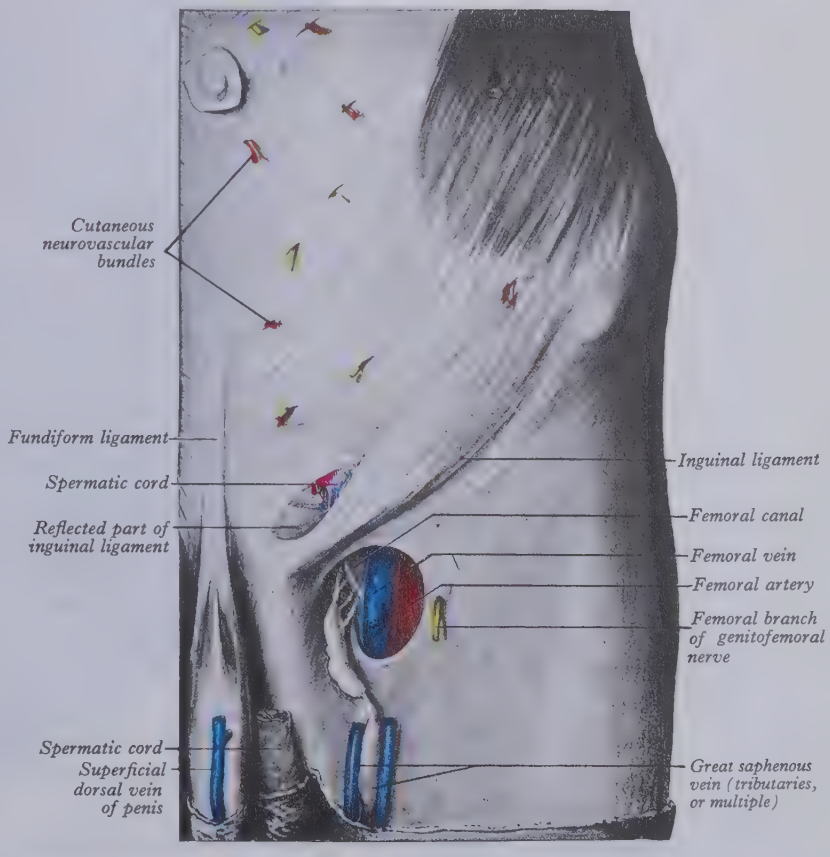
Through the adherence of the superficial stratum to the (contralateral muscle's) deep stratum the two external obliques together form another bilateral digastric muscle.

The external oblique is invested by external and internal fasciae, the former better developed. First and last digitations may be absent; digitations or the whole muscle may be reduplicated. Digitations may also be continuous with pectoralis major or serratus anterior.

Nerve supply: ventral rami of the lower six thoracic spinal nerves.

The inguinal ligament (5.46), the thick, inrolled inferior border of the external oblique aponeurosis, has a grooved abdominal surface ('floor' of the inguinal canal) and stretches from the anterior superior iliac spine to the pubic tubercle. (Synonyms are: Poupart's ligament, crural or superficial crural arch.) Its length is convex towards the thigh and here it is continuous with the fascia lata. In adults it is 12–14 cm in length and inclined 40–35° to the horizonal; its lateral half is rounded and more oblique, its medial half gradually widening towards its pubic attachment, becoming more horizontal where it supports the spermatic cord. Deep fibres of the aponeurosis are *not* initially parallel to the ligament's axis, approaching at an angle of 10–20°, then turning *medially*, the majority then running along the ligament to reach the pubic tubercle. Even deeper fibres splay out posteromedially to the pecten pubis (Lytle 1974).

The lacunar ligament (*pectineal part of inguinal ligament*) (4.58) has been described as composite (Lytle 1974). Its abdominal, 'deep' part (i.e. classic lacunar ligament) extends posterolaterally from the medial part of the inguinal ligament to the medial end of pecten pubis. It is triangular, almost horizontal, a little larger in males and about 2 cm from base to apex. Its thin base, concave laterally, is the femoral ring's medial rim; its apex is attached to the pubic tubercle. Its posterior margin, attached to

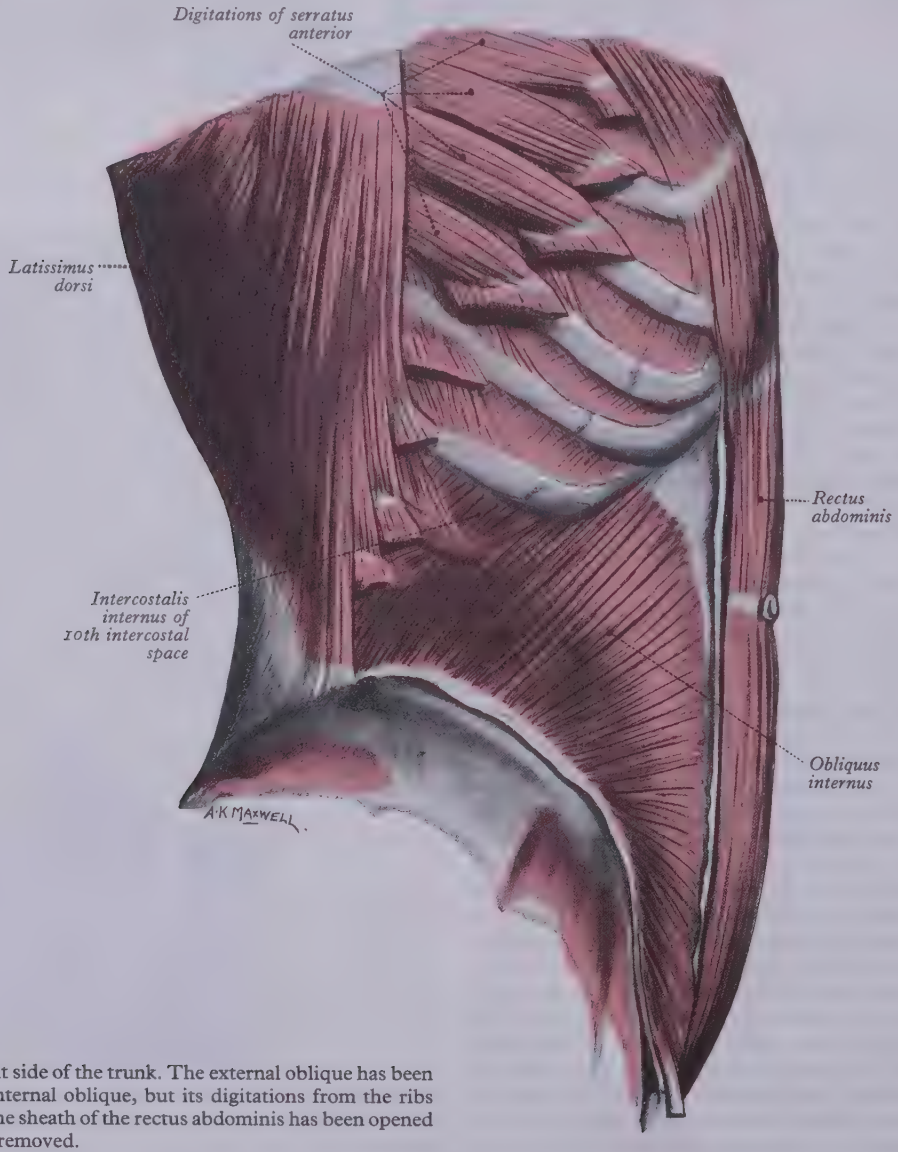


5.45 Superficial structures of the inguinal region and the lower part of the anterior abdominal wall (right side).

pecten pubis, is continuous with the *pectineal fascia*; its anterior margin continues into the main inguinal ligament. It has *superior* and *inferior* surfaces. A strong *pectineal ligament* (of *Astley Cooper*) extends laterally from its base (**4**.58) along the pecten pubis, augmented by pectineal fascia and by a lateral expansion from the linea alba (*adminiculum lineae albae*, p. 603). The lacunar formation as here described is most obvious, at operation or dissection, from its abdominal aspect. In the femoral approach, in the living, a second lacunar fibrous sheet is visible, which is an inflexion of *fascia lata* which joins the inguinal ligament's posterior border and, reinforced by transversalis fascia, fuses with pectineal fascia for about 1 cm before ascending to fuse with periosteum on the pecten pubis. This *fascial lacunar ligament* also has a thick curved lateral border fitting the medial wall of the femoral sheath; because of its pectineal attachment it is about 1 cm *infero-anterior* to pecten pubis and 3 cm lateral to the pubic tubercle. Current descriptions of boundaries of femoral hernia may hence need revision, if these findings are confirmed (McVay & Anson 1940, Lytle 1957, 1974).

The reflected inguinal ligament (**5**.46,50) is an expansion from the lateral crus of the superficial inguinal ring, ascending medially behind the superficial inguinal ring, behind external oblique and in front of the falx inguinalis; fibres of the right and left ligaments decussate in the linea alba.

The superficial inguinal ring (**5**.45,46), an aponeurotic hiatus superolateral to the pubic crest, is somewhat triangular, with its long axis parallel to the deep aponeurotic fibres. Its size varies; usually it does not extend beyond the inguinal ligament's medial third. It is smaller in females, spermatic cords being absent. Its base is the pubic crest, its sides the aponeurotic *crura*. The lateral crus is stronger and its fibres are attached to the pubic tubercle; it is curved into a groove for the spermatic cord. The medial crus is thin, flat and attached to the front of symphysis pubis, interlacing with its fellow. In or seen through the layer of investing fascia superficial to the external oblique, are variable curved fibrous bands at right angles to those in the aponeurosis. Some may arch above the superficial inguinal ring as *intercrural*



5.46 Superficial structures of the inguinal region and the lower part of the anterior abdominal wall (left side). Superficial aponeurotic layer (see text) was removed.

fibres. In the account given above, these have been allocated as the lowest fibre bundles of the superficial aponeurotic layer (derived from the contralateral obliquus abdominis externus).

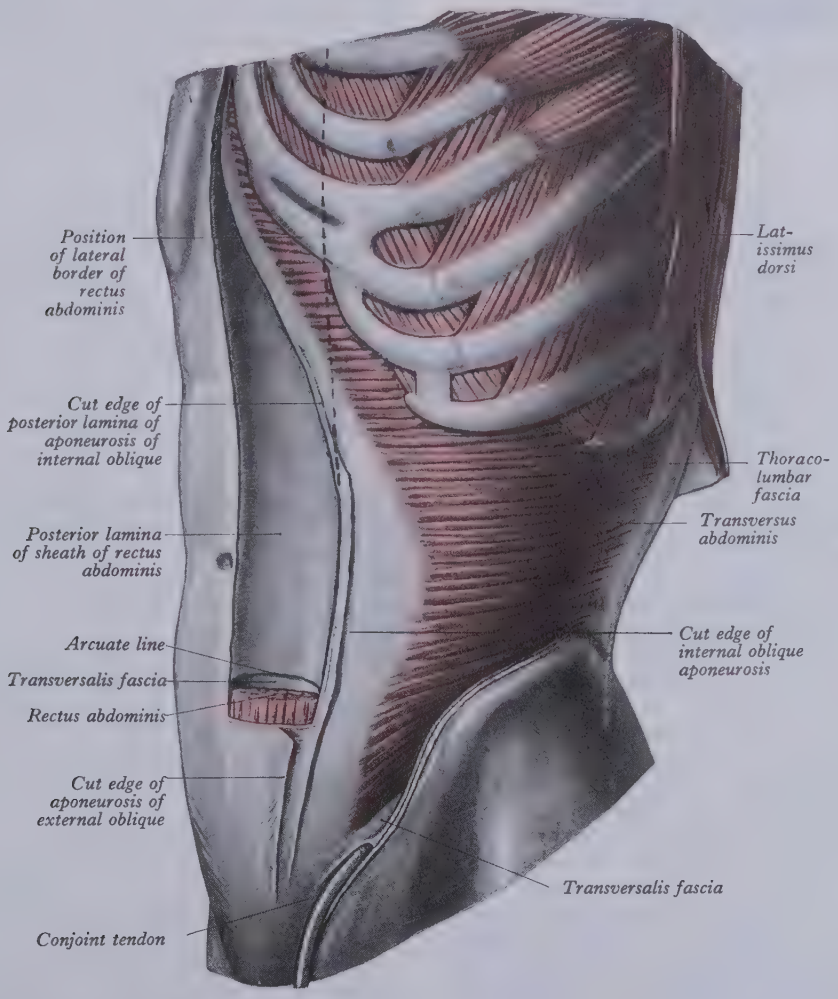
The superficial inguinal ring contains the spermatic cord in males, uterine round ligament in females and ilio-inguinal nerve in both. By invaginating scrotal skin the cord can be followed into the ring, whose crura can be felt and its size assessed. From its margins the external oblique aponeurosis and overlying fascia continue as a tenuous investment around the spermatic cord and testis, the *external spermatic fascia*; the ring is visible only when the continuity of fascia and aponeurosis is severed (Anson et al 1960).

Obliquus internus abdominis (5.47, 53C–E), largely (but not wholly) internal to the external oblique and thinner, has a muscular attachment: to the lateral two-thirds of the inguinal ligament's grooved upper aspect; to the anterior two-thirds of the intermediate line of the ventral segment of the iliac crest; and to the thoracolumbar fascia (5.38). It has been described as attached to the iliac fascia and not directly to the inguinal ligament (McVay & Anson 1940); but fascia and ligament are here adherent (p. 601). Posterior (iliac) fibres ascend laterally to the inferior borders and tips of the lower three or four ribs and their cartilages and are continuous there with the internal intercostals. The lowest fibres, i.e. those from the inguinal ligament, are paler in colour and arch *inferomedially* across the spermatic cord or uterine round ligament, become tendinous and are attached with part of the aponeurosis of transversus abdominis to the pubic crest and medial part of pecten pubis, forming the *falx inguinalis (conjoint tendon)*. Intermediate fibres diverge to end in a bilaminar aponeurosis broadening upwards, the lower fibres being horizontal, while progressively higher fibres are increasingly steep inclining medially and upwards. The uppermost part of the aponeurosis is attached to the outer surfaces and lower borders of the seventh to ninth costal cartilages. Between the costoxiphoid margin and pubis the aponeurosis consists of anterior and posterior layers and their fate is, again, considered at three levels: down to umbilical level; umbilical to iliac crest levels; and between the latter and the pubis. Differing from traditional accounts, some features recorded by Rizk (1980) are given here (in outline only; consult reference for details). The *anterior layer*, down to umbilical level, ascends medially ventral to rectus abdominis, but posterior to the two layers of the external oblique's aponeurosis (providing a *trilaminar* anterior wall to the rectus sheath), then traversing the linea alba; crossing the midline the fibres become directly continuous with the deep aponeurotic fibres of the contralateral external oblique (completing the bilateral digastric muscle mentioned above). Between umbilicus and iliac crest the internal's anterior layer ascends ventral to the rectus to its mid-vertical line where it enters a linear decussation with externus to continue medially as the most superficial (ventral) layer of the trilaminar rectus sheath (i.e. covering the externus aponeurosis). From iliac crest level to pubis the anterior layer blends as one constituent of the falx inguinalis.

The *posterior layer*, down to umbilical level passes medially posterior to rectus, but anterior to the bilaminar aponeurosis of transversus abdominis (providing a *trilaminar* posterior wall to

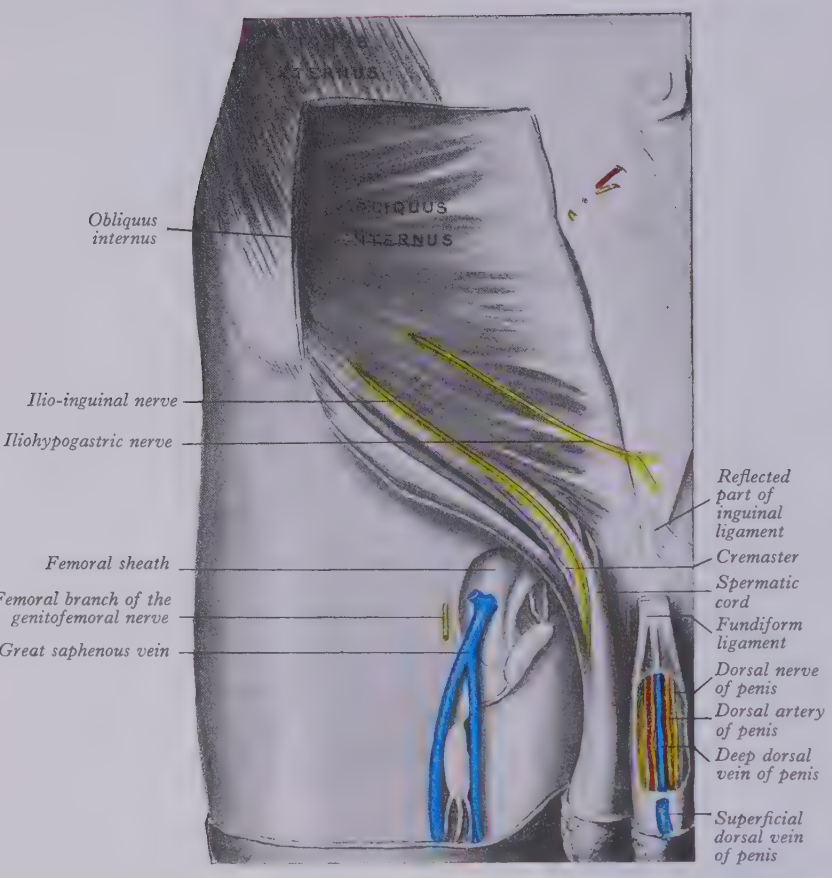
5.47 Muscles of the right side of the trunk. The external oblique has been removed to show the internal oblique, but its digitations from the ribs have been preserved. The sheath of the rectus abdominis has been opened and its anterior lamina removed.

the rectus sheath); crossing the midline in the linea alba the posterior layer fibres of internus become directly continuous with the 'downturned' aponeurotic fibres of the contralateral transversus abdominis (another bilateral digastric muscle). From umbilical to iliac crest levels, however, the posterior layer (aponeurotic fibres of internus) undergoes a vertical linear decussation with the bilaminar aponeurosis of transversus to reach its deep (abdominal) surface. The decussation occurs along the line of the lateral border of rectus, thus between these levels; the most posterior (deepest) stratum of the posterior wall of the rectus sheath is derived from obliquus internus. Below the level of the iliac crest, fibres of the posterior aponeurotic layer of obliquus are gradually and progressively transferred to the anterior layer and thence to the linea alba and (lower fibres) blend with the falx inguinalis (cf. transversus abdominis, vide infra).



Nerve supply: ventral rami of the lower six thoracic and first lumbar spinal nerves.

Cremaster (5.49) consists of loose muscle fasciculi lying along the spermatic cord, united by areolar tissue to form the *cremasteric fascia* around the cord and testis within the external spermatic fascia. Its lateral part, attached to the inguinal ligament, has been variously described as: continuous with the medial edge of the internal oblique; or deep to the internal oblique, extending to the anterior superior iliac spine; or as continuous with either internal oblique or transversus; or as a pointed tendon from the middle of the inguinal ligament, piercing the internal oblique near its medial margin. Sixty subjects all exhibited a tendinous attachment *and* cremasteric fibres derived from obliquus internus and transversus (Blunt 1951). The fibres traverse the lateral aspect of the spermatic cord through the superficial inguinal ring to spread out into loops of increasing length along its anterolateral aspect. The shortest and highest fasciculi turn inwards in front of the cord to join the medial part; longer fasciculi blend with the fascia over the cord and upper tunica vaginalis. The *medial part* of the muscle is variable and may be absent. It is attached to the pubic tubercle and possibly pubic crest, falx inguinalis and lower border of transversus. Its fasciculi loop posteromedial to the cord, interlacing with those of the lateral part. The whole muscle forms continuous loops from the mid-inguinal region to tunica vaginalis, returning to the pubic tubercle. In females a few fibres descending on the round ligament represent the lateral part.



Nerve supply: genital branch of the genitofemoral nerve, from the first and second lumbar spinal nerves.

Action: elevation of the testis towards the superficial inguinal ring. Although its fibres are striated, cremasteric actions are not usually voluntary. Stimulation of medial femoral skin evokes reflex contraction; this *cremasteric reflex* is more active in children. Doubtless this may be protective, but more significantly the cremaster appears to be essential to testicular thermoregulation. Shafik (1977) considers that the position of the testis is adjusted by the cremaster (which he divides into *cremaster internus* and *externus*, separated by internal spermatic fascia) and dartos, attached to the testis by a '*scrotal ligament*' (p. 1431).

Transversus abdominis (5.48, 53C–E), the innermost of the anterolateral abdominal muscles, is attached to the lateral third of the inguinal ligament, the anterior two-thirds of the inner lip of the ventral segment of the iliac crest, the thoracolumbar fascia between the iliac crest and the twelfth rib, and internal aspects of the lower six costal cartilages, where it interdigitates with the diaphragm (5.41). Whether the muscle's inguinal fibres are attached

5.48 The left transversus abdominis. This diagram incorporates the traditional features ascribed to an aponeurosis of transversus (see text and 5.53C–E for alternative analysis).

5.49 Dissection of the regions shown in 5.45, with part of the obliquus externus removed. (See text for additional recent observations on abdominal aponeuroses.)

directly to the ligament or via the iliac fascia, is disputed (McVay & Anson 1940). The muscle ends in a complex and variable bilaminar aponeurosis whose *lower fibres* curve inferomedially blending with those of the internal oblique to reach the pubic crest and pecten, as the *falx inguinalis*. The rest pass medially, variously related to rectus abdominis, then decussate at and blend with the linea alba. The length of transversus muscle fibres varies considerably in accord with the disposition of its posterior skeletal and fascial attachments and the curvilinear line of aponeurosis formation. Upper costal and anterior iliac fibres are short, lower costal and posterior iliac fibres are longer and thoracolumbar fibres are longest. Aponeurosis formation is only 2–3 cm from the linea alba above (i.e. transversus *muscle* extends behind rectus, and decreasingly so down to the level of the tip of the eleventh rib); thus the lateral limit of the aponeurosis, from above, curves first downwards and laterally, is widest (5–6 cm lateral to rectus) at umbilical levels, then recurves downwards and medially towards, but not reaching, the central position of the superior crus of the superficial inguinal ring. The aponeurosis of transversus abdominis is bilaminar, having *anterior* and *posterior* layers but their dispositions vary above and below umbilical levels (Rizk 1980). *Above the umbilicus* fibre bundles segregate into laminae either with their fibres inclined upwards and medially ('upturned') or downwards and medially ('downturned'). In 70% of specimens examined the anterior layer was 'downturned' and the posterior layer 'upturned'; in the remaining 30% the reverse obtained. The layers approached the midline (after forming the two posterior laminae of the trilaminar rectus sheath) and decussated to cross the midline in the linea alba. The decussation was linear, single and median in 30%, or triple with one median and two bilateral lines along the medial borders of recti abdominis. After crossing the midline, the downturned fibres of one transversus are continuous with the upturned fibres of the contralateral transversus and with the posterior layer of the contralateral obliquus internus (vide supra).

Below the umbilicus both layers of the transversus are inclined downwards and medially and in the upper part of the region the anterior and posterior layers are related to rectus abdominis, as their names indicate, i.e. directly in contact with the anterior and posterior surfaces of the rectus. Between the umbilicus and iliac crest the relative positions of the laminae enclosing the transversus strata are reversed (as described with obliquus internus). Proceeding from the umbilicus towards the pubis the fibres of the posterior layer of the transversus aponeurosis are slowly and progressively transferred to the anterior layer; the posterior layer diminishes in thickness and becomes a fine attenuated layer before fading a short distance above the pubic level. The change in character of the posterior wall of the rectus sheath does not occur at an abrupt arcuate line, as in traditional accounts, and its progressive attenuation is compensated for by an increased thickness of fascia transversalis. The lowest aponeurotic fibres of transversus form a principal component of the falx inguinalis. Above this the anterior and posterior fibres of transversus cross the midline and are continuous with the anterior and posterior aponeurotic fibres of the contralateral obliquus internus respectively.

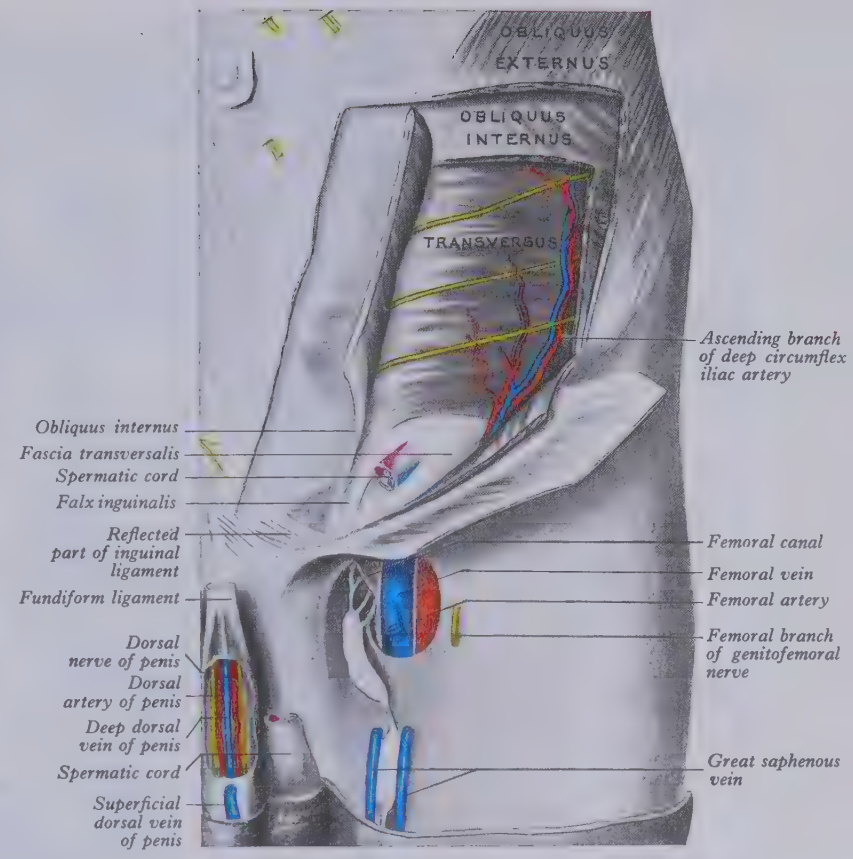
Fusiform defects filled with fascia occur in lower parts of the internal oblique and transversus abdominis. The muscles are sometimes fused; transversus may be absent.

The falx inguinalis (5.50,51), the conjoint tendon of internal oblique and transversus, mainly from the latter's compound aponeurosis, is attached to the pubic crest and pecten. It descends behind the superficial inguinal ring, supporting an otherwise weak area. Attachment to the pecten pubis is often absent. Medially it fuses with the *anterior* wall of the rectus sheath. Laterally, it may blend with an inconstant *interfoveolar ligament* (5.51), which sometimes connects the lower margin of transversus to the superior pubic ramus and occasionally contains a few muscular fibres. Muscular fasciculi, attached to the pecten pubis *behind* the falx inguinalis, may reach the transversalis fascia, the muscle's aponeurosis or even the lateral end of the arcuate line.

Nerve supply: ventral rami of the lower six thoracic and first lumbar spinal nerves.

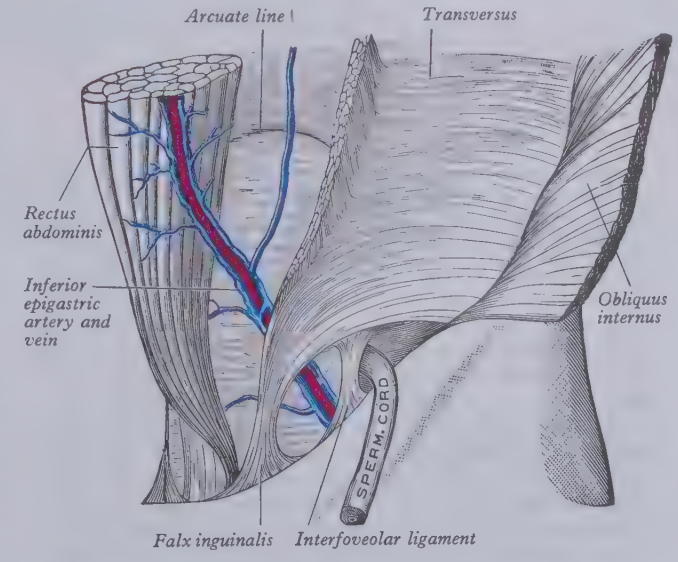
Rectus abdominis (5.52), a long muscular strap, broader but thinner above, descends throughout the abdominal wall, from ventral lower thorax to pubis, and is separated from its fellow by the linea alba. Narrower and thicker below, it springs by two tendons; the larger lateral one is attached to the pubic crest and tubercle and sometimes extends beyond the tubercle to the pecten pubis; the medial tendon, interlacing with its fellow, blends with ligaments anterior to the symphysis pubis and pubic bodies. Some fibres may spring from the linea alba's lower part. The muscle is attached above by three unequal slips to the fifth to seventh costal cartilages; most lateral fibres are usually attached to the ventral end of the fifth rib; this slip may be lacking but conversely the muscle may also reach even the fourth and third ribs; the most medial fibres are occasionally attached to costoxiphoid ligaments and their side of the xiphoid process.

The rectus is interrupted by three *tendinous intersections*: one usually near umbilical level, another near the xiphoid apex, a third about midway between these. Transverse or obliquely zigzag, viewed from the ventral aspect, they rarely extend through the full thickness of the muscle, often only halfway through; they are closely adherent to the anterior compound wall of the rectus sheath. Sometimes one or two incomplete intersections appear below the umbilicus; whether they are myosepta delineating myotomes remains controversial. The muscle is enclosed by aponeuroses of the oblique and transverse muscles, forming a so-called *rectus sheath* (5.44,48,53A–E). **The traditional account** (5.53A,B) of the composition of the rectus sheath is first given here; in part because of its frequent inclusion in introductory courses; also to allow a direct comparison with the modification, revision and strong functional implications that stem from extensive recent investigations; these are summarized below. Traditionally each anterolateral muscle was regarded as initially forming a *single unilaminar* aponeurosis, that was confined to its ipsilateral side and *ended* in the median linea alba. At the lateral margin of the rectus abdominis the internal oblique aponeurosis divides: one lamina passing anterior to the rectus and blended



with the external oblique's aponeurosis; one behind it blending with that of transversus. These laminae blend at the medial border, helping to form the linea alba. Some authors differed in their description, e.g. Walmsley (1937), McVay & Anson (1940), but this arrangement was widely agreed to exist from the costal margin to a variable level, usually midway between the umbilicus and symphysis pubis, where the sheath's posterior wall was described as ending in an *arcuate line*, concave downwards. The upper muscular fibres of transversus abdominis (p. 600) continue behind the rectus abdominis nearly to the linea alba (5.48,53A), the posterior layer of the sheath being here variably muscular. Below the arcuate line all three aponeuroses are anterior to the rectus, those of transversus and internal oblique intimately fused, that of external oblique bound to them by loose tissue except near the midline; this part of the rectus is separated from the peritoneum only by transversalis fascia (5.53B). Since the aponeuroses of the internal oblique and transversus reach only to the costal margin, above that level the rectus rests directly on the costal cartilages, overlapped here merely by the aponeurosis of external oblique.

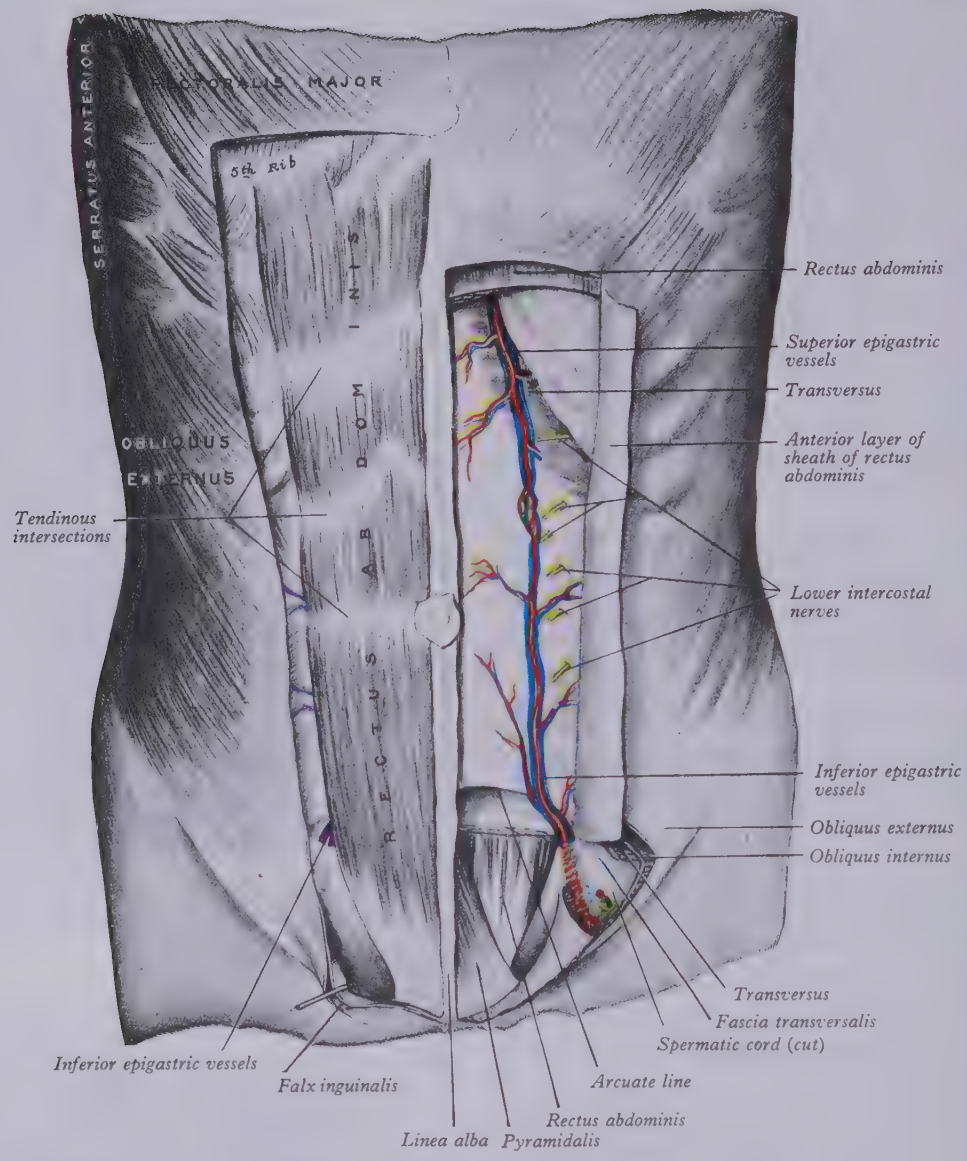
More recent observations (Rizk 1980) on the aponeuroses of the ventrolateral abdominal muscles, rectus sheath, linea alba, linea semilunaris and the site of the so-called arcuate line have been mentioned in the descriptions of individual muscles. With the exception of the arcuate line the general extent of the sheath differs little from the traditional account. Major differences are as follows:



1. The obliquus externus, internus and transversus each form a *bilaminar aponeurosis*.
2. Of the six laminae three pass anterior to rectus and three posterior; i.e. the walls of the rectus sheath are *trilaminar* down to the umbilicus; below this, layers are changed in their superficial-deep sequence and near the pubis they are modified by the formation of the falx inguinalis.
3. The aponeurotic laminae undergo extensive or limited vertical linear *decussations* with either their antimere or another muscle, some at the linea semilunaris, some at the ventral vertical midline of the rectus, but most at the linea alba, in the midline and/or bilaterally.
4. Each aponeurotic lamina crosses the midline and becomes structurally and functionally continuous either with its antimere or another contralateral muscle.
5. The four principal (perhaps unfortunately named, but informative) *bilateral digastric* muscles are: two external obliques together, two transversus muscles together, one internal oblique (anterior layer) with contralateral external oblique (posterior or deep layer) and finally, one internal oblique (posterior layer) with contralateral transversus abdominis (anterior layer). (See 5.53C–E.)

From the costoxiphoid margin to the umbilical level the anterior wall of the rectus sheath is, as stated, trilaminar and consists (from the external surface, deeply) of: (a) an external oblique aponeurosis superficial layer (fibres oblique, disposed upwards and medially), i.e. downwards and laterally when described as continuations from the contralateral external oblique; (b) an external oblique aponeurosis deep layer (fibres oblique downwards and medially); (c) an internal oblique anterior layer (fibres oblique upwards and medially). Thus the layers (a) and (c) have parallel fibres (upwards and medially), and layer (b), sandwiched between them, has inferomedially directed fibres at right angles to them both. This construction has been likened to the cross-grain of plywood and it is also characteristic of the posterior wall of the sheath in at least 70% of individuals. Proceeding from the muscle towards the extraperitoneal fascia, it has: (x) an internal oblique posterior layer (upwards and medially); (y) a transversus abdominis anterior layer (downwards and medially); (z) a transversus abdominis posterior layer (upwards and medially).

As indicated with the individual muscles, the sequence of layers is changed between the umbilicus and the iliac crest levels and the patterns of fibre disposition change accordingly. Also noted previously was the absence of a sudden posterior transition at an arcuate line; instead there is a slow attenuation with transference of fibres to the anterior layer and to the falx inguinalis and a posterior compensatory thickening of the fascia transversalis.



5.50 Dissection of the regions shown in 5.46, with parts of the external and internal oblique muscles removed. (See text for additional recent observations on abdominal aponeuroses.)

5.51 The lower part of the anterior abdominal wall (left side) showing the relations of the spermatic cord at the deep inguinal ring. (Modified from Braune.) Some authorities do not recognize the sharp arcuate line as the abrupt terminus of the posterior wall of the rectus sheath (see text).

The rectus muscle's medial border adjoins the linea alba: its lateral border may show as a superficial, curved *linea semilunaris* from the tip of the ninth costal cartilage to the pubic tubercle and is visible in muscular subjects even when the muscle is relaxed, but usually obscured in the corpulent.

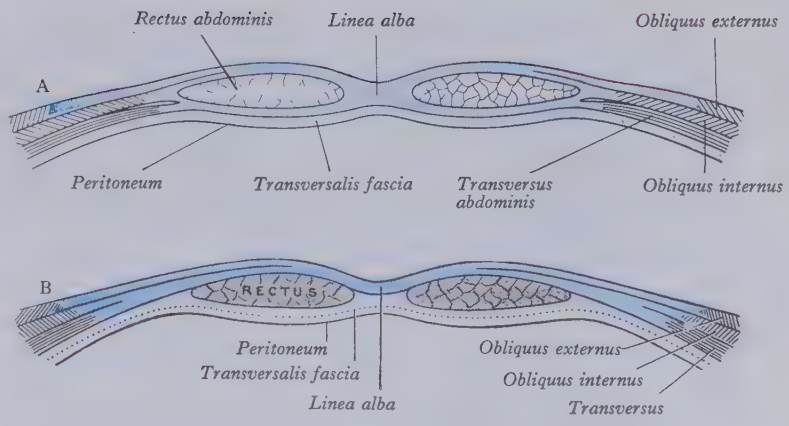
Nerve supply: ventral rami of the lower six or seven thoracic spinal nerves.

5.52 The right rectus abdominis and the left pyramidalis. The greater part of the left rectus abdominis has been removed to show the superior and inferior epigastric vessels. (See text for additional recent observations on the abdominal aponeuroses, rectus sheath and controversial 'arcuate line'.)

Pyramidalis (5.52) is a triangular muscle anterior to the lower part of rectus abdominis and in its sheath; it is attached by tendinous fibres to the front of the pubic body and the anterior ligaments of its symphysis; it ascends, diminishing in size, with its lateral border inclining medially and its pointed end embedded in the linea alba midway between the umbilicus and pubis, sometimes higher. It varies much and may be larger on one side, absent, or sometimes double. Anson et al (1938) found it absent in 76 out of 430 cadavers (17.7%).

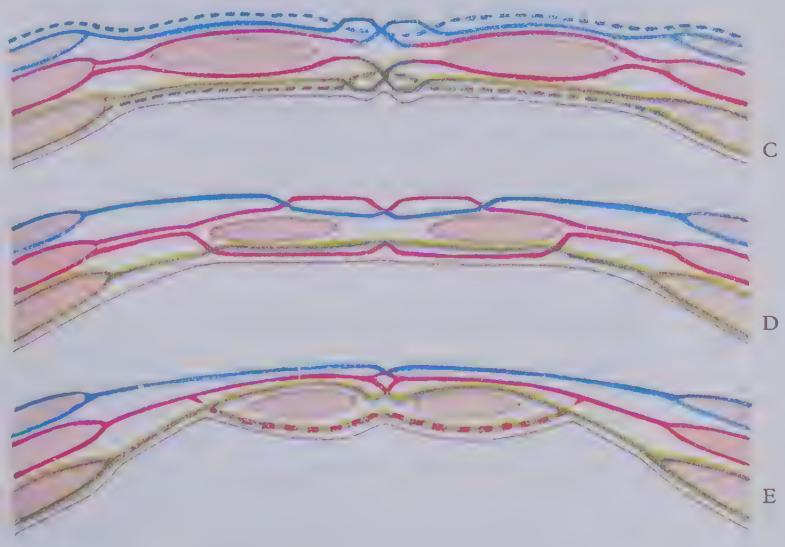
Besides rectus abdominis and pyramidalis the rectus sheath contains superior and inferior epigastric vessels and terminal parts of the lower intercostal nerves.

Nerve supply: subcostal nerve (i.e. the ventral ramus of the twelfth thoracic spinal nerve).



Actions. The anterolateral muscles are a firm but elastic wall retaining abdominal viscera and opposing actions of gravity on them in both erect and sitting postures. However, their most frequent phasic involvement is in respiration.

When the thorax and pelvis are relatively fixed in position (or during minimal strongly controlled movement), contraction of the abdominal muscles 'compresses' abdominal viscera and assists in expelling air during expiration (also faeces, urine, gastric contents, or a fetus), mainly due to the oblique and transverse muscles, which tense the rectus sheaths and lineae alba and semilunaris, the rectus abdominis itself playing a minor role. If the pelvis and vertebral column are fixed, the external oblique muscles further aid expiration by depressing and compressing the lower thorax. When the pelvis is fixed the recti, aided by the obliqui, *flex* the lumbar vertebral column; with the thorax fixed they draw the pelvis up and forwards, also flexing the vertebral column (Floyd & Silver 1950). If the abdominal muscle's action is predominantly unilateral, the trunk is *laterally flexed* to that side. The obliques also co-operate as bilateral digastric muscles in effecting *vertebral rotation*; e.g., as noted, the deep fibres of external oblique decussate at the midline and are continuous with the anterior aponeurotic layer of the internal oblique of the contralateral side. Their actions are complementary; the contraction of one external oblique turns the abdomen and rotates the vertebral column to the contralateral side, while the *opposite* internal oblique turns and rotates them to *its* ipsilateral side, i.e. in the same direction. Electromyography suggests that in most trunk movements, sitting or standing, abdominal musculature is little involved, unless resistance is applied. Extension raises their activity, flexion does not. All activity ceases in the supine position but



the recti at once contract even when the head alone is raised. Further flexion brings the obliques into action, but less forcibly. The obliques appear largely concerned in compressive and twisting movements, the recti in flexion against resistance. In standing there is little activity in abdominal musculature, except for the internal oblique, accessible to electromyography in its lower part (p. 598). Transversus was long assumed to be only compressive and not acting on the vertebral column. However, the more recent analyses of the dispositions of its aponeurotic layers, and particularly the completion of a digastric bilateral muscle between the 'downturned' fibres of one transversus with the posterior layer of the contralateral transversus, makes rotational activity a distinct possibility. Further researches are necessary; unfortunately effective electromyography is difficult. (The *oblique orthogonal* aponeurotic layers cast doubt on the suitability of the name 'transversus'.) Pyramidalis is a tensor of the linea alba.

The linea alba (5.44,53), a complex tendinous raphe extending from the xiphoid process to the symphysis pubis and pubic crest between the recti, is an intermixture of aponeurotic fibres of the oblique and transverse muscles. It was long regarded as a mere moulded feltwork of poorly vascularized collagen that provided a strong structural bond between the rectus sheaths and terminal attachments ('insertions') for essentially unilateral ventrolateral muscles. Its structural status has now been profoundly revised. The three large ventrolateral muscles on both sides each give rise, as noted, to a bilaminar aponeurosis. Having variously contributed to the walls of the rectus sheath, medial to the rectus, six laminae on each side border the interrectal gap. This is occupied by numerous *linear decussations* and together these constitute the linea alba. Each lamina and its antimere may have one or three vertical lines of decussation and this varies between individuals and laminae. When single, the decussation naturally is midline; when triple, one is midline, the others near the medial border of each rectus. The decussations between particular layers are densely packed but occur successively at increasing depths from the surface. After decussation, each layer is continuous with its antimere or with an aponeurotic lamina from another contralateral muscle. Individual examples are mentioned above in the descriptions of particular muscles; note also less prominent sites of decussation, a limited subumbilical length deep to the linea semilunaris and at a similar level ventral to the midline of rectus abdominis. (The positions of the linear decussations and transmedian continuations of aponeuroses are shown in 5.53C–E.) Just below the midpoint of the linea alba is a cicatrix, covered by adherent skin, the *umbilicus*, below which the linea alba is narrow, following the interval between the recti and visible only in the lean and muscular as a slight groove. In its supra-umbilical part, where recti diverge, it is broader and thinner and superficially there is a shallow groove. Inferiorly its superficial fibres pass *in front* of the medial heads of the recti to reach the symphysis pubis; its deeper fibres form a triangular lamella, attached *behind* the recti to the pubic crest on each side as the *adminiculum lineae albae*. Small vessels traverse the linea. The umbilicus transmits umbilical vessels, urachus and, until the third month, the vitelline stalk; it closes a few days after birth, but vestiges of vessels and urachus are attached to its deep aspect (i.e. *hepatic ligamentum teres* and *median* and *medial umbilical ligaments*).

Transversalis fascia is a thin areolar stratum between the transversus and extraperitoneal fat, part of the general layer between the peritoneum and the abdominal walls and continuous with the iliac and pelvic fasciae. In the inguinal region it is thick, dense and augmented by the attenuated aponeurosis of transversus; but it thins as it ascends to blend with the inferior diaphragmatic fascia. Behind, it fuses with the anterior lamina of the thoracolumbar fascia. Below it is attached along the whole iliac crest between the transversus and iliacus and to the posterior margin of the inguinal ligament from the anterior superior iliac spine to the femoral vessels, where it is continuous with the iliac fascia. Medial to these vessels it is thin and fused to the pecten pubis behind the falx inguinalis, with which it blends. It descends anterior to the vessels as the anterior part of the femoral sheath (p. 781); transversalis fascia is here strengthened by transverse arched fibres spreading laterally to the anterior superior iliac spine and diverging medially behind the rectus abdominis, while some

5.53A,B Transverse sections through the anterior abdominal wall, traditional view: (A) immediately above the umbilicus; (B) below the arcuate line. Note the extent to which the external oblique aponeurosis remains as a separate entity, passing medially, ventral to the rectus, before blending with the other aponeuroses; these have already fused lateral to rectus. The traditional view is retained here to maintain historical perspective and for readers whose objectives it remains adequate. (For further analysis see text, 5.53C–E and Rizk 1980.)

5.53C–E Schematic transverse sections through the ventral abdominal wall, showing bilaminar aponeuroses, external oblique (blue), internal oblique (magenta), transversus abdominis (green), and sites of linear decussation (arrows) which compacted form the linea alba. Tenuous layers are dotted or omitted. (See text for details and reference to Rizk 1980.)

descend to the pecten pubis behind the falx inguinalis. These fibres constitute the *deep crural arch*. The spermatic cord or round ligament passes through the transversalis fascia at the *deep inguinal ring*. The *internal spermatic fascia*, derived from the transversalis, is prolonged along these structures to blend with areolar tissue in the parietal layer of the tunica vaginalis (p. 1424); it sometimes contains muscle fibres (Barrett 1951). The deep crural arch thickens the inferomedial part of the deep inguinal ring.

The deep inguinal ring in the transversalis fascia is midway between the anterior superior iliac spine and the symphysis pubis; it is about 1.25 cm above the inguinal ligament. Oval, its long axis vertical, it varies in size, being larger in males. It is related above to the lower margin of transversus abdominis, medially to the inferior epigastric vessels and interfoveolar ligament, when present. Traction on the ring by the internal oblique is perhaps a valvular safety mechanism when intra-abdominal pressure is raised (Lytle 1970).

The inguinal canal contains the spermatic cord or uterine round ligament and ilio-inguinal nerve. *Oblique*, about 4 cm long,

it slants *inferomedially, parallel with* and a little above the inguinal ligament, from the deep to the superficial inguinal rings. *Anterior* to the canal are the skin, superficial fascia, external oblique aponeurosis and, in its lateral third, muscular fibres of the internal oblique. *Posterior* are the reflected inguinal ligament, falx inguinalis and transversalis fascia, separating it from extraperitoneal connective tissue and the peritoneum. *Superior* are the arched fibres of the internal oblique and transversus abdominis. *Inferior* is the union of the transversalis fascia and the inguinal ligament. At its medial end, inferiorly, is the lacunar ligament.

The canal would appear to weaken the lower anterior abdominal wall but this is countered by its obliquity and mural structure. Thus its rings do not coincide; increases in intra-abdominal pressure affect not only the deep ring but also the posterior wall, pressing it firmly towards the anterior. The posterior wall is strengthened by the falx inguinalis and the reflected inguinal ligament that lie directly behind the superficial ring; and, reciprocally, the internal oblique overlaps the deep ring (p. 598). The parts of the internal oblique and the transversus attached to the inguinal ligament (i.e. fibres which 'arch' over the canal) are constantly active in standing; any increase in intra-abdominal pressure (as in coughing or straining) augments contraction of the internal oblique (and probably the transversus).

Extraperitoneal connective tissue is an areolar stratum between the peritoneum and the general fascial lining of the abdominal and pelvic cavities. It varies in distribution, being posteriorly abundant, particularly around the kidneys, where it contains much fat. Anterolaterally it is scanty except in the pubic region, above the iliac crest and in the pelvis. Such fasciae are usually no more than the general connective tissue between differentiated structures. In some regions, however, there occur aligned bundles of collagen, sometimes some elastic fibres and, particularly in the pelvis, bundles or sheets of non-striated muscle. Extraperitoneal tissue is continuous with the epimysium of abdominal muscles and hence with their internal connective tissue.

POSTERIOR ABDOMINAL MUSCLES

Psoas major and minor and iliacus, with their fasciae, though part of the abdominal parietes, are in part muscles of the lower limb and are described with them. Only quadratus lumborum will be considered here.

Enclosing quadratus lumborum are the *anterior* and *middle* layers of the *thoracolumbar fascia* (p. 587). The anterior layer is attached medially to the anterior surfaces of the lumbar transverse processes, below to the iliolumbar ligament and above to the apex and lower border of the twelfth rib. Its upper margin, from the first lumbar transverse process to the lower border of this rib, is the *lateral arcuate ligament* (p. 592). Laterally, this anterior layer blends with the fused posterior and middle strata of the thoracolumbar fascia (5.38).

Quadratus lumborum (5.37,43), irregularly quadrilateral and inferiorly broader, is attached by aponeurotic fibres to the iliolumbar ligament and adjacent iliac crest for about 5 cm; it ascends to the medial half of the lower border of the twelfth rib; it is also attached by four small tendons to the apices of the upper four lumbar transverse processes and sometimes also to the twelfth thoracic. A second layer of muscle may exist anterior to this, passing from the upper borders of the lower three or four lumbar transverse processes to the lower margin and anterior surface of the last rib.

Anterior to quadratus and its fascia are the colon, kidney, psoas major and minor and the diaphragm; the subcostal, iliohypogastric and ilio-inguinal nerves are also anterior to the fascia but bound down by a medial continuation of the transversalis fascia.

Nerve supply: the ventral rami of the twelfth thoracic and upper three or four lumbar spinal nerves.

Actions: fixation of the twelfth rib (a diaphragmatic attachment). With pelvis fixed, there is lateral flexion of the vertebral column to the same side; acting together both muscles may assist lumbar vertebral extension.

5. Pelvic Muscles and Fasciae

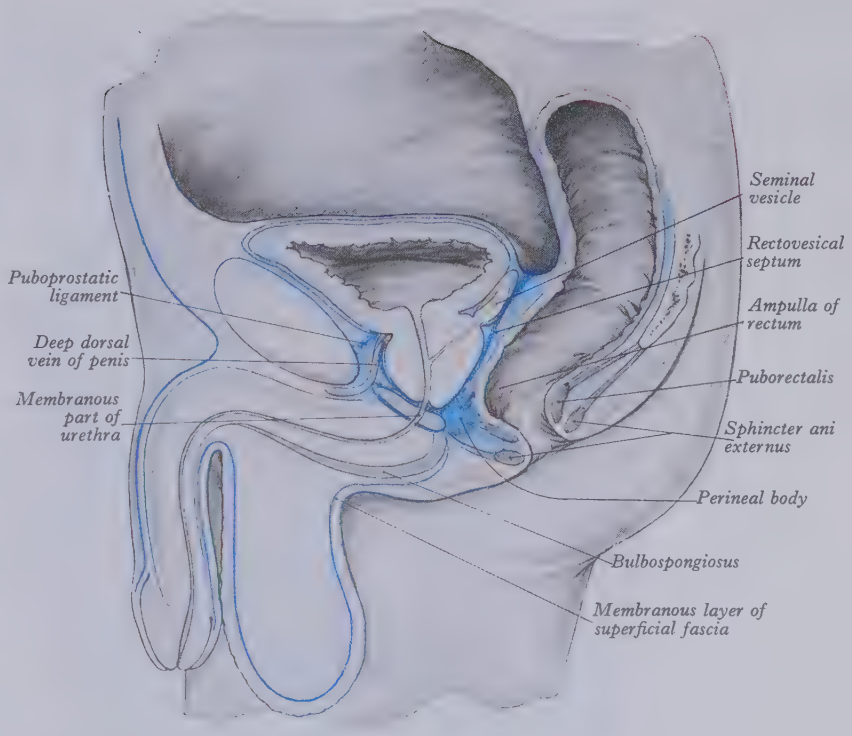
Pelvic muscles form two groups: (1) piriformis and obturator internus, described with muscles of the leg (pp. 642, 643); (2) levator ani and coccygeus which, with their antimeres, form the **pelvic diaphragm**. Their fasciae form a connective tissue continuum (5.54), joined to fascial coverings of pelvic viscera above and perineal fasciae below. (For muscles and fasciae of the **urogenital diaphragm** see pp. 606–608.)

Pelvic fascia may be resolved for description into: (1) *parietal pelvic fasica*, sheaths of pelvic muscles; (2) *visceral pelvic fascia*, sheaths of pelvic viscera, their blood vessels and nerves (see individual organs).

Parietal pelvic fascia on the pelvic surface of obturator internus is well differentiated as *obturator fascia*, connected above to the posterior part of the innominate bone's arcuate line and continuous with the iliac fascia. Anterior to this, as it follows the muscle's attachment, it gradually separates from the iliac fascia, continuity being retained only by the periosteum. It arches below the obturator vessels and nerve, completing their canal, and is attached anteriorly to the back of the pubis. Above the *tendinous arch of levator ani* (vide infra) the obturator fascia is markedly aponeurotic and part of the attachment of levator ani (p. 605); below this it is thin and part of the lateral wall of the ischiorectal fossa (p. 606), where it blends with a fascial sheath around the internal pudendal vessels. It is indirectly continuous behind with fascia on the piriformis.

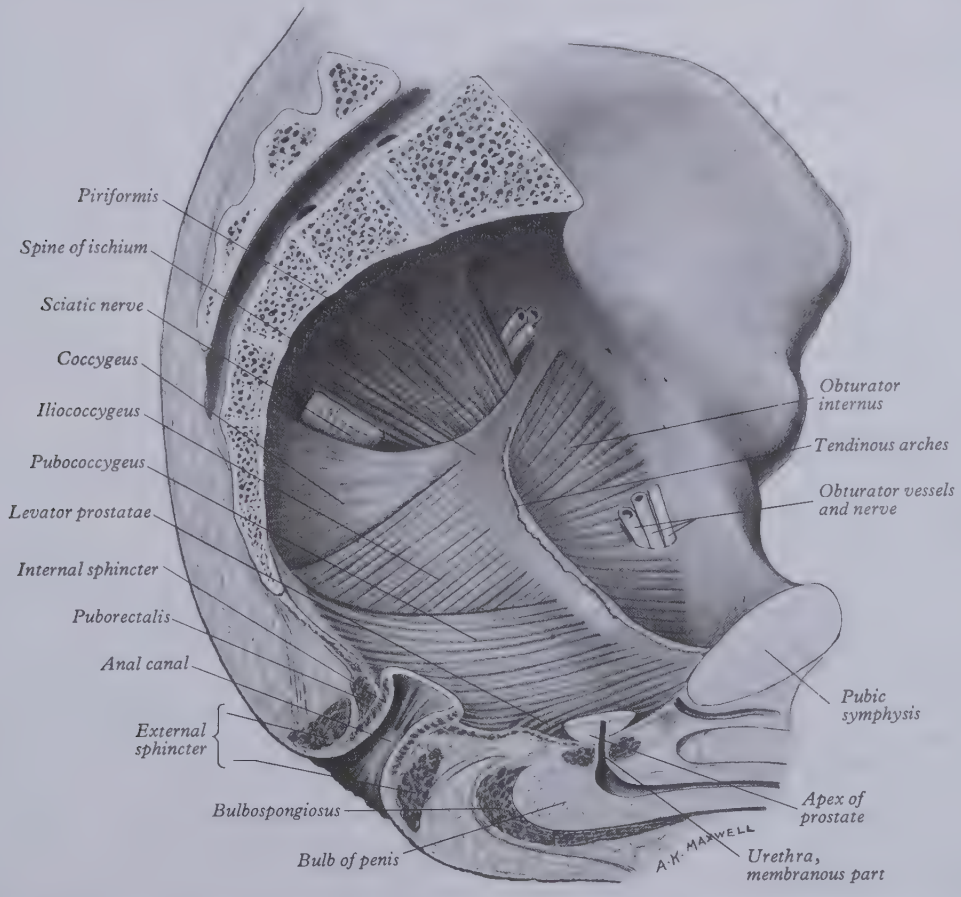
The *piriform fascia* is very thin, fusing with the anterior sacral periosteum at the margins of the anterior sacral foramina, where it *ensheathes* the emerging sacral anterior primary rami, often described as *behind* the fascia. Internal iliac vessels are, however, enclosed in extraperitoneal tissue *anterior* to the fascia and their branches take sheaths of it into the gluteal region, above and below the piriformis.

Fascia of the pelvic diaphragm covers both surfaces of levator ani; below it is the thin, so-called *inferior fascia of the pelvic diaphragm* (anal fascia), which some dispute; it covers the ischiorectal fossa's medial wall and is continuous above with the pudendal sheath and obturator fascia along the attachment of levator ani; it is also continuous with fasciae on the sphincteres urethrae and ani externus. Fascia on the upper surface of the levator ani (*superior fascia of the pelvic diaphragm*) laterally follows the muscle's attachment; anteriorly it is attached to the back of the pubic body, about 2 cm above its lower border, and extends laterally across the superior pubic ramus to blend with the obturator fascia, continuing along an irregular line to the ischial spine. In lower mammals the levator ani springs dorsally (posteriorly) from the pelvic brim but its human attachment is lower (more caudal, or inferior), leaving its aponeurosis as a thickened upper part of the obturator fascia. Tendinous fibres of its attachment may reach the pelvic brim. Medially, the superior pelvic diaphragmatic fascia blends with the visceral pelvic fascia. The fibrous sheets, or the compound 'fascia' on obturator internus above the attachment of levator ani, is therefore composed of (*a*) obturator fascia, (*b*) fasciae of levator ani, and between these (*c*) degenerated levator aponeurosis. The thickened fusion of these structures is the *tendinous arch of the levator ani*. This is to be distinguished from a lower *tendinous arch of the pelvic fascia*, a thick white band within the superior pelvic fascia extending from the lower symphysis pubis to the inferior margin of the ischial spine. This is the attachment of the lateral, 'true' vesical ligament. Anteriorly the same fascia forms two thick bands, the paired *puboprostatic (pubovesical) ligaments*.



The levator ani (5.55), a broad, thin sheet attached to the internal surface of the lesser (true) pelvis, unites with its fellow to form most of the pelvic floor. *Anteriorly* it is attached to the pelvic surface of the pubic body lateral to the symphysis, *posteriorly* to the medial surface of the ischial spine and, between these, to the obturator fascia. Its attachment to the fascia corresponds posteriorly to the tendinous arch of levator ani; but in front the muscle is attached to fascia to a varying extent above the arch, sometimes almost as high as the obturator canal. The muscle's fibres pass medially with varying obliquity; the most anterior sweep back across the side of the prostate to the perineal body

(p. 607), forming a *levator prostatae*; but in females they cross lateral to the vagina, forming an additional sphincter, the *pubovaginalis*. Intermediate fibres slope postero-inferiorly lateral to the prostate and turn medially to meet those from the other side, forming a muscular sling at the anorectal flexure; this thick part is the *puborectalis*. Posterior fibres mingle with those of the deep external anal sphincter. Some intermediate fibres blend with the longitudinal rectal muscle, descending within the puborectal sling as the anal canal's conjoined longitudinal layer (p. 1373). The most posterior fibres are attached to the last two coccygeal segments and anococcygeal ligament (p. 1369).



Morphologically levator ani is divisible into *pubococcygeus* and *iliococcygeus*, a useful approximation for description; but their mammalian homologies are controversial (Wendell-Smith 1967).

Pubococcygeus is attached to the back of the pubic body and anterior part of obturator fascia and passes back almost horizontally lateral to the anal canal to reach the front of the coccyx, where it is attached by a tendinous plate continuous with the ventral sacrococcygeal ligament. *Iliococcygeus* springs from the ischial spine and posterior part of levator ani's tendinous arch; its fibres reach the sides of the coccyx and blend with those of the other side in a median raphe inferior to the tendinous plate of pubococcygeus, contributing to the anococcygeal ligament. Iliococcygeus is usually thin and may be aponeurotic; an accessory slip of its posterior part is the *iliosacralis*. In tailed mammals both muscles are attached only to caudal vertebrae; iliococcygeus effects lateral movements and pubococcygeus draws the tail between the hind limbs. Gradual loss of the tail frees these muscles to make a more complete pelvic floor, particularly necessary in bipeds. Levator and depressor caudae of tailed mammals are said to be represented by the rudimentary human *ventral* and *dorsal sacrococcygeal* muscles.

Relations. The *superior (pelvic) surface* of levator ani is separated only by fascia (superior of the pelvic diaphragm) from

5.54 Median sagittal section through the pelvis, showing the arrangement of the fasciae (blue).

5.55 Pelvic aspect of the left levator ani and coccygeus. The superior gluteal vessels and nerve have been cut close to the upper border of the piriformis; the anal canal has been divided below the anorectal flexure and the greater part of the prostate has been removed. The constituent parts of the levator ani are shown. Note: coccygeus is fused and coextensive with the sacrospinous ligament; the latter is viewed from the gluteal aspect.

the urinary bladder, prostate, rectum and peritoneum. Its *inferior (perineal) surface* is the ischiorectal fossa's medial wall and the superior wall of the fossa's anterior recess (vide infra), both covered by the inferior fascia of the pelvic diaphragm. The muscle's *posterior border* is separated from the coccygeus by areolar tissue. *Medial borders* of both muscles are separated by the *visceral outlet*, through which pass the urethra, vagina and ano-rectum.

Nerve supply: fourth sacral spinal nerve and from the inferior rectal (p. 1149) or perineal division of the pudendal nerve.

Actions: constriction of the rectum and vagina and probably fixation of the perineal body. With coccygei the levatores form a basin-shaped muscular *pelvic diaphragm* supporting pelvic viscera and opposing sudden increases in, but also an important factor in maintaining and controlling, intra-abdominal pressure. Since they are not easily accessible to direct or electromyographic examination, dogmatic views are to be avoided. Modern scanning techniques, however, support the above views.

Coccygeus (5.55) is posterosuperior to, and *in the morphological plane* of, levator ani. A triangular musculotendinous sheet, its apex is attached to the pelvic surface and tip of the ischial spine and is fused with the sacrospinous ligament; its base reaches the lateral margins of the coccyx and fifth sacral segment. It is occasionally absent, varying in proportions of muscular and fibrous tissues. It *is* the pelvic aspect of the sacrospinous ligament, which is commonly regarded as a degenerate part of it, or its aponeurosis. (In topographical studies it is helpful to note that muscle and ligament are *coextensive*, the former viewed from the pelvic aspect, the latter from the gluteal aspect.) The muscle is well developed and the ligament often absent in mammals with a mobile tail. Morphologically coccygeus (*ischio-coccygeus*) is probably part of the iliococcygeal moiety of levator ani.

Nerve supply: fourth and fifth sacral spinal nerves.

Actions. The coccygei probably pull forward and support the coccyx after defaecation or parturition. With levatores ani and piriformes they compress the posterior part of the pelvic cavity and outlet (also the 'birth canal').

Applied Anatomy. Injuries to muscles of the pelvic floor often occur in parturition. Rupture of the perineal body (p. 607), which includes fibres of pubovaginalis, permits divarication of the levatores and may contribute to uterovaginal prolapse.

6. Perineal Muscles and Fasciae

The perineum overlies the **inferior pelvic aperture** (pelvic outlet). Its skeletal boundaries are: *anteriorly*, the pubic arch and arcuate pubic ligament; *posteriorly* the tip of the coccyx; and *laterally* (from before-backwards) the conjoined inferior pubic and ischial rami, ischial tuberosities and sacrotuberous ligaments. This osseoligamentous opening is trapezoid but its anterior and posterior parts are not coplanar (vide infra, and p. 518). Superficially the male perineum is limited by the scrotum, buttocks and the medial sides of the thighs. A transverse line in front of the ischial tuberosities divides the region into two triangular parts: a posterior **anal region** (*anal triangle*) contains the anal canal's ending; an anterior, the **urogenital region** (*urogenital triangle*), contains external urogenital structures. The urogenital triangle inclines downwards and backwards, whereas the anal triangle inclines downwards and forwards; these sloping planes meet laterally at the lowest (most inferior) parts of the boundaries of the pelvic outlet, the massive ischial tuberosities. It is instructive to consider the relative positions of the tuberosities (and their overlying tissues) with those of the urogenital and anal triangles when in a sitting posture on a firm surface.

Perineal muscles and fasciae form, in both sexes, anal and urogenital groups; but they meet at the perineal body and are derived from a single morphological unit, the *sphincter cloacae*.

MUSCULATURE AND FASCIAE OF THE ANAL REGION

The superficial fascia is thick, areolar and adipose. Adipose tissue extends deeply into the right and left, vertical, cuneiform *ischiorectal fossae* between levatores ani and obturatores interni. **The deep fascia** lines each fossa; it includes inferior fascia of the pelvic diaphragm and that part of the obturator fascia below the attachment of levator ani.

The ischiorectal fossa, wedge-shaped, has a superficial, notional base (perineal surface) and a thin edge at the junction of obturator internus and levator ani, covered by the obturator and inferior pelvic diaphragmatic fascia. *Medially* are the sphincter ani externus, inferior pelvic diaphragmatic fascia, *laterally* the ischial tuberosity and obturator fascia. *Posteriorly* the fossa is partly limited by the lower border of gluteus maximus but extends deep to it to the sacrotuberous ligament. *Anteriorly* the fossa is partly bounded by the posterior aspect of the urogenital diaphragm but is prolonged *above* it as a narrow recess reaching almost to the posterior pubic surface. This *anterior recess* retains the same relations between obturator internus and levator ani, but is, as noted, deep (superior) to the muscles and fascia of the urogenital diaphragm; its anterior extent varies, being limited by fusion between the inferior fascia of the pelvic diaphragm and the superior fascia of the urogenital diaphragm. It may reach as far as the retropubic space.

Internal pudendal vessels and accompanying nerves are in the fossa's lateral wall, enclosed in fascia forming the *pudendal canal*; this sheath fuses with the lower part of obturator fascia, which ascends to blend with the inferior fascia of the pelvic diaphragm and descends to fuse with the falciform process of the sacrotuberous ligament (p. 517). It is sometimes termed the *lunate fascia* (8.141B) and regarded as the fossa's roof and lateral wall. It passes forwards above the urogenital diaphragm, blending with its lateral margin at its attachment to the inner surface of the inferior pubic ramus.

Sphincter ani externus (5.56,8.141B, p. 137), around the anal canal's lowest part, is adherent to skin; above, it overlaps the sphincter ani internus. Details appear on p. 1370. Briefly, it has deep, superficial and subcutaneous parts. Its deep part exchanges fibres with the puborectal sling above it (p. 607) and, via the perineal body, with the deep perineal muscles anterior to it. Similarly, the superficial part exchanges fibres with the superficial urogenital muscles; this part and, to a lesser extent, the others are attached to both the coccyx and the anococcygeal ligament. Above this attachment a median *retrosphinteric space* connects the ischiorectal fossae (Courtney 1949).

The anococcygeal ligament is a median, stratified, musculotendinous structure between ano-rectum and coccyx. With the overlying presacral fascia it has been termed the *postanal plate* (Wendell-Smith & Wilson 1977). From above it comprises the tendinous plate of pubococcygeus, the muscular raphe of iliococcygeus and the posterior attachments of the external anal sphincter.

Nerve supply: perineal branch of the fourth sacral spinal nerve and rami of the inferior rectal branch of the pudendal nerve (second and third sacral spinal nerves).

MUSCLES AND FASCIAE OF THE MALE UROGENITAL REGION

Urogenital musculature consists in both sexes (5.56,57) of bulbospongiosus, ischiocavernosus, transversi perinei superficialis and profundus and sphincter urethrae, which are concerned in urination, copulation and general support of the pelvic contents. These may be grouped as (1) *superficial urogenital muscles*: a median bulbospongiosus, right and left ischiocavernosi and transversi perinei superficiales, occupying the *superficial perineal space*; and (2) *deep perineal muscles*: a sphincter urethrae and right and left transversi perinei profundi, forming a **urogenital diaphragm**.

Superficial fascia of this region has a superficial adipose and a deeper membranous layer.

The *adipose layer*, thick, areolar, with variable amounts of fat, is continuous with the thin scrotal dartos muscle, with thicker circum-anal subcutaneous areolar tissue, and laterally with the superficial femoral fascia. In the midline it is adherent to skin and the membranous layer.

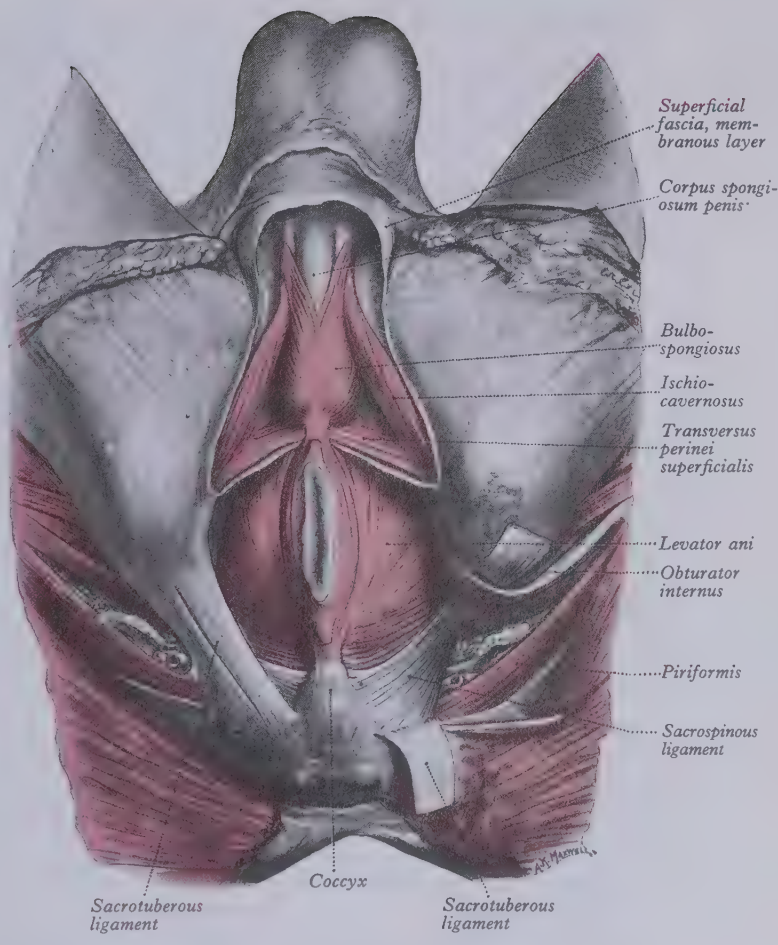
The *membranous layer* (5.54) is thin, aponeurotic and strong, perhaps serving to bind down muscles of the penile root. It is also continuous with the dartos muscle, fascia penis and membranous superficial fascial layer on the anterior abdominal wall; laterally it is attached to margins of the ischiopubic rami, lateral to the crura penis and as far back as the ischial tuberosities; posteriorly it curves round the transversi perinei superficiales to join the posterior margin of the fasciae of the urogenital diaphragm and perineal body. Between this layer and the inferior urogenital diaphragmatic fascia is the **superficial perineal space**.

The perineal body (the official term, *centrum tendineum*, is unsuitable; it is not an insubstantial centre, nor is it tendinous) is a median pyramidal fibromuscular node in the angle between the anal canal and urogenital apparatus, with the *rectovesical (rectovaginal) septum* at its apex. Below this, muscles and fasciae converge and interlace (cf. the *facial modiolus* p. 578). From above downwards these are the two levatores prostatae (pubovaginales), the deep and some superficial perineal muscles. The deep comprise the sphincter urethrae, deep transversi perinei and deep part of sphincter ani externus; the superficial are the bulbospongiosus, superficial transversi perinei and superficial part of the sphincter ani externus. Attachments of these to the pubes, ischia, and coccyx determine the position of the perineal body and hence of the visceral canals.

Transversus perinei superficialis, a narrow muscular strip, traverses the superficial perineal space anterior to the anus. Variable, often feeble and sometimes absent, it springs by tendinous fibres from the medial and anterior aspects of ischial tuberosity, runs medially to the perineal body and joins its antimere and superficial part of the sphincter ani externus behind, and bulbospongiosus in front. Sometimes the deeper layer of the sphincter ani externus decussates anterior to the anus, becomes more superficial and continues into the transversus, some fibres of which may join the ipsilateral bulbospongiosus or the sphincter ani externus.

Action. Contraction of both muscles probably helps to fix the perineal body, but details are uncertain.

Bulbospongiosus (bulbocavernosus) is a median muscle anterior to the anus, composed of two symmetrical parts united by a tendinous raphe. Muscle fibres spring from the median raphe and perineal body, diverging like the halves of a feather; the most posterior, a thin layer, disperse on the inferior fascia of the urogenital diaphragm; the middle fibres encircle the penile bulb and adjacent corpus spongiosum and are attached to an aponeurosis on their dorsal surfaces; anterior fibres spread out over the sides of the corpora cavernosa, ending partly in them, anterior to ischiocavernosus, partly in a tendinous expansion over the dorsal penile vessels.



Actions. Bulbospongiosus helps to empty the urethra; during urination it relaxes, usually contracting only at its end but is able to arrest it. The middle fibres assist in erection, probably by compressing bulbar erectile tissue, and the anterior fibres by compressing the deep dorsal vein (p. 1433). Like other perineal muscles it has been little investigated by electromyography but results suggest that, with the sphincter urethrae, it contracts repeatedly in ejaculation, as simple palpation reveals.

Ischiocavernosus covers the crus penis, attached by tendinous and muscular fibres to the medial aspect of the ischial tuberosity behind the crus and to the ischial ramus along the crural sides. Muscular fibres end in an aponeurosis attached to the sides and inferior aspect of the crus penis.

Action: compression of crus penis, maintaining penile erection.

Between these muscles is a triangular space, bounded medially by bulbospongiosus, laterally by ischiocavernosus, posteriorly by transversus perinei superficialis; its floor is the inferior fascia of the urogenital diaphragm. Posterior scrotal vessels and nerves and the perineal branch of the posterior femoral cutaneous nerve travel forwards in it; the transverse perineal artery follows its posterior boundary on the transversus perinei superficialis.

The deep stratum of urogenital muscles and their fasciae, i.e. transversus perinei profundus and sphincter urethrae, constitute the **urogenital diaphragm**. Inferior (superficial) to them is the *inferior fascia of the urogenital diaphragm* (*perineal membrane*), stretched almost horizontally across the pubic arch. Its posterior

5.56 Muscles of the male perineum. (Modified from Quain's *Anatomy*, 11th edn.)

base is fused with the perineal body and is continuous with the superior fascia of the urogenital diaphragm behind transversi perinei profundi and with the membranous layer of superficial fascia behind the transversi perinei superficiales. Its lateral margins are attached to the ischiopubic rami above the crura penis. Its anterior apex is a thickened *transverse perineal ligament*; between this and the arcuate pubic ligament the deep dorsal vein of the penis or clitoris enters the pelvis and the dorsal nerve leaves it. The diaphragm is perforated as follows: 2–3 cm behind the inferior border of the symphysis by the urethra, its circular aperture about 6 mm in diameter; by arteries and nerves to the bulb and, near the urethra, ducts of the bulbo-urethral glands; by deep penile arteries near the pubic arch and halfway along its margin; by dorsal penile arteries near its apex; in its base also by the posterior scrotal vessels and nerves.

Superior (deep) to the transversi perinei profundi and sphincter urethrae is a less defined *superior fascia of the urogenital diaphragm*, stretching across the pubic arch and continuous laterally with the obturator fascia. Behind, it blends with the inferior diaphragmatic fascia, perineal body and the membranous layer of superficial fascia; it is pierced by urethra and continuous here with the prostatic fascia.

Between the superior and inferior urogenital fasciae is the **deep perineal space**, containing: the membranous part of the urethra, the transversi perinei profundi and sphincter urethrae, bulbo-urethral glands and proximal parts of their ducts, pudendal vessels and dorsal penile nerves (in forward continuations of the pudendal canals), arteries and nerves of the penile bulb and a venous plexus.

Transversus perinei profundus extends from the medial aspect of the ischial ramus to end in the perineal body, joining its antimere, the deep part of the sphincter ani externus behind and

the sphincter urethrae in front, usually exchanging fibres with them.

Action: fixation of the perineal body, but clear functional observations are lacking.

The sphincter urethrae surrounds the membranous urethra. Its *inferior fibres* extend from the transverse perineal ligament and neighbouring fasciae, passing back on each side of the urethra to converge in the perineal body. Its *superior fibres*, some from the inner surface of each pubic ramus, pass medially to encircle the membranous urethra.

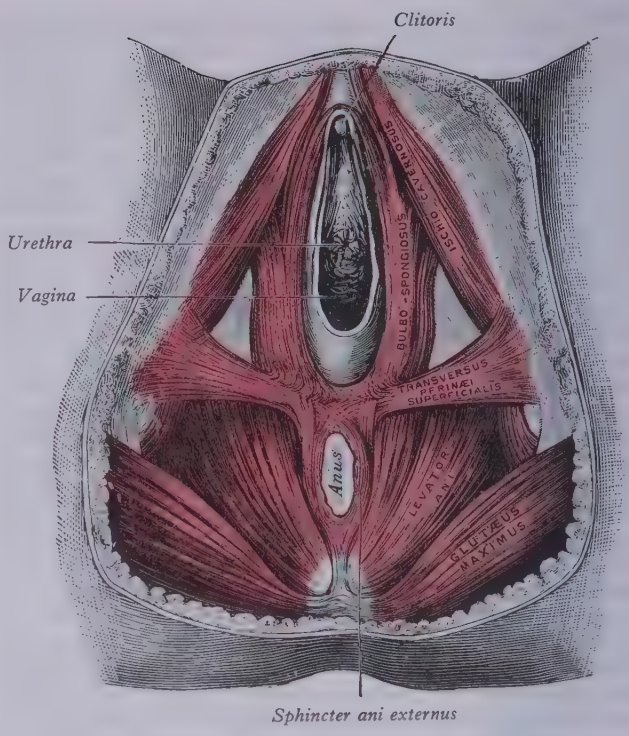
Actions: compression of the membranous urethra, particularly when the bladder contains fluid (Basmajian & Spring 1955). It relaxes during micturition, like bulbospongiosus, but ejects final drops of urine and is also concerned in ejaculation.

Nerve supply. All urogenital muscles are supplied by the perineal branch of the pudendal nerve (second to fourth sacral spinal nerves).

MUSCLES AND FASCIAE OF THE FEMALE UROGENITAL REGION

This includes the same five paired muscles as in males, with differences in size and disposition due to the vagina and external genitalia (5.57). They are similarly grouped into inferior and superior strata, the latter being the *urogenital diaphragm*.

The transversus perinei superficialis is a narrow muscular slip, differing little from its counterpart in males (vide supra).



Bulbospongiosus surrounds the vaginal orifice, covering the lateral parts of the vestibular bulbs, continuous posteriorly with the perineal body and blending with the sphincter ani externus. Its fibres pass forwards on each side of the vagina to the corpora cavernosa clitoridis; a fasciculus crosses over the dorsum of the body of the clitoris.

Actions: constriction of the vaginal orifice. Anterior fibres probably contribute to erection of the clitoris by compression of its deep dorsal vein.

Ischiocavernosus, smaller than in males, covers the unattached surface of the crus clitoridis. Attached by tendinous and muscular fibres to the inner surface of the ischial tuberosity behind the crus clitoridis, and to strips adjacent to crural margins along the ischial ramus, its fibres end in an aponeurosis attached to the sides and inferior surface of the crus clitoridis.

Actions: compression of crus clitoridis, retarding venous return and thus assisting erection.

The *inferior fascia of the urogenital diaphragm* is less extensive, being traversed by the vagina, with whose external coat it blends, and by the urethra, vessels and nerves as described in males (p. 607). It covers the following: parts of the urethra and vagina, transversi perinei profundi and sphincter urethrae, internal pudendal vessels, dorsal clitoridic nerves, arteries and nerves of vestibular bulbs and a plexus of veins.

5.57 Muscles of the female perineum.

Transversus perinei profundus extends from the internal aspect of each ischial ramus, across behind the vagina, to meet its antimere and other structures in the perineal body. More anterior fibres sink into the vaginal wall.

Action: fixation of the perineal body.

Sphincter urethrae, like the corresponding male muscle, has inferior and superior parts. The *inferior fibres* start from the transverse perineal ligaments and sweep back on each side of the urethra, some interlacing with those of the other side between the urethra and vagina, others passing into the vaginal wall. *Superior fibres* encircle the lower urethra.

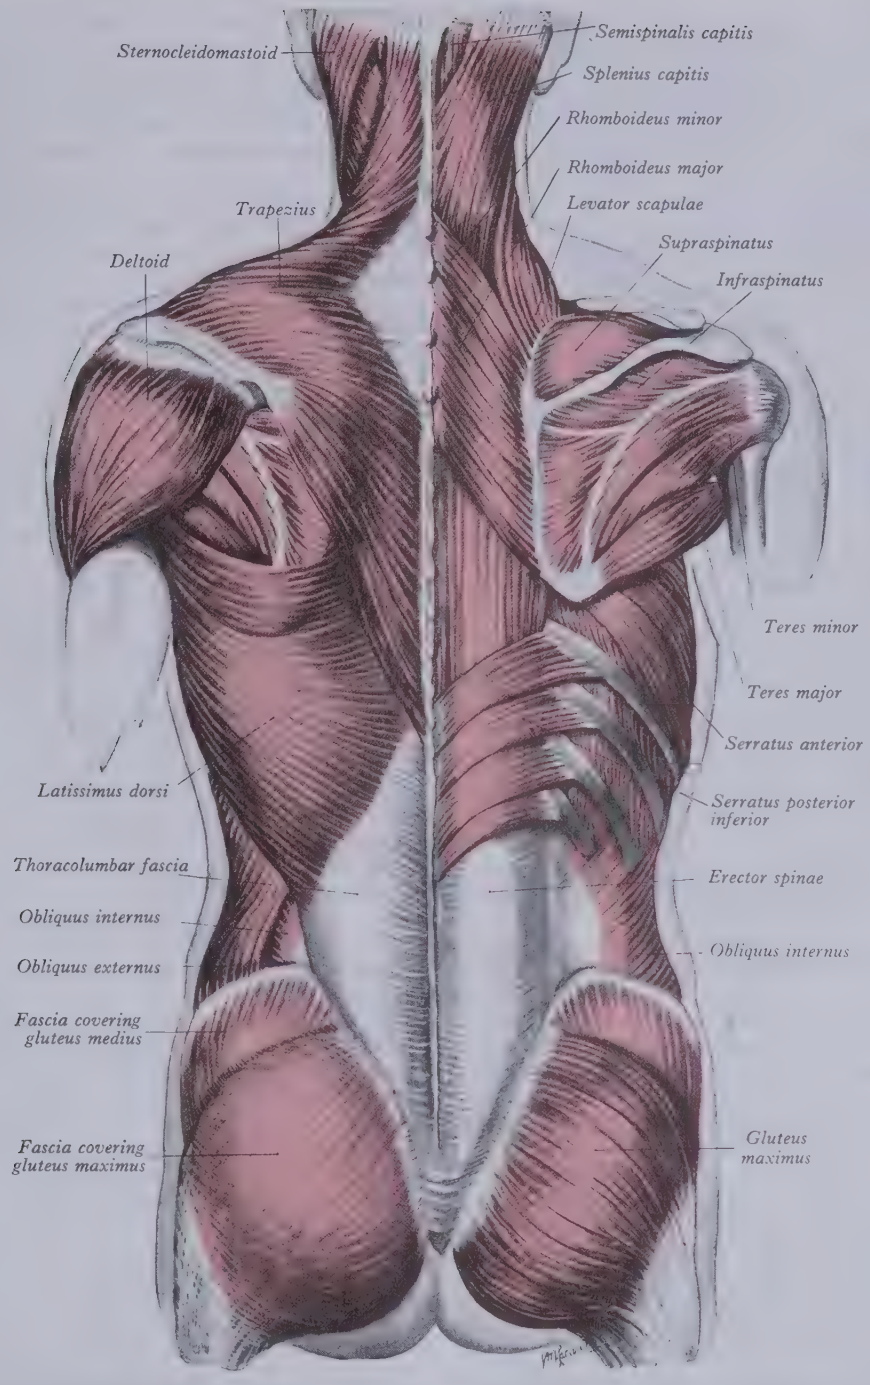
Action: urethral compression.

FASCIAE AND MUSCLES OF THE UPPER LIMB

Muscles of the upper limb may be grouped as follows:

1. Muscles connecting the upper limb and vertebral column.
2. Muscles connecting the upper limb and thoracic wall.
3. Muscles of the scapula.
4. Muscles of the upper arm.
5. Muscles of the forearm.
6. Muscles of the hand.

In this section brackets around numerals indicate doubt that the spinal nerves quoted actually provide a substantial *motor* innervation but are principally, or exclusively, sensory and autonomic. Heavy type indicates that the nerve or nerves indicated are predominant sources of motor supply in addition to the afferent modalities (p. 1130).



1. Muscles Connecting the Upper Limb and Vertebral Column

Trapezius, rhomboid major and minor and levator scapulae extend from the cervico-dorsal vertebral column to the pectoral girdle; latissimus dorsi reaches beyond this to the humerus.

The **superficial fascia** of the cervico-dorsal region, thick, strong, and adipose, is continuous with the general superficial fascia. In the upper neck it is tough, with much white connective tissue attaching it to skin.

The **deep fascia** of the region is a dense fibrous layer attached to the superior nuchal lines and ligamentum nuchae, and to all the thoracic vertebral spines below the seventh cervical and their supraspinous ligaments. Elsewhere it is thinner. It is attached laterally to the spine and acromion of the scapula and is continued over the deltoid into the arm; on the thorax it is continuous with the deep fasciae of axilla and chest, on the abdomen with fascia over the abdominal muscles; below, it reaches the iliac crest.

Trapezius (5.58), flat and triangular, extends over the dorsum of the neck and upper thorax; medially it is attached to the medial third of the superior nuchal line, external occipital protuberance, ligamentum nuchae, apices of the seventh cervical and all the thoracic spinous processes and their supraspinous ligaments. Superior fibres descend, inferior ascend and the intermediate fibres approach the horizontal, all converging laterally to the

5.58 Superficial muscles of the back of the neck and trunk. On the left only the skin, superficial and deep fasciae (other than gluteofemoral) have been removed; on the right, the sternocleidomastoid, trapezius, latissimus dorsi, deltoid and oblique externus abdominis have been dissected away.

shoulder. Here the superior fibres are attached to the posterior border of the clavicle's lateral third, middle fibres to the medial acromial margin and superior lip of the scapular spine's crest; the inferior fibres are attached to an aponeurosis, gliding over a smooth triangular surface at the medial end of the scapular spine to a tubercle at its lateral apex. Occipital attachment is by a fibrous lamina, which is also adherent to skin; spinal attachment is partly a triangular aponeurosis from the sixth cervical to the third thoracic vertebra and below this contains short tendinous fibres. The two muscles form a trapezoid, its lateral angles at the shoulder tips, the superior 'angle' at the occipital protuberance and superior nuchal lines, the inferior angle at the twelfth thoracic spine.

The clavicular attachment varies, sometimes reaching mid clavicle and occasionally blending with the sternocleidomastoid; the vertebral attachment sometimes ceases at the eighth thoracic spine, whereas the occipital is sometimes absent. Cervical and dorsal parts are occasionally separated.

Nerve supply. The accessory nerve (spinal part) is the dominant motor supply with sensory (proprioceptive) branches from the ventral rami of third and fourth cervical spinal nerves (Fitzgerald et al 1982.)

Actions. With other scapular muscles trapezius steadies the bone, controlling it during movements of the arm, maintaining the level and poise of the shoulder; but in the 'unloaded' arm electromyography shows little activity. Heavy loads can be suspended with little contribution from its upper part (Bearn 1960). With levator scapulae, its upper fibres elevate the scapula; with serratus anterior it rotates the scapula forward in raising the arm; with the rhomboids it retracts the scapula. With the shoulder

fixed, trapezius may bend the head and neck posterolaterally. Trapezius, levator scapulae, rhomboids and serratus anterior combine in producing various scapular rotations (p. 613).

Latissimus dorsi (5.58), large, flat and triangular, extends over the lumbar region and lower thorax, converging to a narrow tendon. It is attached medially by tendinous fibres to the lower six thoracic spines anterior to the trapezius and, through an attachment to the posterior layer of thoracolumbar fascia (p. 587), to the lumbar and sacral spines and supraspinous ligaments and the posterior part of the iliac crest. It also springs by muscular fibres from the posterior part (outer lip) of the iliac crest lateral to the erector spinae and by muscular slips from three or four lower ribs, interdigitating with obliquus abdominis externus (5.44). From this wide attachment fibres converge with varying obliquity (the upper ones horizontal, the middle oblique, and lower almost vertical) to form a thick mass overlapping (and usually receiving some fibres from) the inferior scapular angle. The muscle curves (and spiralizes) round the inferolateral border of teres major to its anterior surface. Here it ends as a quadrilateral tendon, about 7 cm long, in front of the tendon of teres major, attached in the floor of the humeral intertubercular sulcus, with an expansion to the deep fascia; this attachment extends proximal to that of teres major. A bursa sometimes occurs between the muscle and the inferior scapular angle. In curving round teres major, constituent fibres are spiralized: fibres which are *lowest* at their midline attachment are attached *highest* on the humerus, *highest* midline fibres are *lowest* at their humeral attachment. Tendons of latissimus and teres major are united at their lower borders, with a bursa between them near their humeral attachments.

Latissimus dorsi and teres major form the posterior axillary fold. In adduction against resistance, this fold is accentuated; then the whole inferolateral border of latissimus dorsi can be traced to its attachment to the iliac crest.

A muscular *axillary arch*, 7–10 cm in length and 5–15 mm in breadth, may cross from the edge of latissimus dorsi, midway in the posterior fold, over the front of the axillary vessels and nerves to, variously, join the tendon of pectoralis major, coracobrachialis or fascia over the biceps. It occurs in about 7% and may be multiple (Kasai & Chiba 1977). Vertebral and costal attachments of latissimus dorsi may be reduced or, more rarely, increased. A fibrous slip usually connects its tendon near its humeral attachment to the long head of triceps; occasionally muscular, it is the homologue of the *dorso-epitrochlearis brachii* of apes.

Nerve supply: the thoracodorsal nerve from the posterior cord of brachial plexus, C. **6, 7** and 8.

Actions. Latissimus dorsi is active in humeral adduction, extension and especially medial rotation. Humeral adduction and extension are most powerful when the initial position of the arm is one of partial abduction, flexion or a combination of these. With the sternocostal part of pectoralis major and teres major it adducts the arm against resistance. It assists backward swinging of the arm, as in walking or many athletic pursuits. When arms are raised high, as in climbing, it assists in elevating the trunk. It is said to take part in all violent expiratory efforts, such as coughing or sneezing; palpation confirms this. Electromyography suggests a role in deep inspiration. When the muscle is stretched, as in elevation of the arm, it presses on the inferior scapular angle.

The muscle's lower, lateral margin is usually separated from the posterior border of the external oblique by a small *lumbar triangle*, its base the iliac crest and floor the internal oblique (5.58). This is to be distinguished from the *triangle of auscultation* which is medial to the scapula, bounded by the trapezius, latissimus dorsi and medial scapular border; part of rhomboideus major is exposed in it. If the scapulae are drawn forwards by folding the arms across the chest and the trunk is bent, parts of the sixth and seventh ribs and their interspace (overlying the apex of the lower pulmonary lobe) become subcutaneous.

Rhomboideus major (5.58) is attached by tendinous fibres to the second to fifth thoracic spines and their supraspinous ligaments, descending laterally to the medial scapular border between the root of the spine and the inferior angle; most of its fibres usually end in a tendinous band between these two points, joined to the medial border by a thin membrane; occasionally this is incomplete and some muscular fibres are then directly attached. Bharihoke & Gupta (1986) studied the muscular attachments along the medial border of the scapula in 60 adult Indians; each of the muscles studied (rhomboideus major and minor, levator scapulae, and serratus anterior) had more extensive attachments than usually described, with 'folds' or extensions passing to both *dorsal* and *costal* aspects of the scapula adjoining its medial margin. The aponeurotic attachment of rhomboideus major was largely confirmed but its lower limit ended a short distance above the inferior angle which was enclosed on *all aspects* by the lowest part of serratus anterior. Rhomboideus major also had a muscular *dorsal* attachment immediately above this lowest part of serratus. *Ventrally*, rhomboideus major had an extensive attachment to the fascia covering serratus anterior, fascial fusion occurring from the medial scapular border, 2–3 cm laterally, and over the full vertical length of rhomboideus.

Rhomboideus minor (5.58) is attached to the lower ligamentum nuchae and seventh cervical and first thoracic spines, extending towards the base of the smooth triangular surface at the medial end of the scapular spine. Here, the authors quoted described it as forming a 'double fold' or asymmetrical U-shaped attachment with dorsal and ventral layers that enclose the inferior border of levator scapula (i.e. where the latter is tendinous and extends down to the level of the scapular spine). The dorsal layer of rhomboideus minor is attached to the rim of the triangular surface, dorsolateral and below levator scapulae; the ventral layer is strong and wide extending 2–3 cm medial to and below the levator; here the fasciae of rhomboideus minor and serratus anterior are tightly fused. Rhomboideus minor is usually separate from rhomboideus major but the muscles overlap and are occasionally united. Vertebral and scapular attachments of rhomboids vary. From the upper border of the minor a slender muscle may reach the occipital bone (*rhomboideus occipitalis*).

Nerve supply: the rhomboid branch of the dorsal scapular nerve, C.4, **5**.

Levator scapulae (5.36,58) is attached by tendinous slips to the transverse processes of the atlas and axis and the third and fourth cervical posterior tubercles, descending diagonally to approach the medial scapular border between its superior angle and the triangular smooth surface at the medial end of the scapular spine. It varies much in its vertebral attachments, and separation into slips, with accessory attachments to the mastoid process, occipital bone, first or second rib, scaleni, trapezius, and serrate muscles. Bharihoke & Gupta (1986) described the scapular end of the muscle as consisting of two 'flaps' or 'folds' partly fused just above the superior scapular angle. The posterior fold had an aponeurotic attachment to the dorsal aspect of the medial margin, opposite the supraspinous fossa. The anterior fold had a fascial attachment 2–3 cm wide to the fascial sheath of serratus anterior, below the muscular attachment of the latter, enclosing the superior scapular angle. Below, the anterior fold tapered to a narrow tendon attached to the costal surface of the medial border at the level of the root of the scapular spine.

Nerve supply: direct branches of the third and fourth cervical spinal nerves and from the fifth cervical via the dorsal scapular nerve.

The blood supply is chiefly from the transverse cervical and ascending cervical arteries, its vertebral extremity by rami of the vertebral, an important consideration in transposition of the muscle (Smith et al 1974).

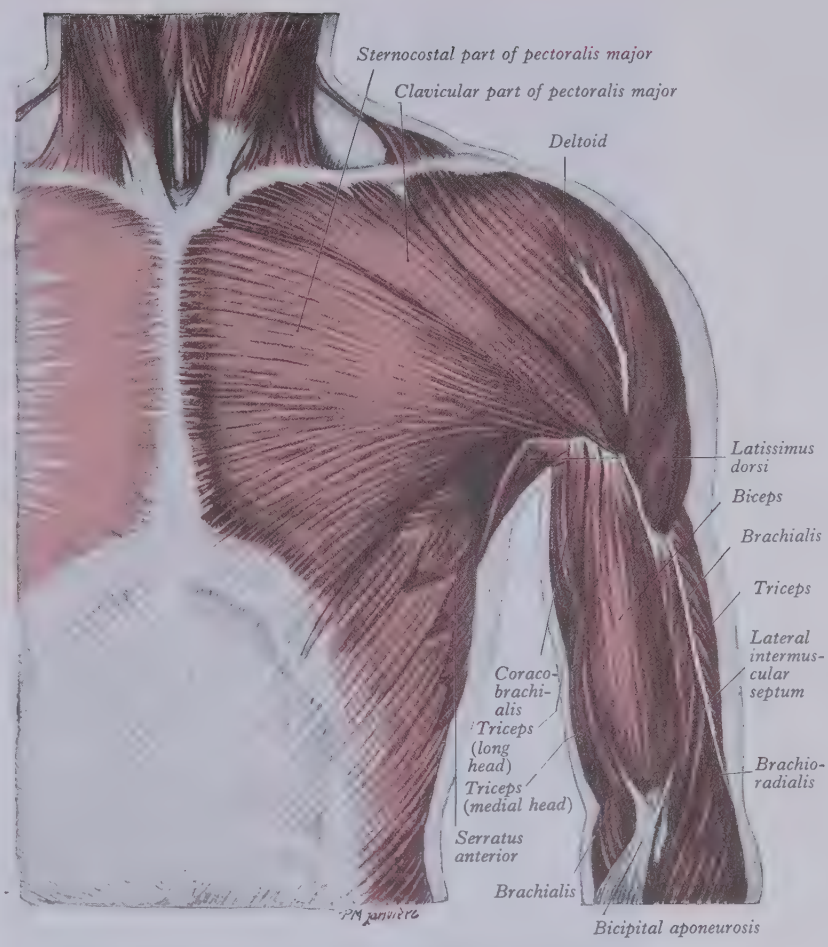
Actions. The rhomboids and levator scapulae assist other scapular muscles in controlling scapular position and movement. With trapezius, rhomboids retract the scapula, with levator scapulae and pectoralis *minor* they rotate it, depressing the shoulder. With the cervical vertebral column fixed, levator scapulae acts with the trapezius to elevate the scapula or to sustain weight on the shoulder; with shoulder fixed the muscle laterally flexes the neck to the same side.

2. Muscles Connecting the Upper Limb and Thoracic Wall

These are serratus anterior and pectoralis minor, connecting the ribs to the scapula; pectoralis major from the ventral thorax (and

upper abdomen) to the humerus; and subclavius connecting the first rib to the clavicle.

Superficial fascia of the anterior thoracic region is continuous with that of the neck, upper limb, and abdomen. It contains the mammary gland, sends numerous septa between its lobes and connects it, by fibrous *mammary suspensory ligaments*, to the skin and nipple.



Pectoral fascia is a thin (deep fascial) lamina over pectoralis major, and prolonged between its fasciculi. It is attached medially to the sternum, above to the clavicle and is inferolaterally continuous with the fascia of the shoulder, axilla and thorax. Although thin over pectoralis major, it is thicker between this and latissimus dorsi to which it crosses as the *axillary fascia* and the latter divides at the lateral margin of latissimus dorsi to ensheathe it, attached behind to the thoracic spines. As the fascia leaves the lower edge of pectoralis major to cross the axilla, a layer from it ascends deep to the muscle, splitting around pectoralis minor, at whose upper edge it becomes the *clavipectoral fascia* (vide infra). The axillary hollow is produced mainly by connections from this fascia to the axillary skin, forming a *suspensory ligament of the axilla*. Axillary fascia is pierced by the tail of the mammary gland (p. 1447). In the lower thoracic region the deep fascia is well developed and continuous with the sheath of rectus abdominis.

Pectoralis major (5.59), thick and triangular, is anteriorly attached to the sternal half of the clavicle, to half the anterior sternal surface to the level of the sixth or seventh costal cartilage, to the first to seventh costal cartilages (first and seventh often omitted), the sternal end of the sixth rib and the aponeurosis of obliquus externus abdominis. Clavicular fibres are usually separated from the sternal by a slight cleft. The muscle converges to a flat tendon, about 5 cm broad, attached to the lateral lip of the intertubercular sulcus. It has anterior and posterior laminae usually blended below. The thicker *anterior lamina* is formed centrally by fibres from the sternal manubrium, joined superficially by clavicular fibres and deeply by those from the sternal margin and fifth costal cartilages. (Thus there occurs some 90° of fibre spiralization in the anterior lamina.) Clavicular fibres may be prolonged into the deltoid tendon. The *posterior lamina* receives fibres from the sixth and often seventh costal cartilages and sixth rib, sternum and aponeurosis of the obliquus abdominis externus. Costal fibres join the lamina without twisting; fibres from the sternum and aponeurosis curve at the lower border, turning successively behind those above them, this part of the muscle being so twisted that the fibres that are *lowest* at their medial attachment are *highest* in the tendon (Ashley 1952). The posterior lamina reaches higher on the humerus, with an expansion covering the intertubercular sulcus and blending with the capsular ligament. An expansion from the lamina's deepest part, at its linear attachment, lines the sulcus; from its lower border a third descends into the deep fascia.

Costal attachments vary, as does separation of the clavicular and costal parts. Right and left muscles may decussate across the sternum. Superficially a vertical slip, or slips, may ascend from the lower costal cartilages and rectus sheath to blend with the sternocleidomastoid or attach to the upper sternum or costal cartilages. This is the *sternalis* (*rectus sternalis*). For variations, including agenesis, consult Cihak & Popelka (1961) and Kasai & Chiba (1977).

The muscle's rounded lower border is the *anterior axillary fold*, conspicuous in abduction. When the arm is swung forwards to the horizontal, the clavicular head is visibly contracted, the sternocostal relaxed; when the flexed arm is swung back against resistance, roles are reversed.

Relations. *Anterior* are skin, superficial fascia, platysma, anterior and middle supraclavicular nerves, mammary gland and deep fascia; *posterior* are sternum, ribs and costal cartilages, clavipectoral fascia, subclavius, pectoralis minor, serratus anterior and external intercostal muscles and membranes. It is the superficial stratum of the anterior axillary wall, and hence lies anterior to axillary vessels and nerves and the upper parts of biceps and coracobrachialis. Its *upper border* is separated from the deltoid by the *infraclavicular fossa*, containing the cephalic vein and deltoid branch of the thoraco-acromial artery. Its *lower border* is the anterior axillary fold. On the medial axillary wall, pectoralis major is

5.59 Superficial muscles of the front of the chest and upper arm (left side).

well separated from latissimus dorsi but these muscles converge towards the axillary lateral wall (i.e. the floor of intertubercular sulcus, between their attachments).

Nerve supply: lateral and medial pectoral nerves; fibres for the clavicular part are from C.5 and **6**, those for the sternocostal from C.7, **8**, and T.1.

Actions. The muscle's two parts may act separately or together. The whole muscle assists humeral adduction and medial rotation. It swings the extended arm anteromedially, its clavicular part (*portio attollens*) acting with the anterior fibres of the deltoid and coracobrachialis; (in this movement the sternocostal part is relaxed). When the opposite movement, usually assisted by gravity, is resisted the sternocostal part (*portio deprimens*) assists latissimus dorsi, teres major and the posterior fibres of deltoid; with raised arms fixed, e.g. gripping a branch, this muscle combination draws the trunk up and forwards in climbing. Pectoralis major is active in deep inspiration. Electromyography suggests that the clavicular part alone acts in medial rotation.

Clavipectoral fascia is a strong fibrous sheet behind the clavicular part of pectoralis major and fills the gap between pectoralis minor and subclavius, anterior to the axillary vessels and nerves. It splits around subclavius and is attached to the clavicle anterior and posterior to the groove for subclavius; the posterior layer fuses with the deep cervical fascia connecting the omohyoid to the clavicle (p. 586) and with the axillary sheath. Medially it blends with fascia over the first two intercostal spaces and is attached to the first rib medial to the subclavius. Laterally, thick and dense, it is attached to the coracoid process, blending with the coracoclavicular ligament. Between the first rib and coracoid process it is often a thickened *costocoracoid ligament*, below which it is thin, splitting around pectoralis minor and descending to blend with the axillary fascia, spreading laterally to the fascia over the short head of the biceps. The cephalic vein, thoraco-acromial artery and vein and lateral pectoral nerve traverse the fascia.

Pectoralis minor (5.60), thin and triangular, is posterior (deep) to pectoralis major. Attached medially to the upper margins and outer surfaces of the third to fifth ribs (frequently second to fourth), near their cartilages, and from the fascia over adjoining external intercostals, its fibres ascend laterally, converging to a flat tendon attached to the medial border and upper surface of the coracoid process. Part or all of the tendon may cross the process into the coraco-acromial ligament, or may pass through this to the coracohumeral ligament, and is then attached to the humerus. The muscle's slips are sometimes separated and vary in number and level; rarely, one passes from the first rib to the coracoid (*pectoralis minimus*). Anson et al (1953) recorded costal attachments of 1000 muscles as: 2nd to 5th ribs—337; 3rd to 5th—334; 2nd to 4th—193; 3rd to 4th—67; the muscle was never absent.

Relations. *Anterior* are pectoralis major, lateral pectoral nerve and pectoral branches of the thoraco-acromial artery. *Posterior* are ribs, external intercostals, serratus anterior, axilla, axillary vessels, lymphatics and brachial plexus. Its *upper border* is separated from the clavicle by a triangular gap filled by the clavipectoral fascia, posterior to which are axillary vessels, lymphatics and nerves. The lateral thoracic artery follows the lower border. The medial pectoral nerves pierce and partly supply the muscle.

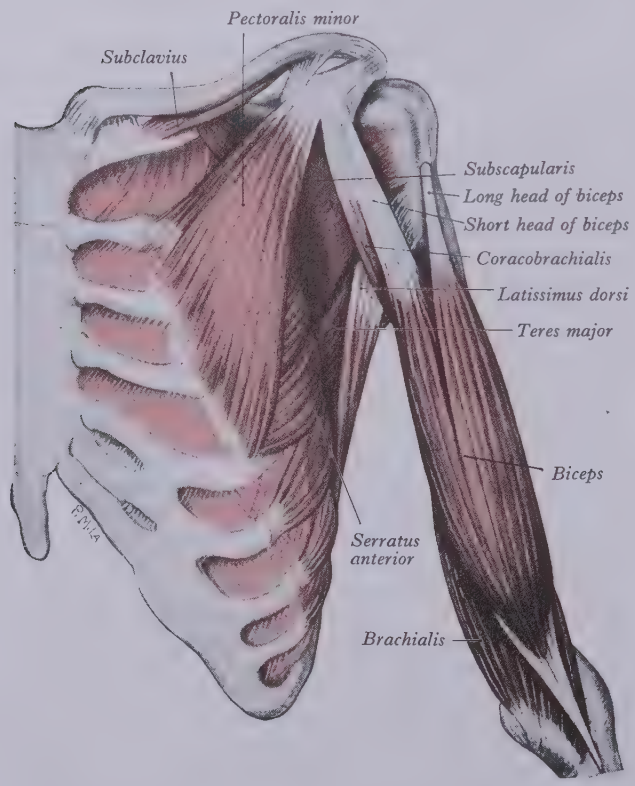
Nerve supply: both pectoral nerves, C.6, 7 and 8.

Actions. The muscle assists serratus anterior in drawing the scapula forwards round the chest wall. With levator scapulae and rhomboids it rotates the scapula, depressing the shoulder. Both pectoral muscles are electromyographically 'quiet' in inspiration, unless this is very forcible.

Subclavius (5.60) is a small, triangular muscle between clavicle and first rib. It is attached by a thick tendon, prolonged at its inferior margin to the junction of the first rib and its costal cartilage anterior to the costoclavicular ligament (Cave & Brown 1952). It ascends laterally to the groove inferior to the middle third of the clavicle, where it is attached by muscular fibres. It may reach the coracoid process in addition to or instead of the clavicle or scapular upper border.

Relations. *Posteriorly* it is separated from the first rib by the subclavian vessels and brachial plexus, *anteriorly* from pectoralis major by the anterior lamina of the clavipectoral fascia.

Nerve supply: the subclavian branch of the brachial plexus containing fibres from C.5. and 6 (p. 1131).



Action. Subclavius probably pulls the shoulder down and forwards and steadies the clavicle against the sternoclavicular articular disc; but it is inaccessible to palpation and difficult to investigate by electromyography.

Serratus anterior (5.60) is a large muscular sheet curving round the thorax from an extensive multidigital costal attachment to the medial scapular border. Its muscular digitations spring anteriorly from the outer surfaces and superior borders of the upper eight, nine or even ten ribs, and fasciae over the intervening intercostals. (These attachments lie along an extensive, slightly curved line that passes inferolaterally across the thorax.) The first springs from the first and second ribs and intercostal fascia, the others from a single rib; the lower four interdigitate with the upper five slips of obliquus externus abdominis. Applied to the thoracic wall, ventral to the scapula, the muscle reaches the latter's medial border as follows: the first digitation encloses and is attached to a triangular area of both costal and dorsal surfaces of the superior scapular angle; the next two or three form a triangular sheet attached to the costal aspect of almost all the medial border. The lower four or five digitations converge to be attached by musculotendinous fibres to a triangular area on the inferior angle's costal surface; however, they enclose the inferior angle and are also attached to a smaller triangular part of its dorsal surface near its tip (Bharihoke & Gupta 1986). Digitations may be absent, particularly the first and eighth but also sometimes the intermediate part. The muscle may be partly fused with levator scapulae, adjacent external intercostals or obliquus externus abdominis.

Nerve supply: the long thoracic nerve (C. 5, **6** and 7), descending on the muscle's external surface.

Actions. With pectoralis minor it protracts the scapula, as prime mover in all reaching and pushing movements. The upper part, with levator scapulae and upper fibres of the trapezius, suspends the scapula but activity is small in the unloaded arm. The lower, major part pulls the inferior scapular angle forwards round the thorax, assisting the trapezius in upward rotation, essential to raising the arm above the head (p. 613). In initial abduction serratus anterior helps other muscles to fix the scapula, so that the deltoid acts effectively on the humerus not the scapula. While the deltoid raises the arm to a right angle with the scapula, serratus anterior and trapezius simultaneously rotate the scapula, so that the arm can be raised to the vertical. To effect upward scapular rotation, forward traction at the inferior angle by the lower digitations of serratus anterior is coupled with superomedial traction on the lateral clavicle and acromion by the trapezius (upper fibres) and inferomedial traction at the base of the scapular spine by its lower fibres. Conversely, slow *downward* scapular rotation assisted by gravity is controlled by lengthening of these muscles; more powerful movement requires balanced contraction of the upper fibres of serratus anterior, levator scapulae, rhomboids, pectoralis minor and the middle part of the trapezius. In the transport of weights serratus anterior prevents backward scapular rotation. Electromyography, it is claimed, has disproved that serratus anterior assists respiration; but Jefferson et al 1960 worked on dogs and a study in human subjects (Catton & Gray 1951) ignored the effects of fixing the scapula by grasping, e.g. a bedrail or railing, as asthmatics and athletes certainly do! The problem is not fully resolved.

Applied Anatomy. When this muscle is paralysed, the scapula's medial border and especially its lower angle stand out prominently. The patient cannot raise the arm fully or push; attempts to do so are followed by further projection ('winging') of the scapula.

5.60 Deep muscles of the front of the chest and arm (left side).

3. The Scapular Muscles

The shoulder joint is closely surrounded by six muscles: deltoid, supra-and infra-spinatus, subscapularis and teres major and minor, all extending from the scapula to the humerus. By their proximity to the joint, which they can move in any direction, they maintain contact of articular surfaces in static and dynamic conditions, at a very shallow multiaxial joint (p. 477).

Deep fascia over the deltoid sends numerous septa between its fasciculi and is continuous with pectoral and infraspinous fasciae; the latter continuation is thick and strong. It is attached to the clavicle, acromion and crest of the scapular spine and is continuous with the brachial fascia.

The deltoid (5.59), a thick, curved triangle of muscle, is attached above to the anterior border and superior surface of the clavicle (lateral third), the acromial lateral margin and superior surface and continues into the lower edge of the crest of the scapular spine (but not its smooth medial triangular surface). The muscle converges inferiorly to a short substantial tendon attached to the deltoid tuberosity, which is lateral on the humeral mid-shaft. Anterior and posterior fibres converge directly to the humeral tendon; the intermediate part is multipennate, four intramuscular septa descending from the acromion to interdigitate with three ascending from the deltoid tuberosity; short muscle fibres connect these, providing powerful traction. The fasciculi are comparatively large, producing a marked coarse striation. It surrounds the joint on all sides except inferomedially, giving the shoulder its rounded profile. In contraction its borders are easily seen and felt. The tendon has an expansion to the brachial deep fascia which may reach the forearm. Commoner variations are partition into the three parts described, union with pectoralis major and additional slips from the trapezius, infraspinous fascia or lateral scapular border.

Relations. *Superficial* are: skin, superficial and deep fasciae, platysma, lateral supraclavicular and upper lateral brachial cutaneous nerves. *Deep* are: the coracoid process, coraco-acromial ligament, subacromial bursa, tendons of pectoralis minor, coracobrachialis, both heads of biceps, pectoralis major, subscapularis, supraspinatus, infraspinatus, and teres minor, long and lateral heads of triceps, circumflex humeral vessels, axillary nerve and humeral surgical neck and upper shaft, including the tuberosities. Its *anterior border* is separated proximally from pectoralis major by the infraclavicular fossa, in which are the cephalic vein and deltoid branches of the thoraco-acromial artery; distally the muscles are in contact, their tendons usually united. Its *posterior border* overlies the infraspinatus and triceps.

Nerve supply: the axillary nerve, C.5 and 6.

Actions. Anterior fibres assist pectoralis major in flexing the arm and in medial rotation. Posterior fibres act with latissimus dorsi and teres major in extension and lateral rotation. The multipennate, acromial part is a strong abductor; aided by the supraspinatus it abducts the arm, until the joint's capsule is tense below (in the scapular plane); only thus can scapular rotation have full effect in raising the arm higher. In true abduction (4.5) acromial fibres contract strongly, clavicular and posterior fibres preventing side-sway. While the deltoid effects humeral rotation, scapular rotation is added (p. 500). In early abduction traction by the deltoid is upward, but the humeral head is denied upward translation by the synergic downward pull of the subscapularis, infraspinatus and teres minor. Deltoid and supraspinatus, with subscapularis, infraspinatus and teres minor, constitute a mechanical couple ensuring steady abduction. Electromyography suggests that the deltoid contributes little to rotation but is active in most other shoulder movements. It may aid supraspinatus in resisting the downward traction of a loaded arm (vide infra). A common action of the deltoid is flexion/extension of the arm in walking. Ergonomic study of its clavicular part by Jonsson & Hagberg (1974) shows its value in adjusting the hand to various heights in manual tasks.

Applied Anatomy. The deltoid atrophies after division of the axillary nerve, simulating dislocation of the shoulder by flattening and apparent acromial prominence; the distance between the acromion and the humeral head is increased; the fingertips can be inserted between them.

The **subscapular fascia** is a thin aponeurosis attached to the circumference of the subscapular fossa; to its deep surface the subscapularis itself is partly attached.

Subscapularis (5.60), large and triangular, fills the subscapular fossa, attached to the periosteum in its medial two-thirds but also to the tendinous laminae in the muscle, which are attached to ridges in the fossa and to the aponeurosis covering it and separating it from teres major and the long head of triceps. It converges laterally into a tendon attached to the lesser humeral tubercle and the front of the articular capsule. The tendon is separated from the scapular neck by a large bursa communicating with the shoulder joint, being really a protrusion of its synovial lining. Variation is unusual; a separate slip may pass from the medial scapular border to the glenohumeral capsule or periosteum medial to the intertubercular sulcus.

Relations. The muscle forms much of the *posterior axillary wall*. Inferomedially its *anterior surface* is related to the serratus anterior, superolaterally to the coracobrachialis and biceps, axillary vessels, brachial plexus and subscapular vessels and nerves. Its *posterior surface* is related to the scapula and glenohumeral capsule. Its *lower border* contacts the teres major and latissimus dorsi.

Nerve supply: upper and lower subscapular nerves, C.5, **6** and (7).

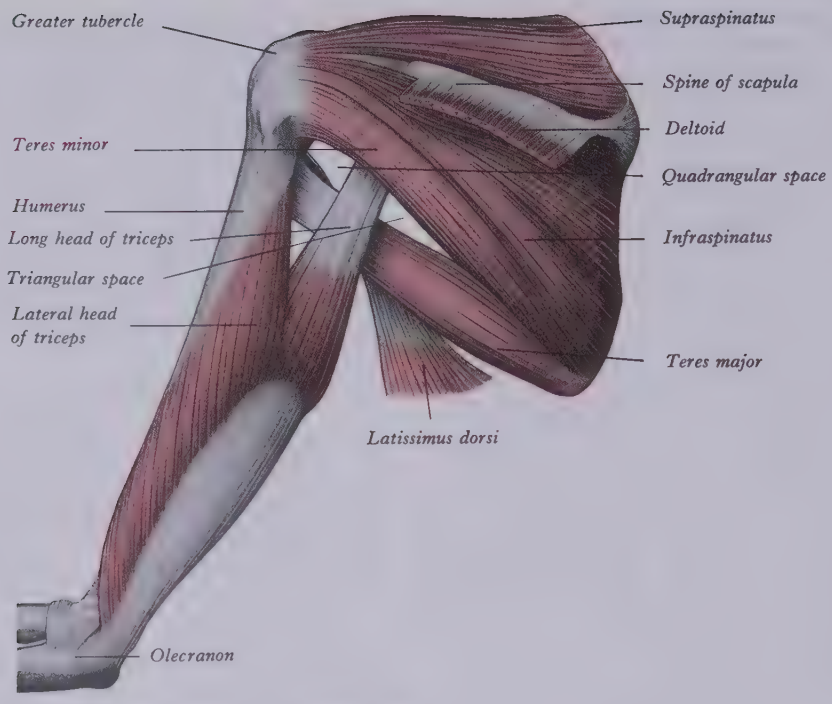
Supraspinous fascia completes an osseofibrous compartment in which the supraspinatus is attached. It is thick medially, thinner under the coraco-acromial ligament. It is attached to the scapula around the limits of attachment of the supraspinatus.

Supraspinatus (5.61) is attached to the medial two-thirds of the supraspinous fossa and supraspinous fascia. It converges, under the acromion, into a tendon crossing above the shoulder joint to the highest facet of the greater humeral tubercle; the tendon is adherent to the articular capsule. A slip may pass from it to that of pectoralis major. Fibrocartilage has been described at this muscle's tendinous attachment (Evans & Benjamin 1984), as in other tendons attached to epiphysial bone.

Nerve supply: suprascapular nerve, C.4, 5 and 6.

Applied Anatomy. The tendon of supraspinatus is separated from the coraco-acromial ligament, acromion and deltoid by the large subacromial bursa; when this is infected, abduction is painful. The tendon is the most commonly ruptured element of the musculo-tendinous cuff around the shoulder joint.

Infraspinous fascia covers the infraspinatus and is attached to the margins of the infraspinous fossa; the muscle is partly attached to its deep surface. It is continuous with the deltoid fascia along the overlapping posterior border of the deltoid.



Infraspinatus (5.61), a thick triangular muscle, occupies most of its fossa, attached periosteally to its medial two-thirds and by tendinous fibres to ridges on its surface; it is also attached to the infraspinous fascia, which separates it from teres major and minor. Fibres converge to a tendon gliding over the lateral border of the scapular spine and passing across the posterior aspect of the articular capsule to a middle facet on the greater humeral tubercle. The tendon is sometimes separated from the capsule by a bursa, which may communicate with the joint; it is sometimes fused with teres minor.

Nerve supply: the suprascapular nerve, C.(4) 5 and 6.

Teres minor (5.61), a narrow, elongate muscle, springs from the upper two-thirds of a flat strip on the scapular dorsum adjoining its lateral border and from aponeurotic laminae separating it from infraspinatus and teres major. Ascending laterally, its upper fibres end in a tendon attached to the lowest facet on the greater humeral tubercle, its lower fibres being attached to bone distally between the facet and the lateral head of triceps. The tendon crosses and is fused to the lower posterior surface of the articular capsule and sometimes with infraspinatus.

Nerve supply: axillary nerve, C. (4), 5 and 6.

Actions. Subscapularis, supraspinatus, infraspinatus and teres minor have an essential steadying effect on the humeral head, maintaining its apposition to the glenoid cavity and checking excessive translation (p. 500). Humeral swings (p. 502) at the glenohumeral joint are accompanied by movements between the articular surfaces which are combinations of rolling, sliding and spinning. Excessive sliding (translation) can easily occur at such a shallow articulation. During initial abduction subscapularis, infraspinatus and teres minor counteract the upward component of pull of the deltoid and thus, aided by supraspinatus, enable the force component *perpendicular* to the humeral shaft to abduct the arm. Infraspinatus and teres minor, with the posterior fibres of the deltoid, are lateral rotators. Subscapularis assists in *medial* rotation. These four muscles form the shoulder joint's '*rotator cuff*'. When the loaded or unloaded upper limb is pendent, a

5.61 The dorsal scapular muscles and triceps (left side). The spine of the scapula has been divided near its lateral end and the acromion has been removed together with a large part of the deltoid. The humerus is laterally rotated and the forearm pronated.

tendency to downward translation of the humeral head in the glenoid cavity is resisted by supraspinatus, rather than the deltoid, according to electromyographic data; the lack of tension in the deltoid can be appreciated by simple palpation. By contrast, anterior and posterior traction on the humerus are resisted by reciprocal parts of the deltoid.

Teres major (5.61) is a thick, flat muscle attached to the dorsal oval area near the inferior scapular angle and to the fibrous septa between it and teres minor and infraspinatus. It ascends laterally to a flat tendon, about 5 cm long, which is attached to the medial lip of the humeral intertubercular sulcus, where it is behind the tendon of latissimus dorsi, separated from it by a bursa; the tendons are united along their lower borders for a short distance. The muscle may be fused with the scapular slip of latissimus dorsi and a slip from it may join the long head of triceps or brachial fascia.

Nerve supply: the lower subscapular nerve, C.**6** and 7.

Actions: posteromedial extension and medial rotation. Electromyographers disagree on the muscle's role even during violent movements but its contribution to the maintenance of static postures and in arm-swinging appears established. Despite a common name, teres major and minor have different nerve supplies and actions.

4. Muscles of the Upper Arm

These include coracobrachialis, acting only on the shoulder joint, biceps and triceps crossing both shoulder and elbow joints, and brachialis acting only at the latter.

Brachial fascia (deep fascia of the upper arm) is continued from the fascia over the deltoid and pectoralis major; it invests muscles of the upper arm, sending septa between them. It is thin over the biceps, thicker over the triceps and humeral epicondyles, strengthened medially by fibrous aponeuroses from the pectoralis major and latissimus dorsi and laterally by the deltoid. Extending from it are strong medial and lateral intermuscular septa, attached to the humeral supracondylar ridges and epicondyles.

The *lateral intermuscular septum* extends distally from the lateral lip of the intertubercular sulcus along the lateral supracondylar ridge to its epicondyle, blending with the tendon of the deltoid. The triceps is attached to it posteriorly, anteriorly the brachialis, brachioradialis and extensor carpi radialis longus. It is perforated near the junction of the upper and middle thirds by the radial nerve and the radial collateral branch of arteria profunda brachii. The thicker *medial intermuscular septum* extends from the medial lip of the intertubercular sulcus, distal to teres major, and attaches along the medial supracondylar ridge to the medial epicondyle, blended with the tendon of coracobrachialis; it affords attachment to the triceps behind, the brachialis in front and is perforated by the ulnar nerve, superior ulnar collateral artery, and the posterior branch of the inferior ulnar collateral artery. At the elbow the brachial fascia is attached to the humeral epicondyles and olecranon and is continuous with the antebrachial fascia. Medially, just below midarm, the basilic vein and lymphatic vessels traverse it and at various levels branches of the brachial cutaneous nerves.

Coracobrachialis (5.60, 62) springs from the apex of the coracoid process where it is blended with the tendon of the short head of the biceps, and also by muscular fibres from the proximal 10 cm of this tendon; it ends on an impression, 3–5 cm in length, midway along the medial border of the humeral shaft between the attachments of the triceps and brachialis. The muscle appears as a faint rounded ridge in the upper medial side of the arm; pulsation of the brachial artery can be felt and often seen behind it. Accessory slips of it may be attached to the lesser tubercle, medial epicondyle or medial intermuscular septum.

Relations. It is traversed by the musculocutaneous nerve and related, *anteriorly*, to pectoralis major and at its humeral attachment to the brachial vessels and median nerve, which cross it; *posterior* are the tendons of subscapularis, latissimus dorsi, and teres major, the medial head of triceps, humerus and anterior circumflex humeral vessels; *medial* are the axillary artery (third part) and proximal parts of the brachial, median and musculocutaneous nerves; *lateral* are the biceps and brachialis.

Nerve supply: the musculocutaneous nerve, C.5, **6** and 7.

Actions. The coracobrachialis flexes the arm anteromedially, especially from a position of brachial extension. In abduction it assists anterior fibres of the deltoid to prevent side-sway.

Biceps brachii (5.60, 62, 63), a large, fusiform muscle in the upper arm's flexor compartment, has proximally two separately attached parts or 'heads'. The *short head* is attached by a thick flat tendon to the coracoid apex together with the coracobrachialis.

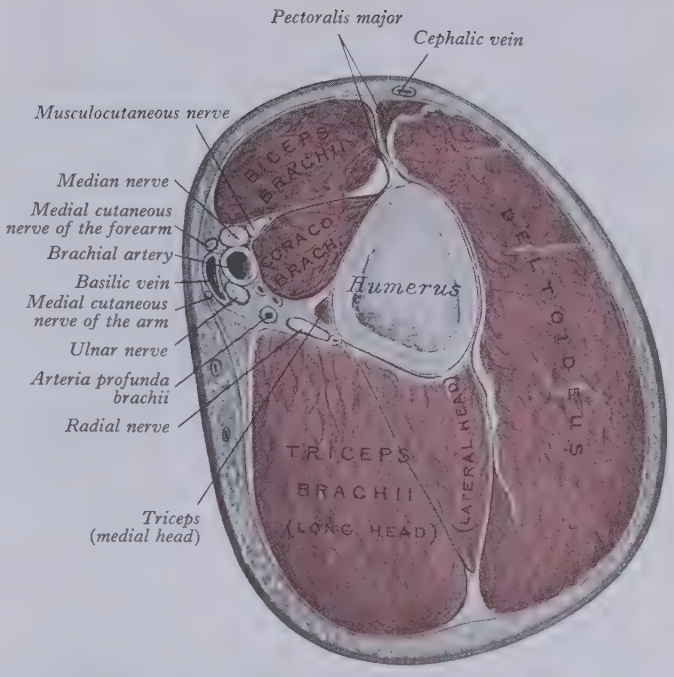
The *long head* starts in the shoulder joint, as a long narrow tendon, running from the supraglenoid tubercle at the apex of the glenoidal cavity, and continuous here with the glenoidal labrum (p. 501). The tendon, enclosed in a double tubular sheath, an extension of the joint capsule's synovial membrane, curves over the humeral head, emerges behind the transverse humeral ligament and descends in the intertubercular sulcus, retained in this by the ligament and a fibrous expansion from the tendon of pectoralis major. Both bicipital tendons lead into elongated bellies which, though closely applied, can be separated to within 7 cm or so of the elbow joint. Here they end in a flat tendon attached to the rough posterior area of the radial tuberosity, a bursa separating tendon and its smooth anterior area. Approaching the radius the tendon twists (spirals), its anterior surface becoming lateral and applied to the tuberosity. The tendon has a broad medial expansion, the *bicipital aponeurosis*, descending medially across the brachial artery to fuse with deep fascia over the forearm flexors (**5**.65 and **6**.93). The tendon can be split to the tuberosity, its anterior and posterior layers corresponding to the short and long heads.

A third head (10%) may extend from the superomedial part of the brachialis to the bicipital aponeurosis and medial side of the tendon; it is usually behind the brachial artery; it may consist of two slips which descend in front of and behind the artery. Other slips may spring from the lateral humeral aspect or intertubercular sulcus.

Relations. Biceps is overlapped proximally by pectoralis major and the deltoid; distally it is covered only by fasciae and skin and is a conspicuous elevation. Its long head passes *through* the shoulder joint; its short head is *anterior*. Distally it is anterior to the brachialis, musculocutaneous nerve and supinator. Its *medial border* touches the coracobrachialis and overlaps the brachial vessels and median nerve; its *lateral border* is related to the deltoid and brachioradialis.

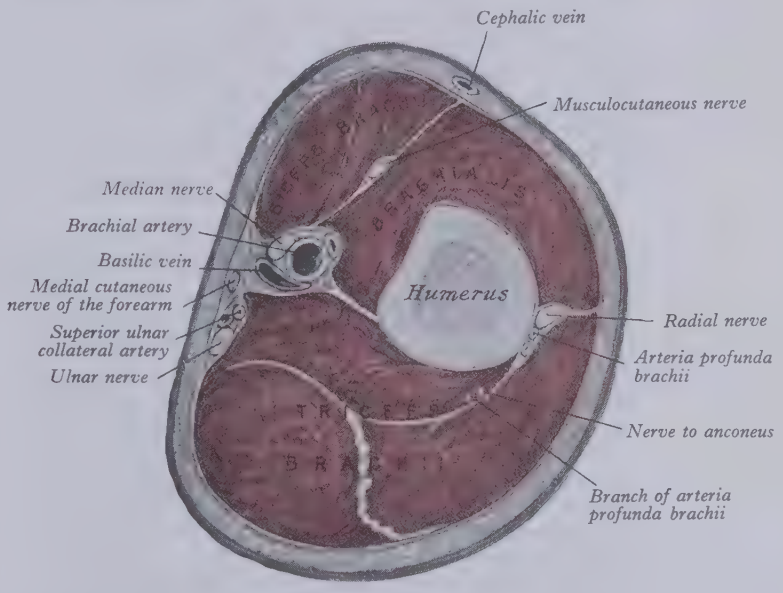
Nerve supply: the musculocutaneous nerve, C.5 and **6**, separate branches passing to each belly.

Actions. Biceps is a powerful supinator, especially in rapid or resisted movements. It flexes the elbow, most effectively with the forearm supinated and, less effectively, the shoulder joint. Its bicipital aponeurosis, being attached to the posterior border of the ulna, draws the latter's distal end medially in supination (p. 506). The long head helps to check upward translation of the humeral head during deltoid contraction. When the elbow is flexed forcibly, the tendon and bicipital aponeurosis are conspicuous.



Many habitual movements involve *increasing tension* despite *increasing length*, e.g. if the hand is lowered under the influence of gravity, extension at the elbow is controlled by just such activity in *flexors*, such as the biceps. As the hand descends and the elbow extends, the vertical through the gravitational centre of the loaded forearm is carried further from the fulcrum of movement and effective load, (i.e. extending torque) and muscle tension increase.

Applied Anatomy. The long bicipital tendon is sometimes dislocated from its groove; the arm is fixed in abduction but the humeral head can be felt in its proper position. The tendon can usually be replaced by flexing the forearm and rotating the limb.

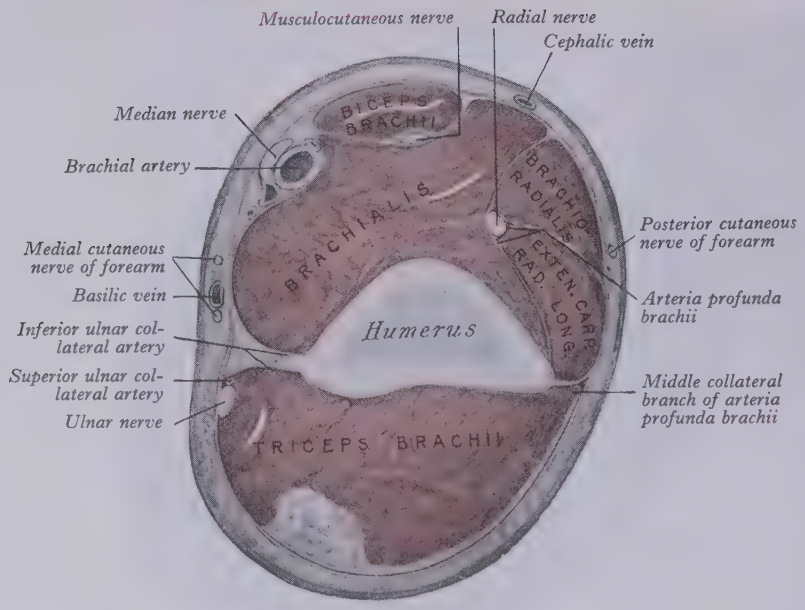


Brachialis (**5**.60, 63, 64) is attached proximally to the lower half of the anterior humeral aspect, from the deltoid tuberosity, which it embraces, to within 2.5 cm of the cubital articular surface. It is also attached to the intermuscular septa, more extensively the medial, being separated distally from the lateral by brachioradialis and extensor carpi radialis longus. Its fibres converge to a thick, broad tendon attached to the ulnar tuberosity and a rough impression on the anterior aspect of the coronoid process. It may be divided into two or more parts, fused with brachioradialis, pronator teres or biceps, or send a tendinous slip to the radius or bicipital aponeurosis.

Relations. *Anterior* are the biceps, brachial vessels, musculocutaneous and median nerves; *posterior* are the humerus and capsule of the elbow joint; *medial* are pronator teres and the medial intermuscular septum separating it from the triceps and ulnar nerve; *lateral* are the radial nerve, radial recurrent and radial collateral arteries, brachioradialis and extensor carpi radialis longus.

Nerve supply: the musculocutaneous nerve, C.5 and **6**, and the radial nerve (C.7) to a small lateral part of the muscle (Ip & Chang 1968).

5.62 Transverse section through the right arm at the junction of the proximal and middle thirds of the humerus: superior (proximal) aspect.



5.63 Transverse section through the right arm, a little below the middle of the shaft of the humerus: superior (proximal) aspect.

Action. Flexion of the elbow joint with the forearm prone or supine, with or without resistance.

The **triceps** (**5**.61, 64), filling most of the upper arm's extensor compartment, has long, lateral and medial heads, hence its name.

The *long head* is attached by a flat tendon to the infraglenoid tubercle, blended here with the glenohumeral capsule; its muscular fibres descend medial to the lateral head, superficial to the medial head, then join them in a common tendon.

The *lateral head* also has a flat tendon attached to a narrow, linear, oblique posterior ridge on the humeral shaft, also to the shaft's lateral border and the lateral intermuscular septum. The attachment ascends with varying obliquity from the lateral border, proximal to the radial groove and behind the deltoid tuberosity, to the surgical neck medial to teres minor. These fibres also converge to the common tendon.

5.64 Transverse section through the right arm, a little proximal to the medial epicondyle of the humerus: superior (proximal) aspect.

The *medial head*, overlapped posteriorly by the lateral and long heads, is attached to a wide posterior surface of the shaft, distal to the radial groove; this attachment extends from that of teres major to within 2.5 cm of the trochlea; the medial head is also attached to the medial humeral border and the back of the distal part of the lateral intermuscular septum. Some muscular fibres reach the olecranon directly, the rest converge to the common tendon.

The tendon of triceps begins near the muscle's midpoint. It has two laminae, one superficial to the muscle's distal half, the other in its substance. Receiving the muscular fibres, the two layers unite above the elbow and are attached, for the most part, to the olecranon's upper surface; a lateral band of fibres continues distally over the anconeus to blend with antebrachial fascia.

The long head descends between teres minor and major, dividing the interval between them and the humerus into triangular and quadrangular parts (5.61). The *triangular space*, containing the circumflex scapular vessels, is bounded above by teres minor, below by teres major, laterally by the long head of triceps. The *quadrangular space* transmits the posterior circumflex humeral vessels and axillary nerve; it is bounded above by subscapularis, teres minor and the articular capsule, below by teres major, medially by the long head of triceps, laterally by the humerus.

The lateral head of triceps, parallel and medial to the posterior border of the deltoid, stands out prominently in extension. The mass medial to it, disappearing under the deltoid, is the long head.

Articularis cubiti (subanconeus) is formed by fibres from the distal deep surface of triceps (medial head) which blend posteriorly with the fibrous cubital capsule.

Nerve supply: radial nerve, C.6, 7 and 8, with separate branches for each head (p. 1136).

Actions. Triceps is the major forearm extensor. The medial head is active in all forms of extension. Lateral and long heads are minimally active except in resisted extension (Basmajian 1967), as in thrusting or pushing or supporting body weight on the hands with semiflexed elbows. When the flexed arm is extended, the long head may assist in drawing back and adducting the humerus to the thorax. The long head supports the shoulder joint from below, especially when the arm is raised. The articularis cubiti probably retracts the cubital capsule during extension. In forceful supination of a semiflexed forearm, involving contraction of supinator and biceps, the triceps contracts synergically to maintain semiflexion. The human triceps brachii is the subject of an interesting comparison of geometric and dynamic parameters by Cnockaert & Pertuzon (1974).

5. The Antebrachial Muscles

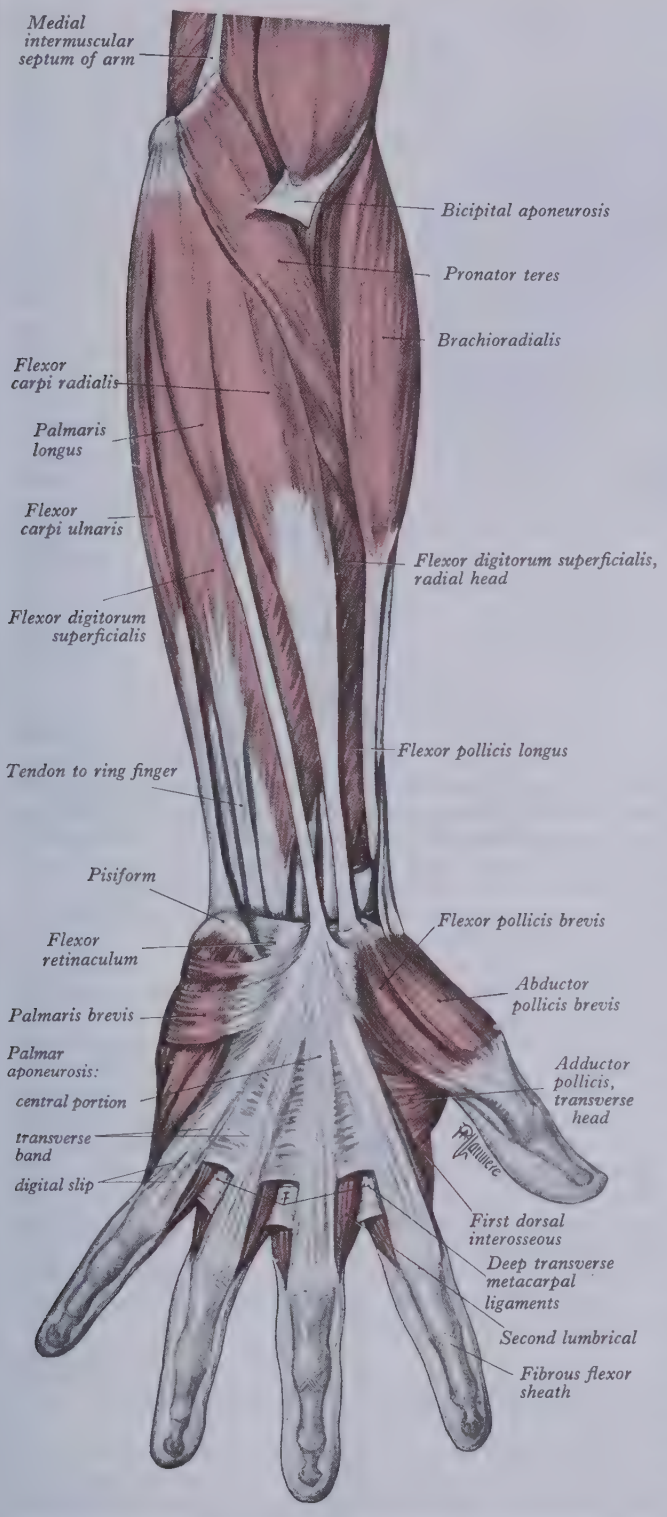
Antebrachial fascia (deep fascia of the forearm), continuous above with the brachial fascia, is a dense general sheath for muscles collectively and individually; it is attached to the olecranon and posterior ulnar border; from its deep surface septa pass between muscles for their partial attachment, some reaching the bone. Muscles also arise proximally from its internal aspect. Transverse septa, anterior and posterior, separate deep from superficial muscles. Fascia is much thicker posteriorly and in the distal forearm. It is strengthened proximally by fibres from biceps and triceps. Localized thickenings, *flexor* (p. 625) and *extensor* (p. 625) *retinacula* near the wrist, retain the digital tendons in position, increasing efficiency. Fascial apertures exist for vessels and nerves; one, large and anterior to the elbow, transmits a communication between superficial and deep veins.

The antebrachial (forearm) muscles are divided morphologically into flexors and extensors (anterior and posterior) but often they co-operate in more complex activities.

(a). The Anterior Antebrachial Muscles

These are superficial flexors, attached proximally and largely (but not exclusively) to the humerus, and deep flexors attached to the radius and ulna. The superficial 'flexors', however, include the pronator teres, while the deep 'flexors' include pronator quadratus.

SUPERFICIAL ANTEBRACHIAL FLEXORS



Attached to the medial humeral epicondyle by a common tendon are pronator teres, palmaris longus, flexores carpi radialis and ulnaris, and flexor digitorum superficialis (5.65,66). They also have attachments to overlying antebrachial fascia and to septa from this passing between individual muscles.

Pronator teres (5.65, 66) has humeral and ulnar attachments. The *humeral head*, the larger and more superficial, is attached just proximal to the medial epicondyle, to the common flexor tendon, to an intermuscular septum between it and flexor carpi radialis, and to antebrachial fascia. The smaller *ulnar head* springs from the medial side of the ulnar coronoid process distal to the attachment of flexor digitorum superficialis, joining the humeral head at an acute angle. The median nerve (83% of cases) enters the forearm between these heads, separated from the ulnar artery by the ulnar head. The muscle inclines across the forearm to a flat tendon attached to a rough area midway along the lateral surface of the radial shaft (at the 'summit' of its lateral curve). Its lateral border is the medial limit of the triangular *cubital fossa* anterior to the elbow joint. The coronoid attachment may be absent. Accessory slips may arise from a supracondylar process, if present, from biceps, brachialis or medial intermuscular septum.

Nerve supply: median nerve, C.6 and 7.

Actions. Rotation of radius on ulna, turning the palm medially and backwards, i.e. pronation and weak cubital flexion. It acts with pronator quadratus (always active in pronation), assisting only in rapid or forcible pronation, but its activity is said to be always less (Basmajian & Travill 1961). (For a further analysis of pronation/supination, including movements of the ulna, see p. 624.)

Flexor carpi radialis (5.65, 66, 69), medial to pronator teres, springs from the medial epicondyle by the common flexor tendon, from antebrachial fascia and adjacent intermuscular septa. Its belly is fusiform and ends rather more than halfway to the wrist in a long tendon, which traverses a lateral canal roofed by laminae of the flexor retinaculum and floored by a groove on the trapezium, within a synovial sheath; it is then attached to the palmar aspect of

5.65 Superficial flexor muscles of the left forearm, the palmar aponeurosis and the digital fibrous flexor sheaths. The fibrous flexor sheaths are depicted as in traditional accounts; for modified description consult text and 5.67B.

the second metacarpal's base, sending a slip to the third; these distal attachments are hidden by the oblique head of adductor pollicis (5.80). In the distal forearm the radial artery is between this tendon and that of brachioradialis.

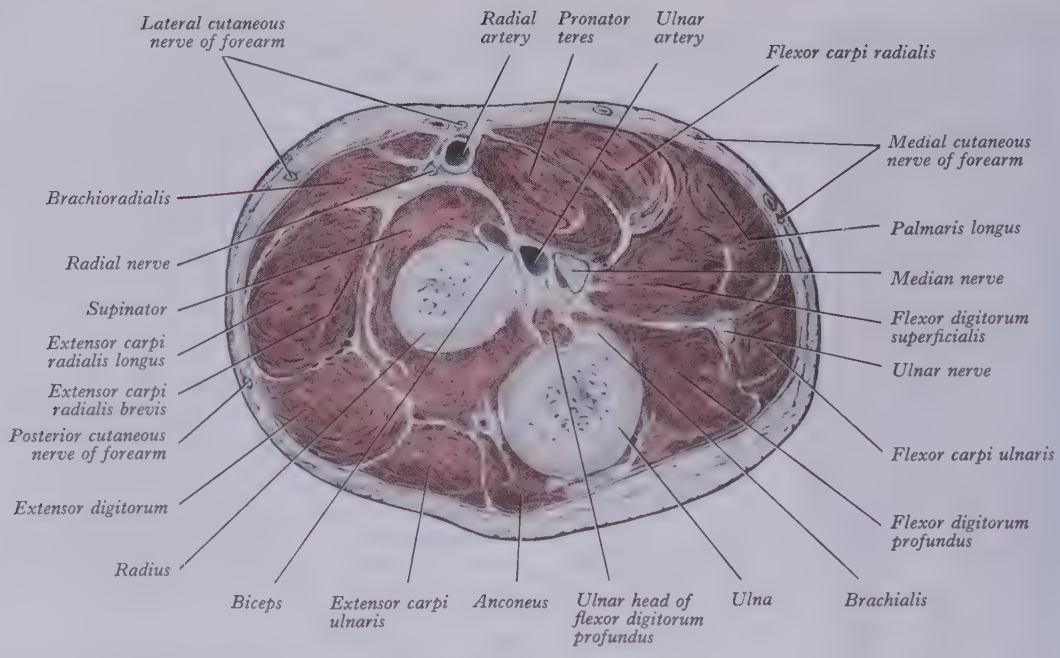
The muscle may be absent or have accessory slips from biceps tendon, bicipital aponeurosis, coronoid process or radius. Distally it may attach also to the flexor retinaculum, trapezium, or fourth metacarpal.

Nerve supply: median nerve, C.6 and 7.

Actions. With flexor carpi ulnaris, and sometimes flexor digitorum superficialis, it flexes the wrist; with radial extensors it abducts the hand.

Palmaris longus (5.65, 66, 79), slender, fusiform and medial to flexor carpi radialis, springs from the medial epicondyle by the common tendon, from adjacent intermuscular septa and antebrachial fascia. Its long slender tendon passes *anterior* to the flexor retinaculum and is attached to the distal half of its anterior surface and centrally to the palmar aponeurosis, often sending a tendinous slip to the thenar muscles. Proximal to the wrist joint the median nerve is deep to the tendon, projecting beyond its lateral edge. Often absent on one or both sides, the muscle is very variable (Machado & DiDio 1967). It may have a proximal tendon or be reduced to a tendinous strand. It may be digastric or reduplicated. It may end in antebrachial fascia, tendon of flexor carpi ulnaris, pisiform, scaphoid, etc. Reimann et al (1944) found the muscle absent in 281 out of 2205 specimens; 15 muscles had accessory slips and four were double.

Nerve supply: median nerve, C.7 and 8.



Actions: carpal flexion; a tensor of palmar fascia.

Flexor carpi ulnaris (5.65,66,69), the most medial superficial flexor, has humeral and ulnar heads connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. The small *humeral head* arises from the medial epicondyle via the common tendon; the *ulnar head* is an extensive attachment from the medial margin of the olecranon and proximal two-thirds of the posterior ulnar border by a common aponeurosis shared with extensor carpi ulnaris and flexor digitorum profundus, and from the septum between it and flexor digitorum superficialis. A tendon forms along the anterolateral border of the muscle's distal half and is attached to the pisiform bone, thence prolonged to the hamate and fifth metacarpal bones by so-called pisohamate and pisometacarpal ligaments (4.50); a few fibres blend with flexor retinaculum. A coronoid slip may occur; a more substantial attachment to the flexor retinaculum and to the fourth or fifth metacarpal bones may exist. Ulnar vessels and nerve are lateral to the tendon.

Nerve supply: ulnar nerve, C.7 and 8.

Actions. With flexor carpi radialis, palmaris longus, and flexor digitorum superficialis, it flexes the wrist; with extensor carpi ulnaris it adducts the hand. Flexor and extensor carpi ulnaris are synergists preventing abduction when the pollex is extended at its carpometacarpal joint. It also fixes the pisiform bone during abduction and/or flexion of the minimus. When the wrist flexes against resistance, two tendons stand out: flexor carpi radialis and palmaris longus, approximately central near the wrist. Flexor carpi ulnaris can also be identified by palpation proximal to the pisiform.

The flexor digitorum superficialis (5.65, 66, 69) is deep to the preceding muscles; the largest superficial flexor, it has two heads. The *humero-ulnar head* arises from the medial epicondyle via the common tendon, also from the anterior band of the ulnar collateral ligament, adjacent intermuscular septa and the medial side of the coronoid process proximal to pronator teres. The *radial head*, a thin sheet, arises from the anterior radial border between the radial tuberosity and the attachment of pronator teres. The median nerve and ulnar artery descend between the heads. The muscle usually has two strata; a superficial one, joined laterally by the radial head, divides into tendons for medius and annularis; a deep stratum gives a slip to the superficial fibres for annularis and then ends in tendons for the index and minimus. As the tendons pass behind the flexor retinaculum they are arranged in pairs; the superficial pair are for medius and annularis, the deep for index and minimus. They diverge in the palm, and opposite the bases of proximal phalanges each divides around a tendon of flexor digitorum profundus, the slips twisting to reverse their surfaces and borders before they reunite and partially decussate, thus forming a groove for the profundus tendon. The superficial tendon divides again and ends at the *sides* of the shaft of its middle phalanx. Dimensions of these tendons have been detailed by Shrewsbury & Kuczynski (1974), who have also estimated tendon excursions and bowing ranges during action, correlating these data with an analysis of fibrous architecture, particularly of tendinous *scissural bands* and *chiasmata*.

5.66 Transverse section through the forearm at the level of the radial tuberosity.

The radial head may be absent. A slip from the deep stratum may provide most or all the fibres acting on the index. The part for minimus may be absent and replaced by a separate slip from ulna, flexor retinaculum or palmar fascia. The tendons also vary. Dylevský (1968) has advanced developmental explanations of variations in deep and superficial digital flexors, assigning them to separate initial strata, not a single blastema. However, Chaplin & Greenlee (1975) confirmed the usual description of an initial single blastema for all digital flexor tendons.

Relations. *In the forearm* the muscle is *deep* to palmaris longus, flexor carpi radialis, pronator teres, brachioradialis, radial artery and nerve; and *superficial* to: flexor digitorum profundus, the upper part of the ulnar artery and the median nerve (closely bound to it by areolar tissue) and flexor pollicis longus. *At the wrist* tendons pass *deep* to flexor retinaculum, *superficial* to the tendons of flexor digitorum profundus but in a common synovial sheath (5.76); the flexor pollicis longus tendon and median nerve are lateral. *In the hand* tendons are *deep* to the palmar aponeurosis, the superficial palmar arch and digital branches of the median and ulnar nerves but *superficial* to tendons of flexor digitorum profundus, the lumbrical muscles and the deep palmar arch.

Nerve supply: median nerve, C.7 and **8** and T.1.

Actions: flexion of the middle and then proximal phalanges and carpal flexion, particularly in rapid, forceful flexion of the digits in grasping, but is electromyographically silent in gentle flexion.

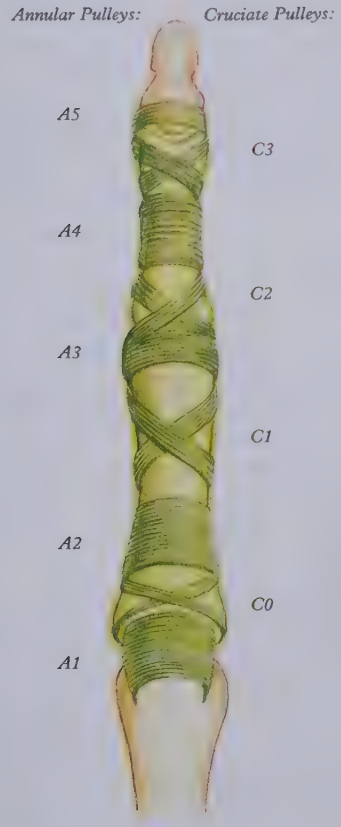
DEEP ANTEBRACHIAL FLEXORS

The group comprises flexor digitorum profundus, flexor pollicis longus and pronator quadratus.

Flexor digitorum profundus (5.66, 67, 69) arises deep to the superficial flexors from about the upper three-quarters of anterior and medial surfaces of the ulna, embracing the attachment of brachialis and extending distally almost to pronator quadratus; it also arises from a depression on the medial side of the coronoid process and proximal three-quarters of the posterior ulnar border by a common aponeurosis shared with the flexor and extensor carpi ulnaris; it also springs from the anterior surface of the ulnar half of the interosseous membrane. It ends in four tendons, initially posterior (deep) to those of flexor digitorum superficialis and to the flexor retinaculum. The part acting on the index finger is usually distinct but tendons for other digits are interconnected by areolar tissue and tendinous slips as far as the palm. Anterior to their proximal phalanges the tendons pass through those of flexor digitorum superficialis (p. 617) to attachments on palmar aspects of distal phalangeal bases. The tendons undergo fascicular rearrangement as they traverse those of superficialis (Wilkinson 1953, Martin 1958). The muscle forms most of the surface elevation medial to the palpable posterior ulnar border.

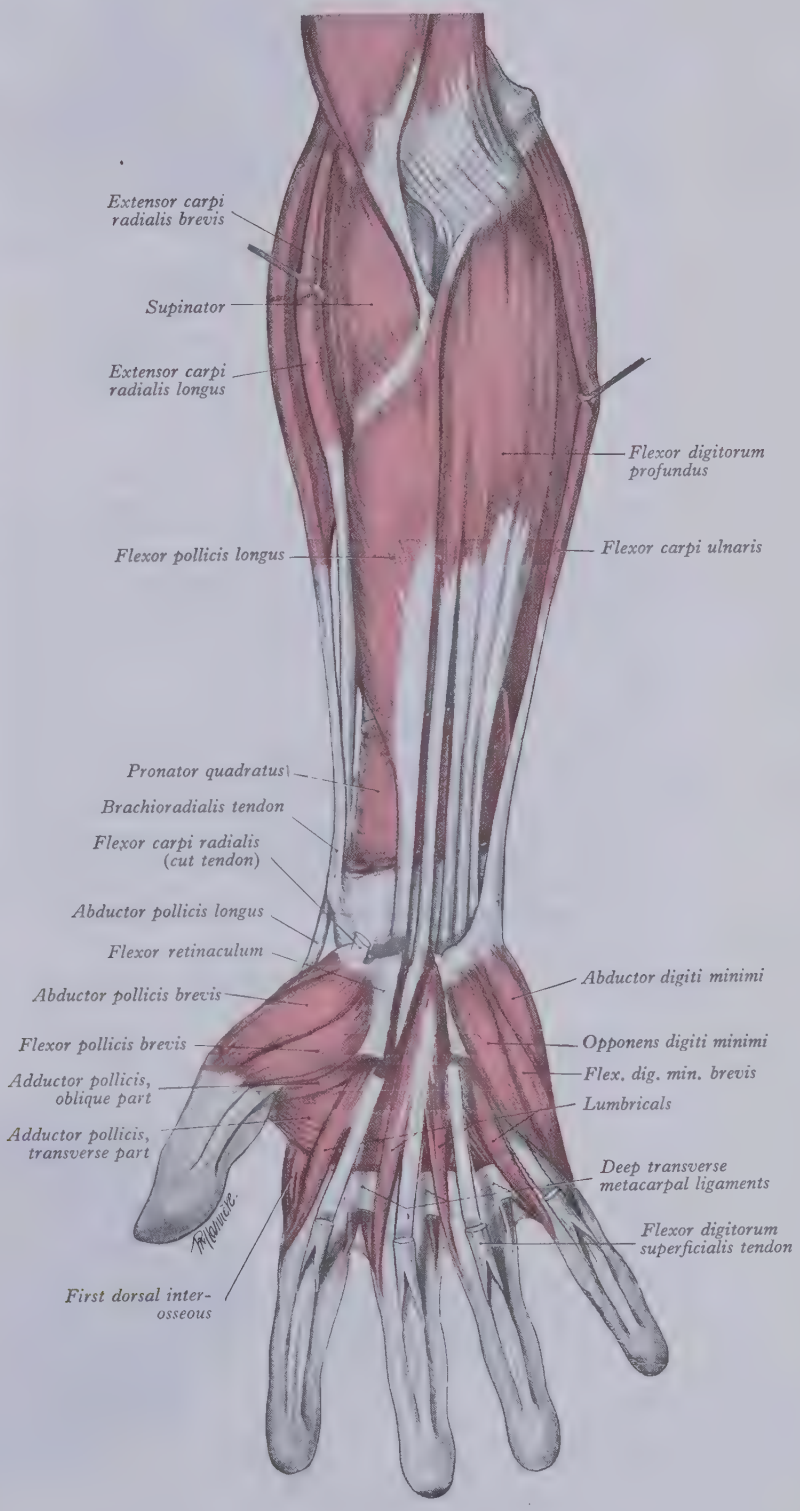
Accessory slips from radius (acting on index), from flexor superficialis, flexor pollicis longus, the medial epicondyle or coronoid process may join the muscle.

Nerve supply: medial part by the ulnar nerve, the lateral by the anterior interosseous branch of the median nerve, C.**8** and T.1.



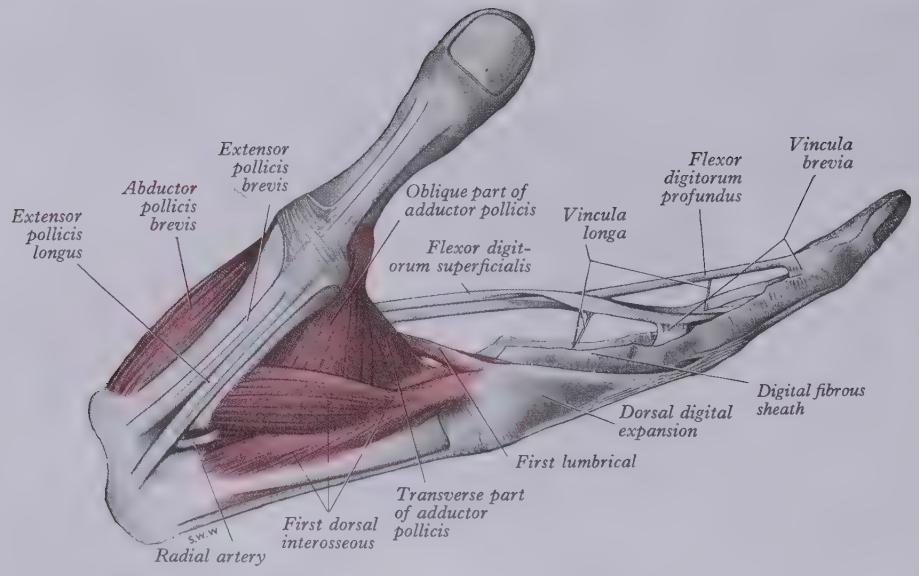
Actions. Flexion of distal phalanges, after flexion of the middle by superficialis. Assists carpal flexion. When all fingers are flexed, the digital extensors relax; but when individual digits flex, activity is sustained in the antagonist extensors (Person & Roschina 1958). More complex movements involve the synergic action of the interossei and lumbricals (p. 632). Electromyographically (Long 1968) flexor digitorum profundus is alone active in gentle digital flexion and superficialis added for greater force and/or velocity.

Lumbrical muscles are attached to tendons of flexor digitorum profundus in the palm (p. 630).



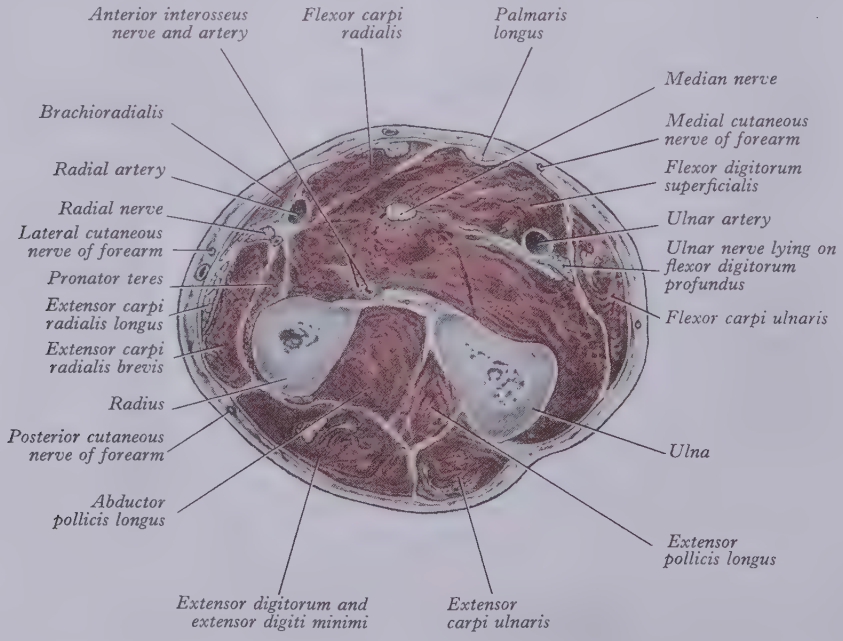
FIBROUS SHEATHS OF FLEXOR TENDONS

In the digits both tendons of deep and superficial flexors are in osseo-aponeurotic canals (5.77,79), formed by the phalanges, their joints and by *digital fibrous sheaths* arching anteriorly across the tendons and attached to the periosteal margins of the phalanges and the palmar ligaments of their interphalangeal joints. Similar fibrous dispositions, however, continue proximally into the palm to include the metacarpophalangeal joints. It was early recognized that the sheath had regional variations in thickness and fibre architecture; despite some minor variations, the view widely held for over the first 75 years of this century may be summarized briefly. 'Midway along proximal and intermediate phalanges the bands are strong, their fibres transverse (*annular part*); opposite joints they are thinner and of oblique fibres (*cruciform part*)'; however, vide infra. Each canal, from metacarpal head to terminal phalangeal base, is lined throughout by a double-walled (parieto-visceral) synovial sheath. The parietal layer, complex in form, is closely adherent to the specialized palmar ligaments, periostea, and internal aspects of fibrous flexor



sheaths, forming, in effect, the internal free surface of these structures. Thus they exhibit undulations corresponding to constrictions or expansions and the recently observed '*steps*' and *recesses* or *pouches* between thick and thin zones (Jones & Amis 1987), vide infra. They also noted specific forms of folding and repositioning of zones during flexion and continuing researches are directed, also, to regional structural differences in these parietal strata. The parietal synovium is reflected, at restricted loci, as a 'visceral' layer tightly enclosing and fused to the surfaces of the contained tendons, its shape, therefore, reflecting precisely the exquisite mutual adaptation of the tendons whose profiles change continuously proximodistally as they approach and reach their phalangeal attachments. The dictates of modern hand surgery (Doyle & Blythe 1975, Lundborg & Myrhage 1977, Schneider & Hunter 1982, Lister 1985) demonstrated that the traditional account of the fibrous flexor sheath was inadequate: oversimplified, positionally incorrect and with prominent features lacking. A new terminology has been devised and is currently widely used in surgical literature. Although possibly requiring some future revision, it will be briefly summarized here (**5**.67A). The fibrous flexor sheath is considered as extending from the metacarpal head to the base of the terminal phalanx and presents a series of *thick zones* with intervening *thin zones*. The thick zones, collectively termed *pulleys*, may be *annular* or *cruciate*. The *annular pulleys*, systematically numbered proximodistally A1–5, alternate with the four *cruciate pulleys* C0–3, the thin zones occupying the modifiable interpulley gaps. On occasion pulleys C0, C3 and A5 are poorly developed or undetectable and sometimes a cruciate pulley consisted of a single oblique band. In an extended finger the approximate positions of the pulleys in relation to the underlying bones and joints are: A1—ventral to the metacarpophalangeal joint; A2—centred over the junction of the proximal and middle thirds of the proximal phalanx; A3—proximoventral to the proximal interphalangeal joint; A4—ventral to the middle third of the middle phalanx; A5— distoventral aspect of the distal interphalangeal joint; C0 (between A1 and A2)—ventral to the proximal shaft of the proximal phalanx; C1 (between A2 and A3)

5.67A The digital fibrous flexor sheath: an increasingly accepted classification of the thickened annular pulleys A1–A5, cruciate pulleys C0–C3 and thin areas (light green) of the sheath.



5.67B The deep flexor muscles of the right forearm.

5.68 Lateral part of the right hand showing the tendons and vincula tendinum of the index finger and the muscles in the first intermetacarpal space.

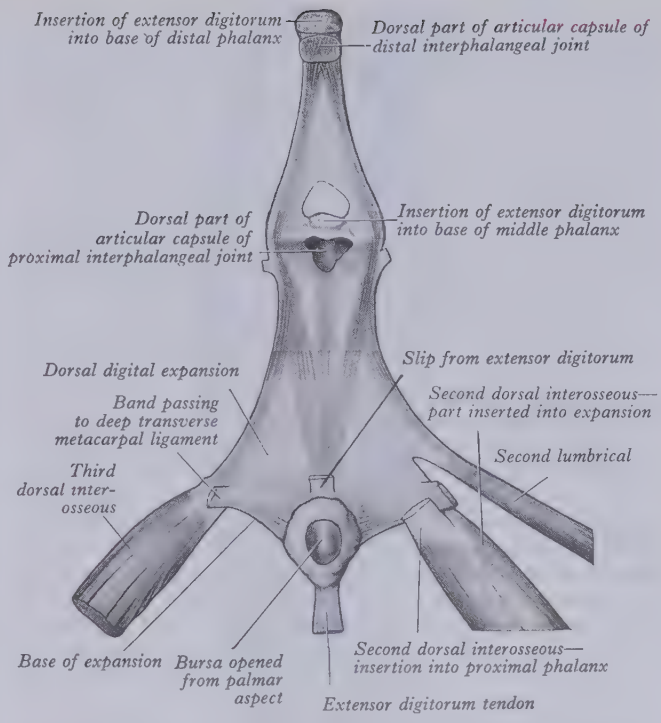
—ventral to the junction of the middle and distal thirds of the proximal phalanx; C2 (between A3 and A4)—ventral to the proximal shaft of the middle phalanx; C3 (between A4 and A5) —ventral to the narrow distal shaft of the middle phalanx. Thus of the five annular pulleys two are related to phalangeal shafts, the remaining three closely related to the three synovial joints; the cruciate pulleys are all related to shafts but not far distant from neighbouring joints. Jones & Amis (1987) in a detailed study of fibrous flexor sheaths confirmed the general nature and distribution of the annular and cruciate pulleys, but extended this to a quantitative (and projected functional) analysis of the 'deep pockets' noted by Lundborg & Myrhage (1977). Best viewed from the internal (parietal synovial) aspect, it was observed that thin zones did not smoothly join edge to edge with their adjacent pulley, but either joined the most superficial stratum of the thick zone or passed for some distance *superficial* to the thick zone before joining its superficial surface. Thus, the thick pulley possesses, internally, margins that are protruding (proximally, distally or both), either 'step-like' or 'free-edges', external to which a probe may pass on to the thick tissue's superficial surface as far as the attachment of the thin zone. The mean depth of the *overlap (recess* or *pouch)* was 0.5–1.0 mm, but pooled data for the distal end of A2 in index, medius and annularis was 2.4 mm. During flexion the thin zones fold in a specific pattern *superficially* into potential areolar spaces and *away* from the underlying tendons or a related joint line. Also during continued flexion the margins of the thick pulleys approach each other more and more closely until the tendons are encased ventrolaterally by a virtually continuous curved sheet of tough, deformation-resistant, thick fibrous tissue. (Consult Jones & Amis 1987 for detailed mensuration.) The results of further biomechanical analyses of these regions are awaited with interest.

As the flexor tendons approach their attachments they connect to the dorsal (parietal) aspects of their synovial sheaths and adjoining bone or ligament by triangular or filiform bands of synovial membrane termed *vincula tendinum* (5.68), which convey

 5.69 Transverse section through the middle of the left forearm.

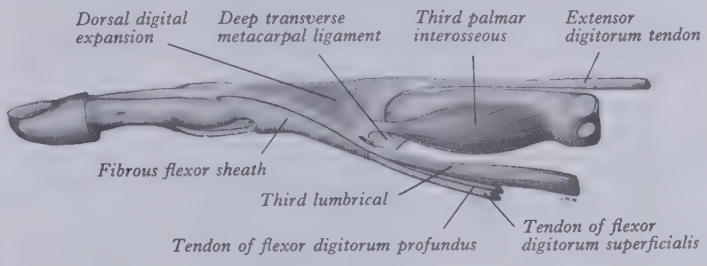
minute vessels to the tendons. They are of two kinds. *Vincula brevia*, two in each finger, are triangular bands attached to deep surfaces of tendons near their attachment; one connects a superficial tendon to its proximal interphalangeal joint capsule and adjacent proximal phalanx, the other connects a deep tendon to its distal interphalangeal joint capsule and adjacent middle phalanx. The *vincula longa* are filiform, usually two attached to each superficial tendon, one to each deep tendon. Those of flexor superficialis are connected to the slips of tendon where they fold over a tendon of flexor digitorum profundus, passing around its sides to attach to the sheath at the lateral margins nearer the proximal end of its proximal phalanx. Vincula longa of flexor digitorum profundus, fixed to its tendons shortly after they pierce the superficial tendons, perforate one of the two slips of the latter tendon or pass between them, thereafter blending with vincula brevia of flexor digitorum superficialis, attached to the dorsal wall of the synovial sheath to the distal ends of proximal phalanges.

Flexor pollicis longus (5.67,76), lateral to flexor digitorum profundus, arises from the grooved anterior surface of the radius between its tuberosity and the upper attachment of pronator quadratus, also from adjacent interosseous membrane, and often by a variable slip from the lateral or, more rarely, medial border of the coronoid process or the medial epicondyle (Martin 1958). The muscle ends as a flat tendon, passing behind the flexor retinaculum, between opponens pollicis and the oblique head of adductor pollicis, to enter an osseo-aponeurotic canal like those in the fingers, to be attached on the palmar aspect of the thumb's distal phalangeal base. The anterior interosseous nerve and vessels descend on the interosseous membrane between flexor digitorum profundus and flexor pollicis longus, which is sometimes connected to either the digital flexor or to pronator teres. The interosseous attachment may be lacking or the whole muscle absent.



Nerve supply: the anterior interosseous branch of the median nerve, C.8 and T.1.

Action: flexion of pollicial phalanges (p. 630).



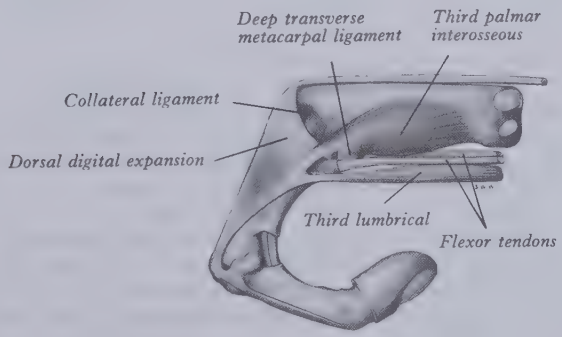
Pronator quadratus (5.67), flat and quadrilateral, extends anteriorly across the lower parts of the radius and ulna. From the oblique ridge on the anterior surface of the ulna (3.141) and also the medial part of this surface and from an aponeurosis over the muscle's medial third, it passes laterally and a little distally to the distal quarter of the radial anterior border and surface; deeper fibres reach the triangular area proximal to the ulnar notch of the radius.

Nerve supply: the anterior interosseous branch of median nerve, C.8 and T.1.

Action: the principal pronator of the forearm, assisted by pronator teres in rapid and/or forceful pronation. Deeper fibres oppose separation of distal ends of the radius and ulna when thrusts are transmitted through the carpus.

5.70A The dorsal digital expansion of the middle finger, showing some of its principal connections (viewed from the palmar surface, the basal angles having been drawn out and the whole expansion kept taut and flattened). Compare with 5.70B and C. Immediately distal to the bursa which overlies the metacarpophalangeal joint, a small slip from the extensor digitorum tendon is inserted into the base of the proximal phalanx. This slip is not always present.

5.70B The ring finger dissected to show the dorsal digital expansion and its principal connections (lateral aspect). Note the position of the base of the expansion when the finger is extended and compare with 5.70C.



(b) Posterior Antebrachial Muscles

These muscles form superficial and deep groups.

SUPERFICIAL EXTENSOR GROUP

All these muscles (5.72,75), except brachioradialis and anconeus, which act at the elbow alone, extend (or act synergically in other movements) at a series of joints. Extensores carpi radiales longus and brevis and extensor carpi ulnaris act on radiocarpal and carpal joints; extensores digitorum and digiti minimi extend digits and may extend the carpus.

Brachioradialis (5.65,66,69), the most superficial muscle along the radial side of the forearm, forms the lateral border of the cubital fossa. It arises from the proximal two-thirds of the lateral supracondylar ridge and anterior surface of the lateral intermuscular septum. The radial nerve and an anastomosis between arteria profunda brachii and radial recurrent artery are between the septum and brachialis. Its muscle fibres end proximal to mid forearm level in a flat tendon which extends to attach laterally on

5.70C The dorsal digital expansion of the ring finger in flexion. Compare with 5.70B, and note that the base of the expansion has moved distally. Compare 5.70A, B and C which were prepared by Professor James Whillis. Additional details and nomenclature are shown in 5.71A, B and C.

the distal end of the radius, proximal to its styloid process. The tendon is crossed near its distal termination by those of abductor pollicis longus and extensor pollicis brevis; the radial artery is medial. The muscle is often fused proximally with brachialis. Its tendon may divide into two or three slips. Rarely it is double or absent. Its radial attachment may be much more proximal.

Nerve supply: the radial nerve, C.5, **6** and (7).

Action: *flexion* of elbow (though supplied by an 'extensor' nerve), most effectively in mid-pronation, when it stands out prominently, particularly when carried out against resistance. It is minimally active in slow, easy flexion, or with a supine forearm; but develops a powerful burst of activity in both *rapid flexion and extension*; during these activities it is principally a 'shunt' muscle (p. 569), providing centripetal force towards the elbow to balance the centrifugal force of rapid swings in either direction (MacConaill 1949, Basmajian 1959).

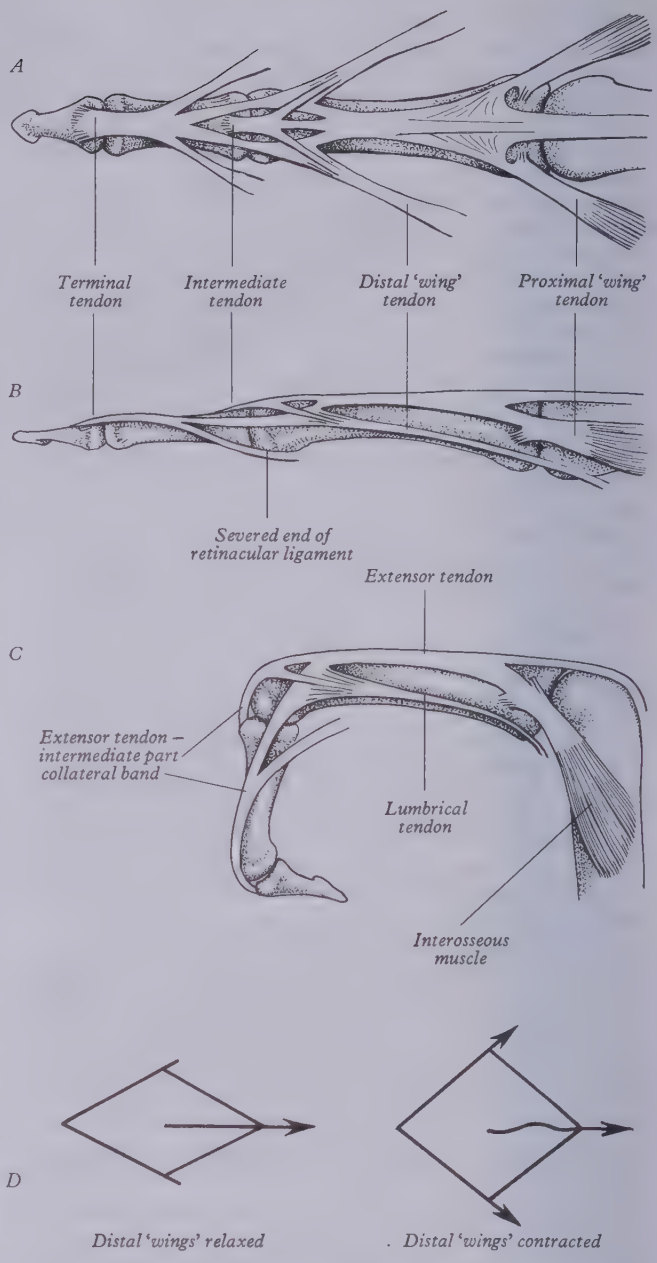
Extensor carpi radialis longus (5.69,72), partly overlapped by brachioradialis, is attached mainly to the distal third of the lateral supracondylar ridge and lateral intermuscular septum and partially to the common extensor tendon. The belly ends at the junction of the proximal and middle thirds of the forearm in a flat tendon along its lateral radial surface, deep to abductor pollicis longus and extensor pollicis brevis; this passes under the extensor retinaculum in a groove on the dorsum of the radius behind its styloid process and is distally attached on the radial side of the dorsal aspect of the second metacarpal base. It may send slips to the first or third metacarpal bones and contributes to intermetacarpal ligaments.

Nerve supply: the radial nerve, C. 6 and 7.

Extensor carpi radialis brevis (5.69,72,76) is shorter than and covered by the preceding muscle. It is attached to the lateral epicondyle by the common extensor tendon (vide infra), to the radial collateral ligament, to a strong aponeurosis covering its surface and to adjacent intermuscular septa. Its belly ends about mid forearm in a flat tendon accompanying that of the long carpal extensor to the wrist; it passes deep to abductor pollicis longus, extensor pollicis brevis and the extensor retinaculum to be attached dorsally to the third metacarpal base on its radial side, distal to its styloid process, and on adjoining parts of the second metacarpal. Under the extensor retinaculum the tendon is in a shallow groove, medial to that of extensor carpi radialis longus, separated by a low variably marked ridge.

Nerve supply: the posterior interosseous nerve, C.7 and 8.

Tendons of the radial carpal extensors pass under the extensor retinaculum in a single, common synovial sheath. They are easily identified as the fist is clenched and relaxed. Both may split into slips, variably attached to the second and third metacarpal bones. The muscles may be united or may exchange muscular slips.



Actions. Both muscles act synergically with the digital *flexors*. With extensor carpi ulnaris they extend the wrist; with flexor carpi radialis they abduct it. They are more often synergic than prime movers, particularly extensor carpi radialis longus, which is less active than the brevis in pure extension (Tournay & Paillard 1953), even when this is rapid. The longus is much more active than the brevis in grasping or clenching.

Extensor digitorum (5.69,72,76) springs from the lateral epicondyle by the common extensor tendon, from the adjacent intermuscular septa and antebrachial fascia. It divides distally into four tendons, which traverse, with the tendon of extensor indicis, a separate tunnel under the extensor retinaculum in a common synovial sheath. These diverge on the dorsum, one to each finger; that to the index is accompanied by extensor indicis, medial to it. On the hand's dorsum adjacent tendons have three variable *intertendinous connections*, inclined distolaterally. The medial connection is strong and pulls the tendon of minimus towards that of the fourth digit; the connection between the middle two tendons is weak and may be absent (Leslie 1954). The function of these bands is not clear; they *may* affect independent extension of digits; a gem of apocryphal anatomy is that their division benefits pianists!

Digital attachments are complicated by a fibrous expansion dorsal to the proximal phalanges in which lumbrical, interosseous and digital extensor tendons all participate.

A dorsal digital expansion is a small aponeurosis covering the dorsum of a proximal phalanx and the sides of its base. It is triangular; its proximal base enwraps dorsal and collateral aspects of the metacarpophalangeal joint. A tendon of extensor digitorum blends with the expansion along its axial region, separated from the joint by a small bursa (5.70A). The base connects this tendon on each side with adjoining interosseous muscles and has many transverse fibres. A short band links each basal angle to the deep transverse metacarpal ligaments, separating the *phalangeal* attachment of a dorsal interosseous from the rest of the muscle, and also a palmar interosseous from a lumbrical muscle (5.70A–C).

Margins of these expansions are thickened laterally by tendons of lumbrical and interosseous muscles and medially by an

5.71 Detailed diagrams to illustrate the digital extensor mechanisms: A. viewed from the dorsal aspect with digit in full extension; B. viewed from the side, also in full extension; C. viewed from the side, in full flexion. Note particularly the terminal and intermediate parts of the long extensor tendon, the proximal and distal 'wing' tendons, the dorsal extensor expansion, the diamond-shaped complex of tendons dorsal to the proximal interphalangeal joint and the retinacular ligaments. Note also the changing disposition of the tendinous and ligamentous elements in relation to the digital joints, as the digit passes from extension (B) to flexion (C). D is a diagram showing changes in the 'diamond' complex with contraction of the lumbrical musculature. See text for discussion. (Modified from diagrams by Graham Stack 1962, 1963.)

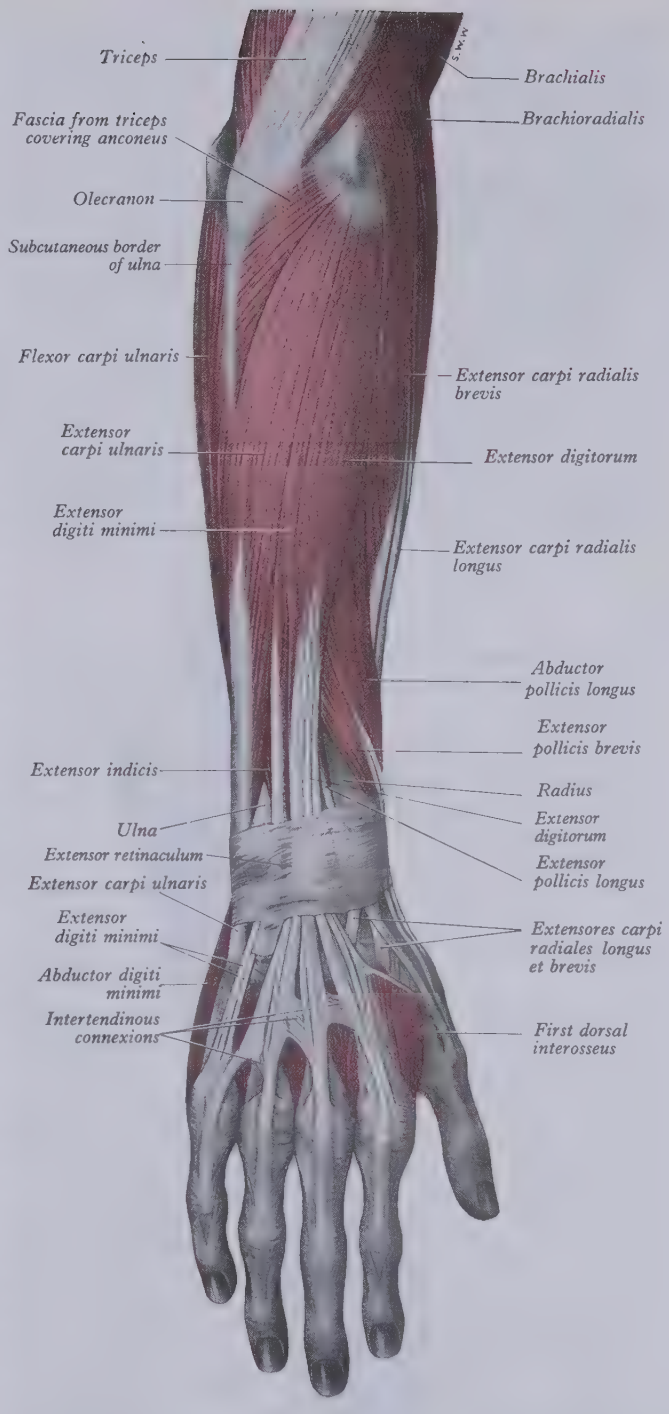
interosseous alone or, in the fifth digit, by abductor digiti minimi. These attachments of intrinsic muscles are termed '*wing tendons*'. Proximal and distal 'wings' can usually be identified (5.71) on both sides of each expansion. Attachments of interossei to these has led to a classification as 'distal' and 'proximal' in place of the more usual palmar and dorsal (see also 5.70A–C, 5.71A–D, and p. 630). Between its margins and the extensor tendon the expansion is almost translucent (5.70A). Near proximal interphalangeal joints extensor tendons divide into an axial part and collateral slips. The former, receiving some fibres from lumbrical and interosseous tendons (Landsmeer 1949), passes over the joint to the base of a middle phalanx. Each collateral slip is joined by a corresponding thickened border of the expansion and they unite to be attached dorsally on the base of a distal phalanx. The distal 'wing tendon' is proximal to this attachment.

Each expansion is a movable hood (Bunnell 1949), moving distally when a metacarpophalangeal joint flexes and proximally in extension when it is most closely curved round the joint. Landsmeer (1949) and Haines (1951) have described *retinacular ('link') ligaments* correlating movements at interphalangeal joints (5.71A–C); from proximal attachments to the sides of a proximal phalanx, where the fibrous sheath reaches bone and from the sheath itself they extend distally to blend with the margins of a dorsal expansion (5.71C). They thus reach the bases of terminal phalanges, two in each digit (p. 632).

Tendons of extensor digitorum tendons may be variably deficient, but more often are doubled or tripled in one or more digits, most often the index or medius. A tendon to the thumb occasionally exists.

Nerve supply: the posterior interosseous nerve, C.7 and 8.

Actions: digital extension at metacarpophalangeal and interphalangeal joints, opening the hand to relax the grip or prepare for grasping. The digital extensor is the prime mover with carpal extensors in carpal extension. It tends to spread the index, ring and little fingers but has no such action on the middle. Attachment of the lateral bands of its tendons to deep transverse metacarpal ligaments greatly limits the extensor effect at interphalangeal joints, an action only completed by the attachments of intrinsic muscles, especially lumbricals, to lateral extensor bands *distal* to these joints.



Flexion of metacarpophalangeal combined with *extension* of interphalangeal joints, and its converse, enter into most fine digital movements, especially in the activities of index finger and thumb, as in attempts to thread a needle; but the fine adjustments in approach (flexion at metacarpophalangeal and extension at interphalangeal joints) and withdrawal (extension at metacarpophalangeal and flexion at interphalangeal joints) of thread to needle merely illustrate movements used in a multitude of other common activities. Metacarpophalangeal flexion, due to lumbricals and interossei, allows sufficient relaxation of digital flexors to let extensor digitorum extend interphalangeal joints (Braithwaite et al 1948). However, interossei, working over the distal border of the deep transverse metacarpal ligaments, are advantageously placed to extend interphalangeal joints via dorsal digital expansions and can be trained to do so in radial nerve palsy (Sunderland 1945).

Extensor digiti minimi (5.72), a slender muscle, medial and usually connected to extensor digitorum, arises from the common extensor tendon by a thin tendinous slip and from adjacent intermuscular septa. Its long tendon slides in a separate compartment of the extensor retinaculum just behind the inferior radio-ulnar joint, dividing distally into two, the lateral slip joined by a tendon of extensor digitorum (5.72); all three are attached to the dorsal digital expansion of the fifth digit. The muscle usually arises also from antebrachial fascia. Its tendon may not divide or may send a slip to the fourth digit. It is rarely absent but sometimes fused with extensor digitorum.

Nerve supply: the posterior interosseous nerve, C.7 and 8.

Actions: extension of minimus and carpus, with extensor digitorum.

Extensor carpi ulnaris (5.69, 72) is attached to the lateral epicondyle by the common extensor tendon, also to the posterior ulnar border by the common aponeurosis shared with flexor carpi ulnaris and flexor digitorum profundus and to overlying

5.72 Muscles of the extensor aspect of the right forearm: superficial layer.

antebrachial fascia. It can be felt lateral to the groove which overlies the ulna's posterior subcutaneous border. It ends in a tendon sliding in a groove between the ulnar head and its styloid process in a separate compartment of extensor retinaculum, and is attached to a tubercle on the medial side of the fifth metacarpal base.

Nerve supply: posterior interosseous nerve, C.7 and 8.

Actions. With extensores carpi radiales longus and brevis it acts synergically with digital flexors to extend and fix the wrist when objects are gripped or the fist clenched. It is impossible to grip strongly unless the wrist is extended. With flexor carpi ulnaris it adducts the hand.

Anconeus (5.72,73), small and triangular and behind the cubital joint, is partially blended with triceps, of which it is an integral part in some primates. It has a separate tendon attached

posteriorly to the lateral epicondyle; its fibres diverge medially towards the ulna, covering the annular ligament and it is attached to the lateral aspect of the olecranon and proximal quarter of the posterior surface of the shaft of the ulna. The muscle is variably fused with triceps or the extensor carpi ulnaris.

Nerve supply: radial nerve, C.7, 8 and (T.1).

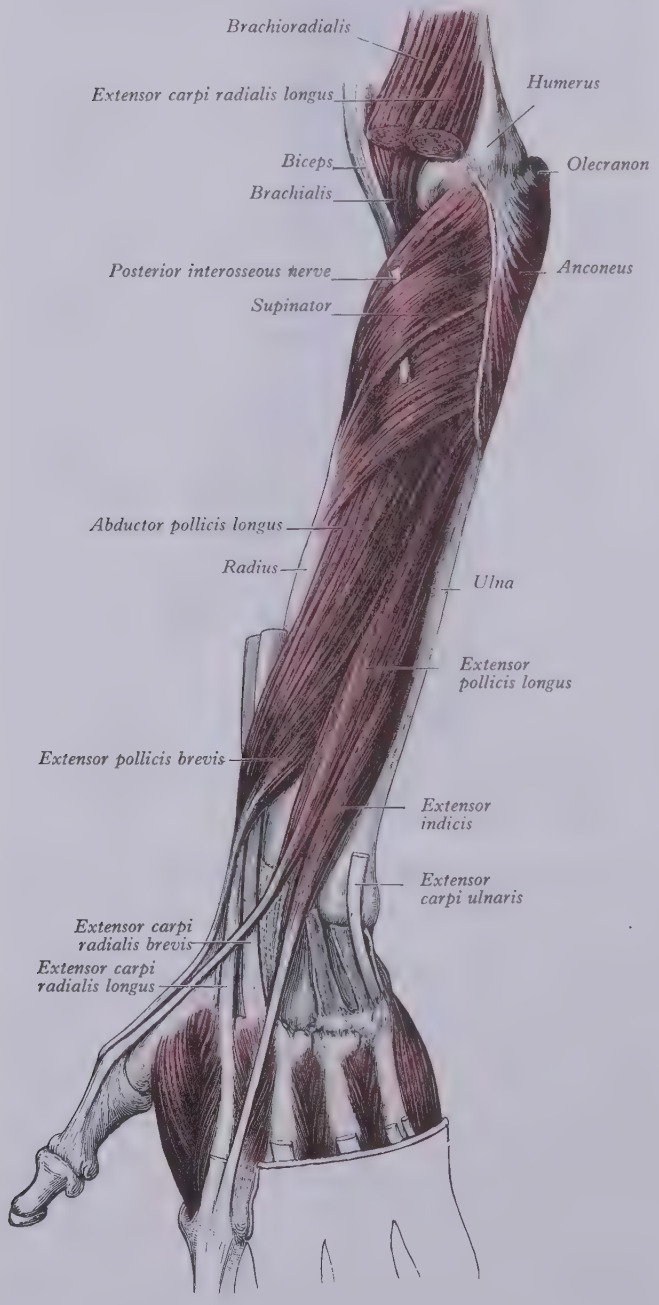
Action. It assists triceps in cubital extension and is often considered responsible for movement of the ulna in pronation (p. 616). Electromyography has not confirmed the latter; adequate investigations are, however, far from complete. Ulnar abduction in pronation, necessary if the forearm is to revolve the hand without translating it medially, can be voluntarily varied in degree. A tool can be revolved 'on the spot' or swept through an arc.

DEEP EXTENSOR GROUP

The deep forearm extensors (**5**.73,75) comprise three acting on the pollex (abductor pollicis longus and extensores pollicis longus et brevis), together with extensor indicis and supinator. Apart from supinator, all are attached proximally only to forearm bones.

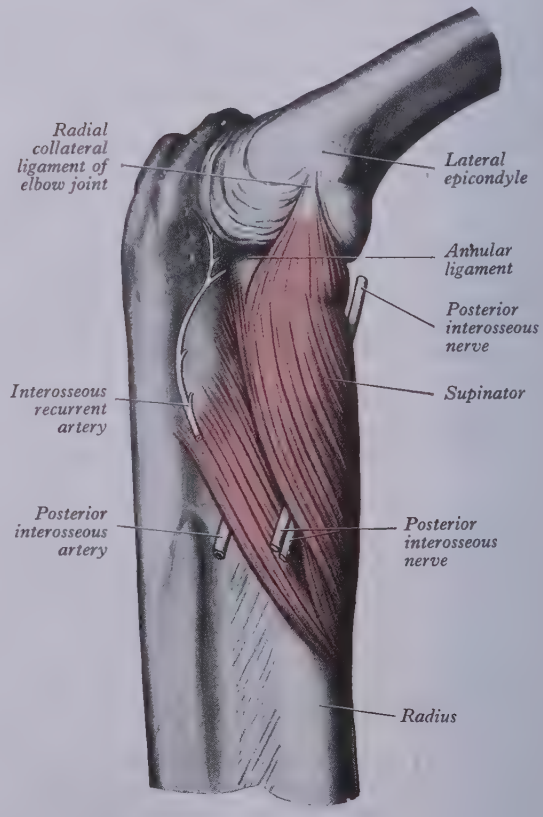
Supinator (**5**.67,73,74) surrounds the proximal third of the radius and has superficial and deep strata, between which is the posterior interosseous nerve (**5**.73). They arise by superficial tendinous and deep muscular fibres from the lateral epicondyle, radial collateral ligament, annular ligament, supinator crest of ulna with the posterior part of a triangular depression in front of it and from an aponeurosis over the muscle. Distal attachment is to the lateral surface of the proximal third of the radius, reaching the distal attachment of pronator teres. The radial attachment extends to the anterior and posterior surfaces (p. 411, **3**.142), between the anterior oblique line and fainter posterior oblique 'ridge'. The muscle is subject to frequent variation, small parts of it often receiving individual names, e.g. lateral and medial tensors of the annular ligament (Hast & Perkins 1984).

Nerve supply: the posterior interosseous nerve, C.5 and **6**.



Action: radial rotation to bring the palm anterior, acting alone in slow, unopposed supination and in fast or forceful supination joined by biceps brachii. Objects, which may be heavy, are often picked up with the forearm initially pronated. The more powerful supinators lift it against gravity, often combined with increasing flexion to bring the hand's burden towards the eyes.

Abductor pollicis longus (**5**.69,72,73) is attached, distal to the supinator and close to extensor pollicis brevis, to the posterior ulnar surface distal to the anconeus, to the adjoining interosseous membrane and middle third of the posterior radial surface distal to the supinator. It inclines laterally, becoming superficial in the distal forearm, visible as an oblique elevation (**5**.72). Its belly ends in a tendon just proximal to the carpus; this is in a groove on the lateral side of the distal end of the radius together with the tendon of extensor pollicis brevis. The tendon usually splits, one slip being attached to the radial side of the first metacarpal base, one to the trapezium. Further fasciculi may continue into opponens pollicis or abductor pollicis brevis. The muscle may be wholly or partially divided.



Nerve supply: the posterior interosseous nerve, C.7 and **8**.

Actions. With abductor pollicis brevis it abducts the pollex and with pollicial extensors extends it at its carpometacarpal joint (p. 629).

Extensor pollicis brevis (**5**.72,73), medial and connected to abductor pollicis longus, arises from the posterior radial surface

5.73 The deep extensor muscles of the left forearm.

5.74 The right supinator muscle: posterolateral aspect.

distal to it and from the adjacent interosseous membrane. It descends with the abductor, its tendon in the same groove on the lateral side of the distal radius, to be attached to the dorsolateral surface of the base of the proximal pollicial phalanx. Attachment to the base of the *distal* phalanx, usually through a fasciculus joining the tendon of extensor pollicis longus, is common (Muller 1959). The muscle may be absent or fused with abductor longus. Its tendon sometimes unites with the long pollicial extensor.

In the distal forearm abductor pollicis longus and extensor pollicis brevis *emerge* between extensor carpi radialis brevis and extensor digitorum; crossing obliquely the tendons of the radial extensors, they cover the distal part of brachioradialis and traverse the most lateral compartment of the extensor retinaculum in a common single sheath, finally crossing superficial to the radial styloid process and radial artery to reach the base of the proximal pollicial phalanx.

Nerve supply: the posterior interosseous nerve, C.7 and **8**.

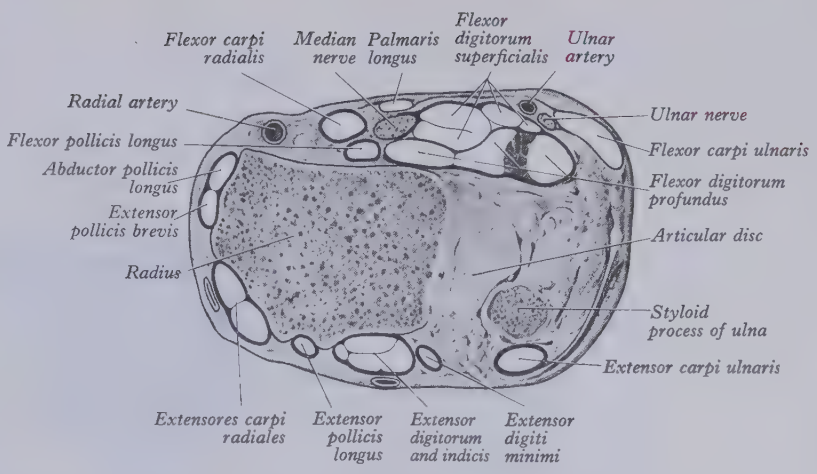
Actions: extension of the proximal pollicial phalanx and, in continued action, metacarpal extension.

Extensor pollicis longus (**5**.72,73) is larger than the brevis, the proximal attachment of which it partly covers. It arises laterally from the middle third of the posterior ulnar surface, distal to abductor pollicis longus, and from the adjacent interosseous membrane. It ends in a tendon traversing a separate compartment of the extensor retinaculum, in a narrow, *oblique groove* on the dorsum of the distal radius. It crosses obliquely over tendons of carpal extensors (**5**.73) but is separated from extensor pollicis brevis and clearly seen when the pollex is extended by a triangular depression, jocularly termed the 'anatomical snuff-box', in which the radial artery can be felt. (Bony structures felt in the floor of the fossa by deep palpation are proximodistally: the radial styloid, the smooth convex articular surface of the scaphoid, the trapezium and the first metacarpal's base. The latter are more pronounced during metacarpal movement and the scaphoid during adduction–abduction of the hand. The scaphoid and the trapezium are effectively palpated bidigitally between the examining index and thumb, one in the fossa, the other on the palmar tubercle or crest respectively.) The tendon of extensor pollicis longus is attached to the base of the distal pollicial phalanx; dorsal to the proximal phalanx its sides are joined laterally by expansions from tendons of abductor pollicis brevis and medially from the first palmar interosseous and adductor pollicis.

Nerve supply: the posterior interosseous nerve, C.7 and **8**.

Actions: extension of the distal pollicial phalanx; with extensor pollicis brevis and abductor pollicis longus, extension of the proximal phalanx and metacarpal. In continued action, owing to its tendon's obliquity, the muscle adducts the extended thumb and rotates it laterally (p. 513).

Applied Anatomy: avascular necrosis is probably a factor in rupture of the tendon of extensor pollicis longus, which may complicate Colles' fracture. Proximal to the carpus, the blood supply is mainly from the anterior interosseous artery and distally from the radial and pollicial arteries (Davies 1951).



Extensor indicis (**5**.73), narrow and elongated, is medial and parallel to extensor pollicis longus. It arises from the posterior surface of the ulna distal to extensor pollicis longus and from the adjacent interosseous membrane. Its tendon passes under the extensor retinaculum in a compartment containing tendons of extensor digitorum; near the second metacarpal head it joins the ulnar side of the index tendon of extensor digitorum. It may exchange accessory slips with other extensor tendons and is occasionally interrupted on the dorsum of the hand by an additional belly (*'extensor indicis brevis manus'*).

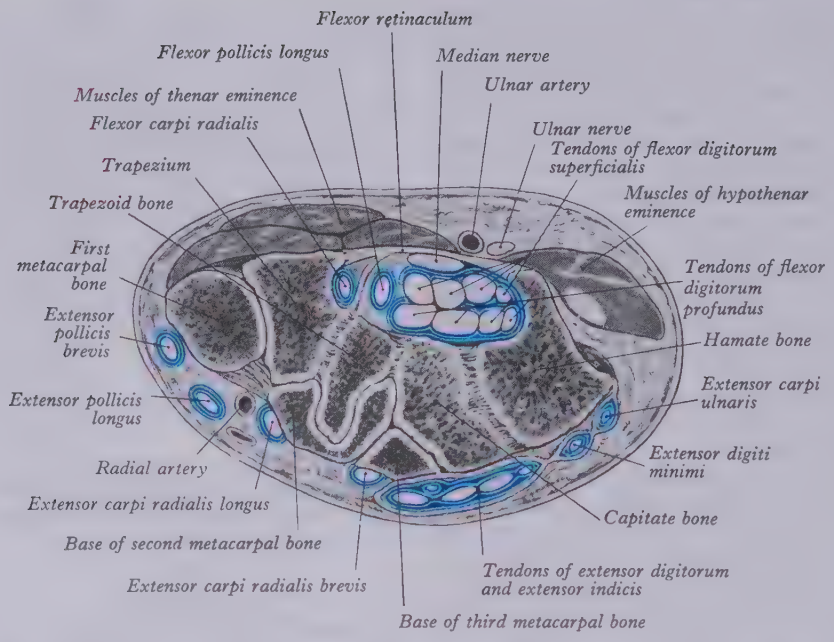
Nerve supply: the posterior interosseous nerve, C.7 and **8**. Distribution of muscle spindles in this muscle has been assessed by Gorp & Kennedy (1974); the greatest density is near the entry of its nerve.

Actions: assists extension of the index and carpus.

The Hand

Human hands, working with eyes in complex synergies mediated by nervous connections of unlimited variation, have been paramount in the evolution of human skills. Despite an astonishing multitude of tools and techniques produced to extend these skills, hands will continue to refine, develop and invent further tools. Being put to such multiple and frequent uses they are often damaged. For both reasons an immense literature, impossible even to abbreviate here, has accumulated on the structure, actions, injuries and reparative surgery of hands. For guidance the works of Wood Jones (1941), Napier (1966), Kaplan (1965), Stack (1973) and Landsmeer (1976) are valuable, especially since each has contributed notably in this field.

5.75 Transverse section, passing through the distal end of the right radius and the styloid process of the right ulna, made with the hand and forearm in full supination: distal (inferior) aspect.



RETINACULA, FASCIAE AND SYNOVIAL SHEATHS OF THE CARPUS AND HAND

Before proceeding to manual muscles, the disposition of local retaining bands, deep fascia and synovial tendon sheaths must be considered.

The flexor retinaculum (**5**.76,77), a thick strong, fibrous band, converts the anterior concavity of the carpus into a *carpal tunnel* in which are digital flexor tendons and the median nerve (p. 1133). The retinaculum is a mere 2.5–3 cm transversely, with a similar proximodistal length. It is attached medially to pisiform bone and the hook of the hamate; laterally it splits into a superficial lamina attached to the tubercles of the scaphoid and trapezium and a deep lamina attached to the medial lip of a groove on the trapezium (**5**.76). With this groove the laminae form a tunnel containing the tendon of flexor carpi radialis and its synovial sheath. The retinaculum is continuous, proximally, both with the fascia over flexor digitorum superficialis and with general antebrachial fascia; it is these layers which separate at the trapezium. It is crossed superficially by the ulnar vessels and nerve, and palmar cutaneous branches of the median and ulnar nerves. To its anterior surface tendons of palmaris longus and flexor carpi ulnaris are partly attached; distally some intrinsic muscles of pollex and minimus are attached. It is continuous distally with the palmar fascia, including its central aponeurotic fibres, associated with palmaris longus.

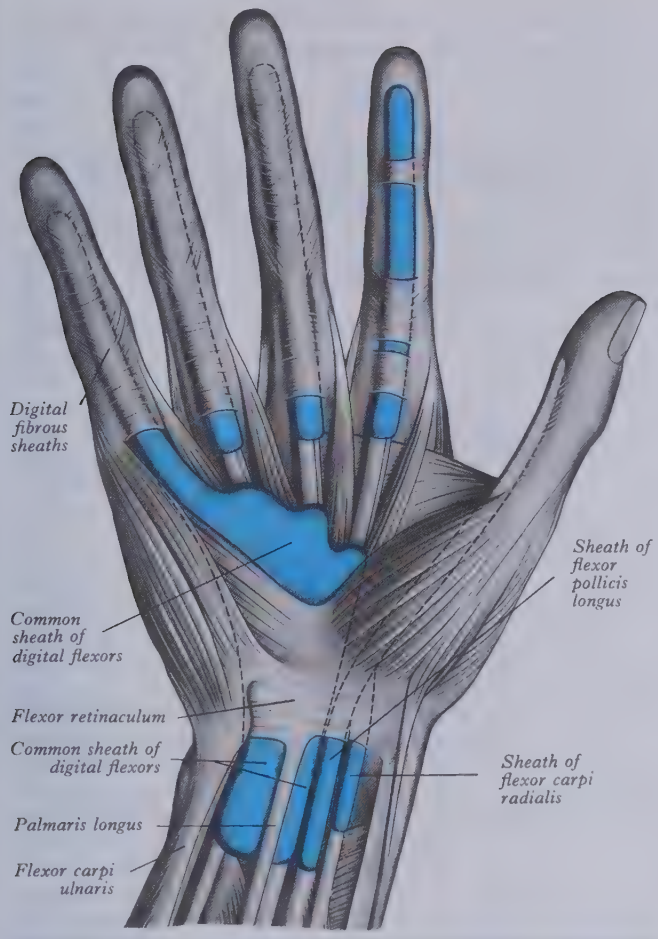
A localized thickening in the antebrachial fascia extends laterally from the pisiform bone as a *superficial part of the flexor retinaculum*, crossing superficial to the ulnar vessels and nerve to blend with the retinaculum lateral to them. (This 'superficial part' is to be carefully distinguished from the laterally placed superficial lamina mentioned above.)

The extensor retinaculum (**5**.78), a strong, fibrous, oblique band, extends across the radiocarpal dorsum, composed of antebrachial fascia, strengthened by oblique transverse fibres. It is attached laterally to the anterior border of the radius, medially to the triquetral and pisiform bones, and between two ridges on the dorsal aspect of the distal radius.

5.76 Transverse section through the left wrist, showing the tendons and their synovial sheaths. The section is slightly oblique and divides the distal row of the carpus and the bases of the first, second and third metacarpal bones. The arrangement of the tendons of the flexors of the fingers shown in the figure is not diagrammatic but represents the actual condition at this level. Observe that the carpometacarpal joint of the thumb is separate from the joint between the trapezium and the base of the second metacarpal bone.

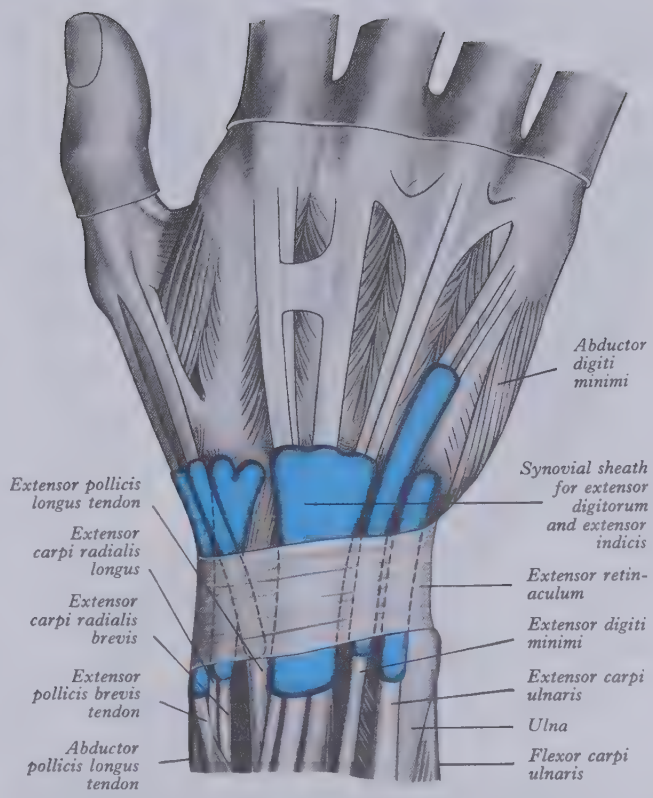
SYNOVIAL SHEATHS OF FLEXOR TENDONS

Two synovial sheaths envelop the digital flexor tendons in the carpal tunnel, one for flexores digitorum superficialis and profundus, the other for flexor pollicis longus (5.76). These extend into the forearm about 2.5 cm proximal to the retinaculum and are occasionally interconnected deep to it. The digital flexor sheath reaches about halfway along the metacarpal bones, ending in blind diverticula around tendons to the index, medius and annularis (5.77), but prolonged around tendons to minimus and usually continuous with the latter's digital sheath. A transverse carpal section (5.76) shows the tendons as if invaginated from the lateral side into the sheath. A parietal layer lines the retinaculum and carpal tunnel's floor and is reflected as a visceral layer over the ventral and dorsal aspects of superficialis and profundus respectively. The visceral layer is again reflected *between* the tendons, passing mediolaterally, as a double fold, on to the dorsal aspect of the tendons of flexor digitorum profundus. Thus from their medial aspect a *recess* of the visceral layer insinuates between the two groups of tendons and passes laterally at a variable distance. The sheath of flexor pollicis longus, usually separate but, as noted, sometimes connected to the common flexor sheath, usually behind the retinaculum, is continued through the pollex to the tendon's end. Fibrous sheaths of the terminal parts of digital flexor tendons are described on p. 618.



SYNOVIAL SHEATHS OF CARPAL EXTENSOR TENDONS

Deep to the extensor retinaculum are six tunnels for extensor tendons, each with a synovial sheath (5.78). They are: (1) lateral to the radial styloid process for tendons of abductor pollicis longus and extensor pollicis brevis; (2) behind the styloid process for tendons of the radial carpal extensors; (3) medial to the dorsal radial tubercle for the tendon of extensor pollicis longus; (4) medial to (3) for tendons of extensor digitorum and extensor indicis; (5) between the radius and ulna for extensor digiti minimi; (6) between the ulnar head and its styloid process for the tendon of extensor carpi ulnaris. The tendon sheaths of abductor pollicis longus, extensores pollicis brevis et longus, extensores carpi radiales and extensor carpi ulnaris cease proximal to the metacarpal bases; those of extensor digitorum, extensor indicis and extensor digiti minimi are sometimes prolonged somewhat distally along the metacarpus.

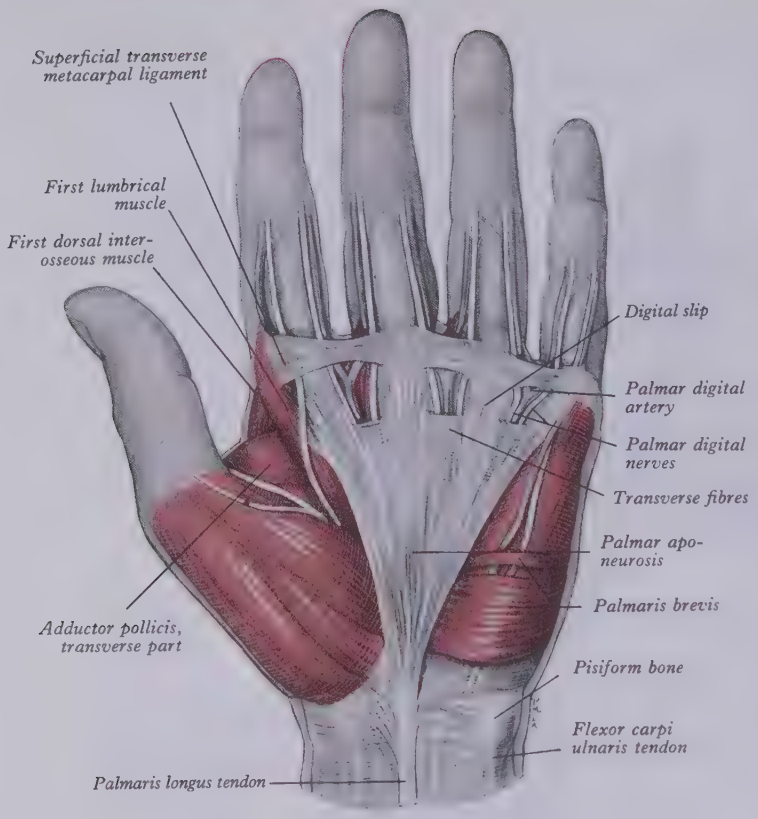


FASCIAL ARRANGEMENTS IN THE HAND

No region has provided so fertile an arena for dissection of connective tissue as the hand, with consequent identification of sheets, septa, bands and ligaments of almost tiresome numerosity and often doubtful validity. From a great number of studies, spread over more than two centuries, major features have received general accord, including fibrous flexor sheaths, dorsal digital expansions, tranverse metacarpal ligaments, and palmar fascia or aponeurosis. As Wood Jones emphasized (1941), every structure— muscle, tendon, nerve and vessel—is surrounded by connective tissue separating it from the others to a degree dependent upon local need of mobility. Constant thickenings of such 'sheaths' also serve to restrain or bind together some structures; and in the hand (and foot) subcutaneous tissue is traversed by numerous dense bands or 'skin ligaments', which tie skin to deeper fasciae and hence to bone for obvious functional reasons. These are little developed on the dorsum of the hand but marked in palm and flexor aspects of digits, especially in their pulps. Deeper connective tissue is often compacted and sometimes aponeurotic, blending with periosteum wherever nothing intervenes, and forming septa between some muscles.

Successive studies have added many details. In finer points authorities differ; individual variation doubtless occurs and functional comprehension is not always thus advanced. Such complexities must hence be here reduced to simpler concepts. At simplest it is clear that the deep fasciae of the hand are extensively connected on one side to skin, on the other to bone, including not only carpals, metacarpals and phalanges, but also proximally to the radius and ulna. At well recognized sites, where cutaneous flexion furrows are usually apparent, skin fixation is firmest. Between such sites of maximal anchorage many smaller fixation bands exist, interspersed by cushioning pads of adipose tissue which, though largely restrained by connective tissue bands, permit a small range of tangential movement; and since some displacement is possible, skin and subcutaneous tissue are easily

5.77 The synovial sheaths of the tendons on the front of the right wrist and hand (preparation by Professor J C B Grant). Where they are exposed, the synovial sheaths are shown in blue but, where they are hidden by overlying structures, their margins are indicated by interrupted black lines. For simplicity and clarity the digital synovial sheaths are represented as smooth cylinders; in reality they have complex undulant contours (p. 619). The traditional form of the fibrous flexor sheaths shown have been reclassified (see p. 618, 5.67A).



5.78 Simplified representations of the synovial sheaths of the tendons on the back of the right wrist (preparation by Professor J C B Grant). The synovial sheaths are shown in blue, but they have not been coloured where they lie deep to the extensor retinaculum. In this situation, and where one sheath lies deep to another, the margins of the sheaths are indicated by broken lines.

indented, with resilient recovery almost immediately distorting force ceases. These arrangements have obvious protective value; fat pads in interdigital webs are said to 'protect' digital vessels and nerves from adjacent tendons; thenar and hypothenar pads are clearly useful cushions in applying various tools. Less obvious is pliant conformation of grasping surfaces to the contours of objects grasped, however irregular. The hand can evaluate shape, weight, consistency of an infinity of external objects (p. 634), putting them to limitless uses, often involving large forces, the skilful and safe transmission of which depends as much on skin and fasciae as muscle and bone. Like muscle, skin and fasciae respond to use by hypertrophy, as may the bones while still able to grow. Skin in the hand shows general responsive thickening and also localized callosities (e.g. over metacarpal heads), sometimes characteristic of occupations. Palmar fascia sometimes responds excessively, with resultant disabling contractures. For details consult Kaplan (1965), Stack (1973), Bojsen-Møller & Schmidt (1974) and Landsmeer (1976). Fasciae also help to maintain the palmar concavity to restrain flexor tendons, perhaps to aid venous return.

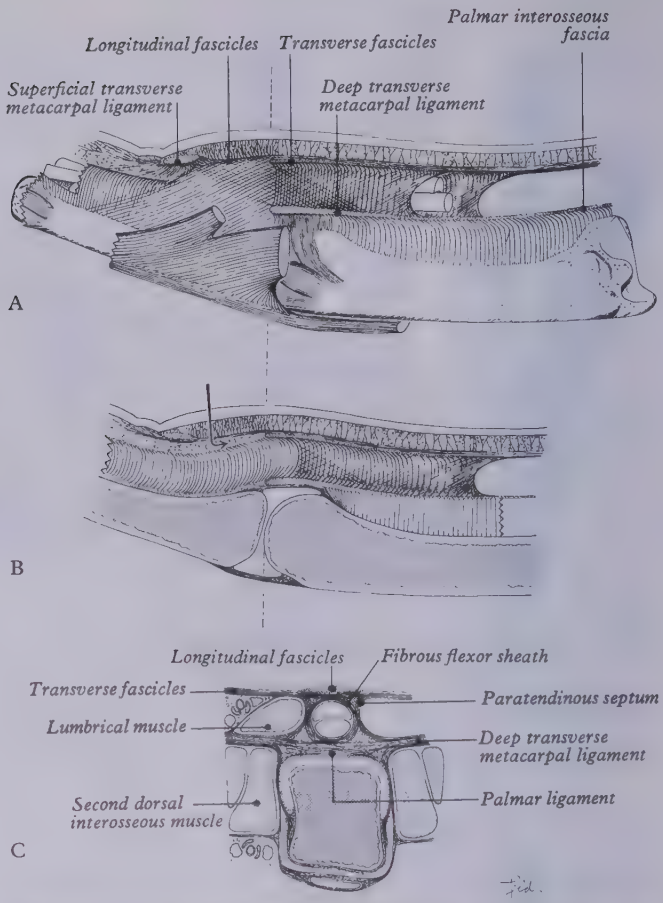
The palmar aponeurosis (5.79), directly related to palmar muscles and tendons, accordingly consists of central, lateral and medial parts, covering long tendons centrally and thenar and hypothenar muscle masses.

The *central part* is triangular, strong and thick, its apex continuous with the flexor retinaculum; the tendon of palmaris longus expands into it. Its distal base divides into slips, one to each finger, their superficial fibres reaching palmar and digital skin; in the palm they join the dermis at parts of two major transverse palmar furrows *over* the metacarpophalangeal joints and the multiple transverse folds and furrows at the roots of digits (and a few centimetres *distal* to the metacarpophalangeal joints). Deeper regions of each slip divide into two processes, in part continuous with the fibrous flexor sheaths and also partly attached to the deep transverse metacarpal ligaments, metacarpophalangeal capsules and the sides of proximal phalangeal bases. Short channels are thus formed anterior to the metacarpal heads for flexor tendons. Intervals between the slips are traversed by digital vessels and nerves and lumbrical tendons. Numerous transverse fibres bind slips at their origins. The central palmar aponeurosis is tied to the skin by dense fibrous tissue; to its proximal medial margin palmaris brevis is attached. It covers the superficial palmar arch, the digital flexor tendons, the preterminal median nerve and the superficial terminal branch of the ulnar nerve, as well as deeper structures.

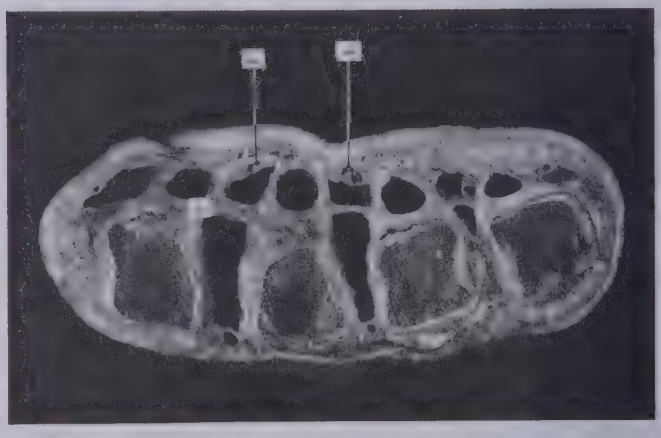
Lateral and *medial parts* of the palmar aponeurosis are thin, covering thenar and hypothenar muscles and continuous with its central part and marginally with the dorsal fascia of the hand. A septum passes dorsally from each border of the central palmar aponeurosis. The *medial palmar septum* is lateral to opponens digiti minimi and reaches the fifth metacarpal bone's palmar surface; it is distally continuous with a slip of the palmar aponeurosis to the lateral side of the flexor sheath of the minimus; proximally the septum reaches the hamate hook and pisohamate ligament and is pierced by deep branches of the ulnar nerve and artery. The *lateral palmar septum* reaches the palmar surface of the first metacarpal bone, passing medial to flexor pollicis brevis and

5.79 The left palmar aponeurosis.

opponens pollicis and lateral to the flexor pollicis longus tendon and its sheath. Proximally it reaches the trapezial tubercle and is pierced by a branch of the median nerve to the thenar muscles.



Fascial spaces of the palm. The central palm, deep to the central palmar aponeurosis and between the medial and lateral palmar septa, is divided by a thin intermediate palmar septum into the so-called *middle palmar* and *thenar spaces*. (Perhaps these names are unfortunate and even potentially misleading. Preferable terms would be: the *medial central palmar space* and the *lateral central palmar space*.)



The intermediate palmar septum is between flexor tendons of the index laterally and second lumbrical medially. Distally it blends with a slip of the palmar aponeurosis to the medial side of the indicial flexor sheath and the adjoining deep transverse metacarpal ligament. Dorsally it blends with fasciae over the distal part of the second palmar interosseous and transverse head of adductor pollicis, passing medially on this to the third metacarpal bone. Ventrally it is attached to palmar aponeurosis, but proximally meets the common flexor synovial sheath, blending with connective tissue on its dorsal aspect. Although it is a tenuous structure, pus may gather on either side of it; adjoining areolar tissue may be compressed against it to form an effective septum.

The *middle palmar space* (or *medial central palmar space*), between medial and intermediate septa, is dorsally limited by the third to fifth metacarpal bones, the fascia over the interosseous muscles in the third and fourth spaces and the medial part of the transverse head of adductor pollicis. The central palmar aponeurosis is ventral, the common flexor synovial sheath proximal. The space contains the third to fifth digital flexor tendons and the second to fourth lumbrical muscles, the superficial palmar arch and digital vessels and nerves for the third to fifth digits and ulnar side of the index. Distally it communicates with subcutaneous tissues at the digital webs; proximally, it may extend dorsal to the common flexor sheath. Bojsen-Møller & Schmidt (1974) regard the middle palmar 'space' as divided distally into independent channels for lumbrical muscles and common digital vessels and nerves (5.80D).

The *thenar space* (or *lateral central palmar space*), flanked by lateral and intermediate palmar septa, is ventral to the fascia

FASCIAL SPACES IN THE HAND

5.80 A. Drawing of the course of the fibres of the fasciae around the left third metacarpal bone and proximal phalanx viewed from the radial side. The deep transverse metacarpal ligament connects both with the metacarpal bone and with the longitudinal and transverse fibres of the palmar aponeurosis and, via their retinacula, with the skin. The palmar interosseous fascia is connected by means of a sagittal septum to the shaft of the third metacarpal bone. B. Sagittal section through the centre of the third metacarpal bone. The fibrous sheath of the flexor tendons extends for some distance between the transverse fascicles of the palmar aponeurosis and the deep transverse metacarpal ligament. Between the longitudinal fibres in the palmar aponeurosis and the fibrous sheath, a connective tissue space affords cleavage for demonstration of the paratendinous septa by dissection (arrow). C. Transverse section through the head of the third metacarpal bone showing the course of the fibres between the palmar aponeurosis and the deep transverse metacarpal ligament, and their attachments to the metacarpal bone. D. Section through the hand at the level of the heads of the metacarpal bones (2–5). The subdivision of the distal part of the central compartment into eight narrow compartments is demonstrated. The interdigital nerves and vessels (nv) have been left to show their relation to the lumbrical compartments. The deep transverse metacarpal ligaments (dt) and palmar aponeurosis (pa) are also shown (from Bojsen-Møller & Schmidt 1974, by courtesy of the authors and the Cambridge University Press). Compare A–C with the recent descriptions of the fibrous flexor sheaths mentioned on p. 619 and 5.67A.

covering the transverse head of adductor pollicis and, beyond this, the first dorsal interosseous muscles, while ventral to it is the palmar aponeurosis. It contains the tendon of flexor pollicis longus and its sheath, indicial flexor tendons, the first lumbrical muscle, palmar digital vessels and the nerves to pollex and the radial side of the index. Distally the space extends to subcutaneous tissues in the web of the pollex and proximally behind the flexor retinaculum.

All these 'spaces' are in fact *regions* in which relatively loose connective tissue allows some mobility but also little opposition to the spread of infection, whereas their boundaries, being denser, may contain an infection.

The superficial transverse metacarpal ligament is a thin strap (5.79) across the digital roots in superficial fascia, attached to the skin in digital clefts and to the fifth metacarpal bone, forming rudimentary webs. Digital vessels and nerves pass dorsal to it. Since it adjoins the bases of proximal phalanges, it is more appropriately named the *palmar digital ligament* (Bojsen-Møller & Schmidt 1974).

Applied Anatomy. The palmar aponeurosis is liable to a progressive disabling contracture (Stack 1973). Owing to constant exposure to injury and contamination, the fingers are liable to infection. In the digital *pulp*, ventral to most of the terminal phalanx, pus may be confined by strong septa radiating between the skin and periosteum, which sometimes entails necrosis of its diaphysis by obstruction of the blood supply from the digital arteries traversing the pulp. The epiphysis may escape, because its vessels leave digital arteries before entering the pulp. Inflammation may spread along flexor sheaths; in synovial sheaths of the pollex or minimus this may be more serious because these may communicate with the principal flexor sheath; infection may hence spread into the palm and behind the flexor retinaculum to the forearm.

Chronic inflammation of the common flexor sheath, a *compound palmar 'ganglion'*, presents a bilobar outline, a swelling proximal to the carpus, another palmar, the constriction corresponding to the flexor retinaculum. Fluid contents can be forced from one to the other behind the retinaculum. Although such pathological significance of fasciae and ligaments in the palm and digits must receive due emphasis, their basic function is to transmit tangential forces from skin to skeleton in the hand. Contraction of palmaris longus and extension at carpal and metacarpophalangeal joints all tense the palmar aponeurosis, with profound and advantageous effects on the mechanics of the normal hand.

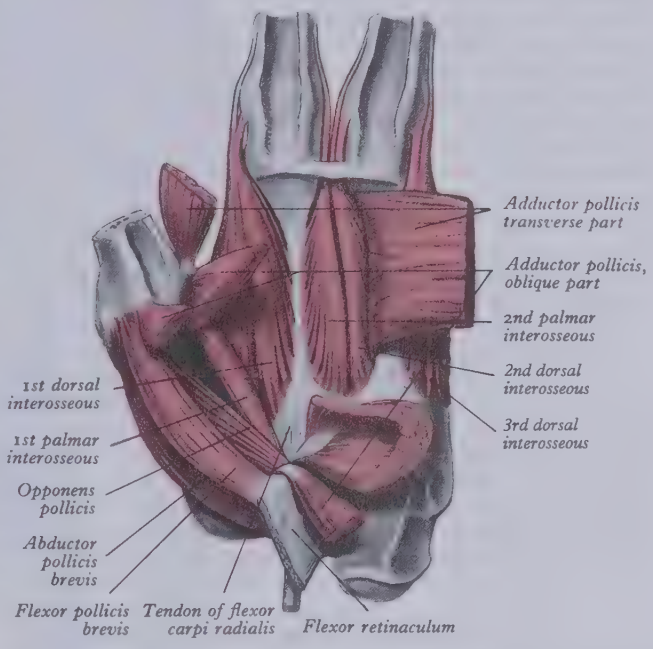
6. Muscles of the Hand

The intrinsic manual muscles form three groups: (a) three pollicial muscles in the *thenar eminence*; (b) muscles of the minimus in the *hypothenar eminence*; (c) lumbrical and interosseous muscles of the *central palm* and *intermetacarpal spaces* and finally adductor pollicis with its muscular heads sited with group c, but its main actions associated with group a.

(a) THENAR MUSCLES AND ADDUCTOR POLLICIS

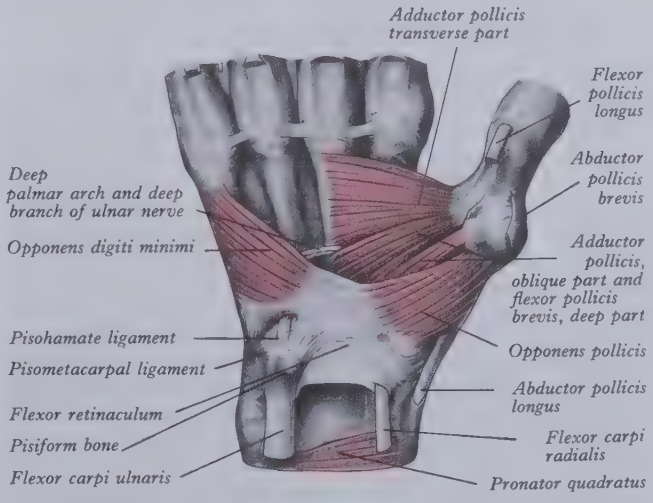
The pollex has intrinsic muscles to flex, abduct, oppose and adduct it. The first three form the thenar eminence.

Abductor pollicis brevis, a thin, subcutaneous muscle lying lateral in the thenar eminence, arises mainly from the flexor retinaculum; but a few fibres arise from the tubercles of scaphoid and trapezium and the tendon of abductor pollicis longus (p. 624). Its medial fibres are attached by a thin, flat tendon to the radial side of the proximal phalangeal base in the pollex; its lateral fibres join the pollicial dorsal digital expansion. Accessory slips may spring from the long and short pollicial extensors, opponens pollicis or the radial styloid process.



Nerve supply: the lateral terminal branch of median nerve, C.8 and T.1.

Actions. The muscle draws the pollex ventrally in a plane at right angles to the palm (abduction) also, to some degree, rotating it medially at metacarpophalangeal and carpometacarpal joints. *Both* actions occur at *both* joints, so that in full abduction the pollex is *not* in line with its metacarpal bone and different degrees of mutual rotation have occurred. 'Pure' abduction cannot occur because conjunct medial rotation accompanies movement at both joints and the total pollicial movement is considerably more complex.



Opponens pollicis (5.80, 81), deep to the abductor, extends from the trapezial tubercle and flexor retinaculum to the whole lateral border and adjoining lateral half of the palmar surface of the first metacarpal bone.

Nerve supply: the lateral terminal branch of the median nerve, C.8 and T.1 and commonly a ramus of the deep terminal branch of the ulnar (C.8 and/or T.1). Dissections by Day & Napier (1961), Forrest (1967) and electromyographic tests by Harness et al (1974) indicate double innervation in 92 out of 120 hands, to be regarded, therefore, as the usual arrangement.

Actions. The muscle flexes the metacarpal bone medially across the palm, also rotating it medially (p. 632). By this *opposition*, the palmar ('pulpal') aspect of the terminal segment may

5.81A Dissection of the left thenar eminence and palm over the two lateral intermetacarpal spaces. The parts of the adductor pollicis, including that sometimes designated 'the deep head' of flexor pollicis brevis, have been transected.

5.81B Deep dissection of the right palm, showing the opponens pollicis and opponens digiti minimi and the two parts of the adductor pollicis including the 'deep head' of flexor pollicis brevis. The superficial thenar and hypothenar muscles and palmaris longus have been removed.

contact the flexor aspects of any other digit. Flexion and (varying degrees of) medial rotation are simultaneous and movement also initially involves some abduction. Continuous smooth opposition involves carpometacarpal *and* metacarpophalangeal joints. During opposition, fingers flex at the metacarpophalangeal joints and variably at interphalangeal joints. The pollex may contact any part of a palmar digital aspect from base to tip. Digital flexion also involves some *lateral rotation* to meet the pollicial pulp en face, which is least marked in the index and greatest in minimus, in which displacement also occurs at its carpometacarpal joint (vide infra, opponens digiti minimi).

Flexor pollicis brevis (5.82), medial to abductor pollicis brevis, arises by superficial and deep heads, the superficial from the distal border of the flexor retinaculum and distal part of the trapezial tubercle; it passes along the radial side of the tendon of flexor pollicis longus to be attached by a tendon containing a sesamoid bone to the *radial* side of the pollicial proximal phalangeal base. It is often blended with opponens pollicis. The deep part arises from both trapezoid and capitate bones and the palmar ligaments of the distal carpal row, passing deep to the tendon of flexor pollicis longus to unite with the superficial head at its sesamoid bone. The deep head varies in size and may be absent.

Nerve supply: the superficial head, usually the lateral terminal branch of the median nerve; deep head, deep branch of the ulnar nerve, C.8 and T.1. Variations occur (Day & Napier 1961).

Actions: flexion of the proximal phalanx and, if continued, flexion and medial rotation of the metacarpal in co-operation with opponens pollicis (p. 629).

Adductor pollicis (5.81) arises by the oblique and transverse heads, the *oblique head* being attached to the capitate bone, the second and third metacarpal bases, carpal palmar ligaments and the tendon sheath of flexor carpi radialis. Most fibres converge into a tendon containing a sesamoid bone and joining that of the transverse head to be attached to the *ulnar* side of the proximal phalangeal base. The deepest fibres may reach the medial side of the dorsal digital expansion. Lateral to the oblique head a fasciculus passes deep to the tendon of flexor pollicis longus to join the flexor pollicis brevis as a 'deep head' of flexor pollicis brevis (Day & Napier 1961). The *transverse head* (5.81), deepest of the pollicial muscles, is triangular and arises from the distal two-thirds of the palmar aspect of the third metacarpal, converging with the oblique head and the first palmar interosseous muscle to the base of the proximal phalanx. The two parts vary in relative size.

Nerve supply: the deep branch of ulnar nerve, C.8 and T.1.

Action. The muscle approximates the pollex to the palm, acting at greatest advantage when the abducted, rotated and flexed pollex has been opposed to the fingers in gripping. Thus it is the antagonist of the complex muscular interplay involved in opposition (vide supra).

(b) THE HYPOTHENAR MUSCLES

Apart from palmaris brevis, a superficial muscle, this group flexes, abducts and opposes the fifth digit (5.79,81,82).

Palmaris brevis (5.79) is thin, quadrilateral and subcutaneous on the ulnar side of the palm, attached to the flexor retinaculum and the medial border of the central palmar aponeurosis; it ends in the dermis of the hand's ulnar border, superficial to the ulnar artery and the superficial terminal branch of the ulnar nerve.

Nerve supply: the superficial branch of the ulnar nerve, C.8 and T.1.

Action. It wrinkles the skin on the ulnar side of the palm, deepening a longitudinal hollow or groove along the medial aspect of the hypothenar eminence, and slightly accentuating the eminence. It may contribute to the palmar grip. Clinically, thumbnail pressure on the medial aspect of the pisiform often stimulates its nerve, causing it to contract.

Abductor digiti minimi (5.82) arises from the pisiform bone, the tendon of flexor carpi ulnaris and the pisohamate ligament. Its flat tendon divides into two slips, one attached to the ulnar side of the proximal phalangeal base of minimus, the other to the ulnar border of the dorsal digital expansion of extensor digiti minimi. The muscle may have two or three slips or be fused with flexor brevis. A slip may also variously arise from the flexor retinaculum, antebrachial fascia, tendons of palmaris longus or flexor carpi ulnaris. It may be partly attached to the fifth metacarpal by a slip from the pisiform.

This muscle has been used to calculate force and work efficiency generated by muscles, using various techniques, by Neto et al (1984).

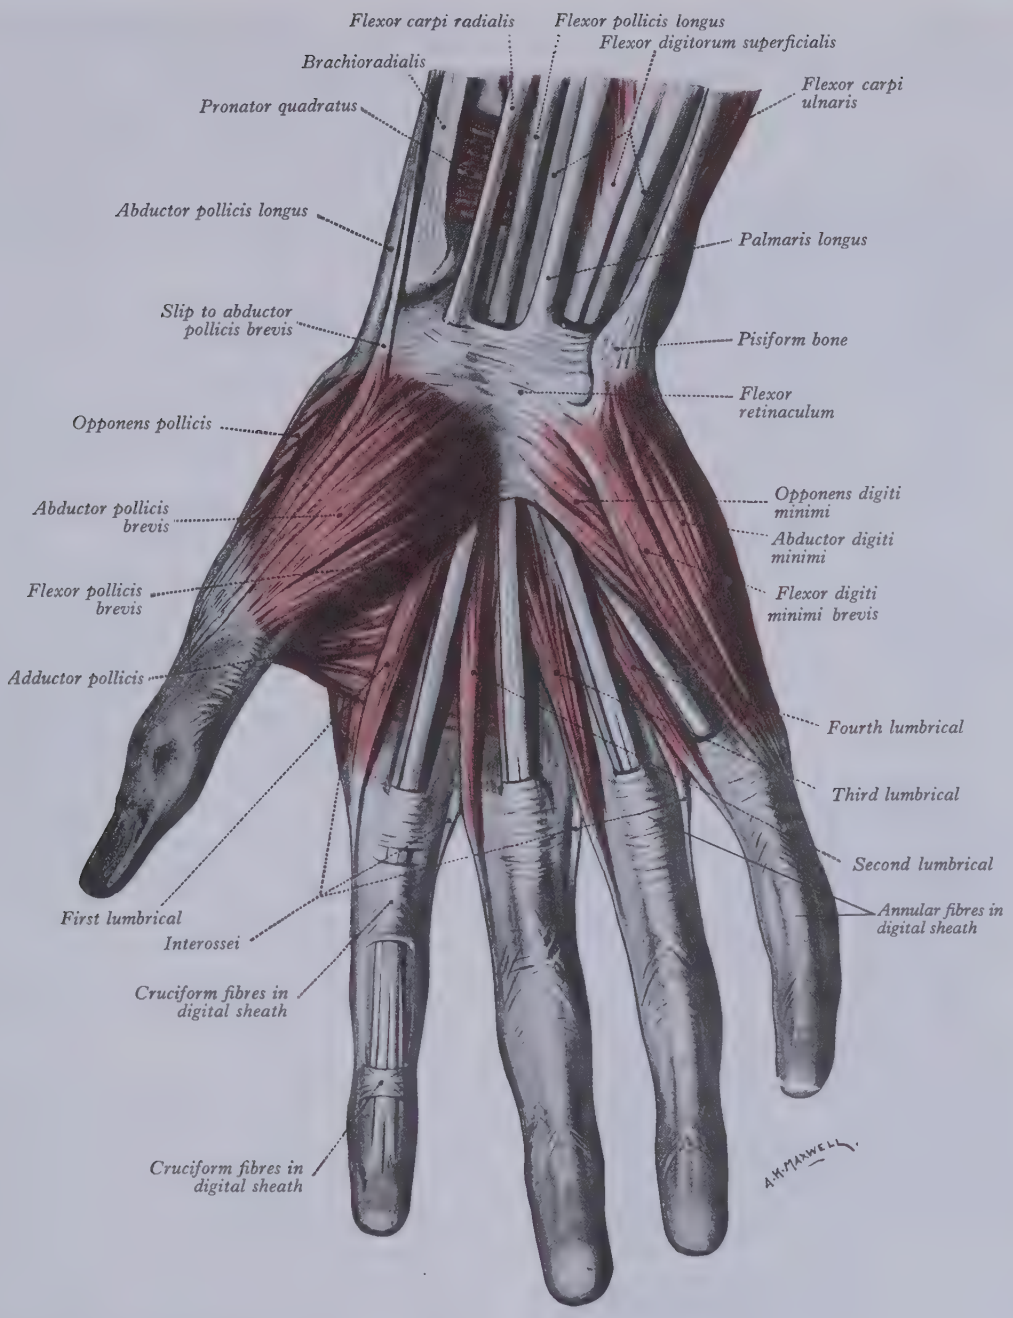
Action: abduction of minimus from annularis, e.g. in synergic spreading of extended digits. Abduction of minimus may also occur with digits 2–4 tightly adducted and either flexed or extended.

Flexor digiti minimi brevis (5.82), lateral to the abductor, arises from the convex aspect of the hamate's hook and of palmar surface of the flexor retinaculum and is distally attached to the ulnar side of the proximal phalangeal base with abductor digiti minimi. It is separated from the abductor proximally by deep branches of the ulnar artery and nerve. It may be missing or fused with the abductor. A slip may reach the distal end of the fifth metacarpal.

Action: flexion of minimus at its metacarpophalangeal joint, together with some lateral rotation.

Opponens digiti minimi (5.81) is triangular, deep to the flexor and abductor, arising from the convexity of the hamate's hook and the contiguous flexor retinaculum; it ends along the fifth metacarpal's whole ulnar margin and adjacent palmar surface, often divided into two lamellae by deep branches of the ulnar artery and nerve. It is variably blended with its neighbours.

Action. It flexes the fifth metacarpal, rotating it laterally at the carpometacarpal joint, deepening the palmar hollow. With the addition of flexion and lateral rotation at the metacarpophalangeal and interphalangeal joints, it *opposes* the minimus to the pollex.



Nerve supply: all muscles of the minimus are supplied by deep branch of the ulnar nerve, C.8 and T.1.

(c) THE LUMBRICAL AND INTEROSSEOUS MUSCLES

The lumbricals (5.82) are four small fasciculi arising from tendons of flexor digitorum profundus: the first and second from the radial sides and palmar surfaces of tendons to the index and medius; the third from *adjacent* sides of the tendons to medius and annularis; the fourth from *adjoining* sides of the tendons to the annularis and minimus. Each passes to the *radial* side of the corresponding digit and here is attached to the lateral margin of its dorsal digital expansion (5.70). Variations in attachments are common. Any may be unipennate or bipennate, arising from the adjoining tendons of flexor digitorum profundus and from that of flexor pollicis longus, when the first is bipennate (Goldberg 1970). Accessory slips may also be attached to an adjacent tendon of flexor digitorum superficialis.

Nerve supply: first and second, median nerve, C.8 and T.1; third and fourth, deep terminal branch of ulnar, C.8 and T.1. The third is often supplied by the median nerve. This arrangement is remarkably constant but details of muscular rami vary. The first and second are also sometimes supplied by the deep terminal ulnar branch (Mehta & Gardner 1961).

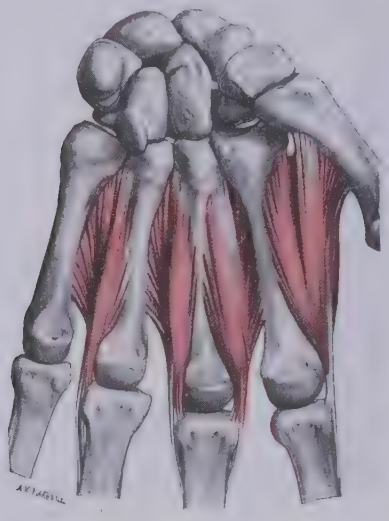
Actions. Lumbrical muscles link *flexor* to *extensor* tendons, a unique arrangement apart from the foot. Actions are hence likely to be complex (p. 633), depending not only on their own length and tension but also on these parameters in their long flexors and extensors. Descriptions of their activities often disregard these facts, being based on incomplete assumptions, the proximal attachments being considered as fixed and their attachment to the dorsal extensor apparatus alone as mobile, and with their line of pull slightly ventral to the transverse axes of the metacarpophalangeal joints. Hence often simply regarded as flexors, they are probably weak in this; since the axes of these joints move ventrally during flexion, lumbrical flexor effect may not be augmented (but, rather, diminished) by increasing flexion. By their attachments to dorsal expansions lumbricals should extend interphalangeal joints. There is direct evidence of this. As long ago as 1954 Backhouse & Catton confirmed this action by inserting electrodes into a number of 2nd lumbrical muscles; Long & Brown (1964) made similar observations. The

5.82 Superficial dissection of muscles of the palm of the right hand. The annular and cruciform fibres in the digital fibrous flexor sheath are here positioned as in traditional accounts. For a more recent and comprehensive classification see p. 618 and 5.67A.

well-known 'claw' deformity after ulnar nerve lesions provides further evidence.

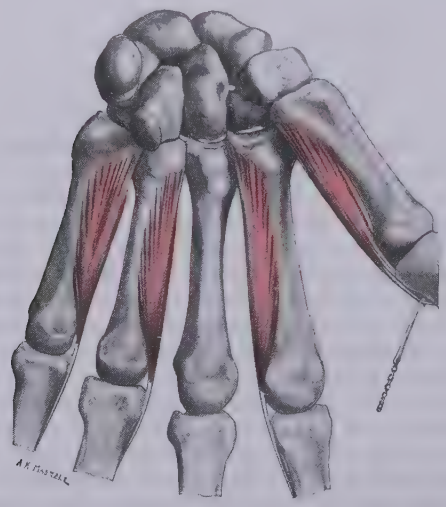
When the third, fourth or fifth finger is individually fully flexed at its metacarpophalangeal and proximal interphalangeal joints (with the other digits extended), its distal phalanx can be neither flexed, extended, or 'fixed' voluntarily. This is due to the mode of attachment of extensor tendons; a terminal phalanx can be extended only when the middle one is also extended (p. 633).

The *interossei* occupy the intervals between the metacarpal bones, and are divided into dorsal and palmar sets.



Dorsal interossei (5.83A), four bipennate muscles, arise from the adjacent sides of metacarpal bones, more extensively from the metacarpal whose digit they enter. They are attached distally to their proximal phalangeal bases and separately to their dorsal digital expansions (p. 622). Between their proximal attachments are narrow triangular intervals; through the first the radial artery passes and through the others perforating rami of the deep palmar arch. The *first* and largest muscle (*abductor indicis*) ends at the radial side of the proximal phalanx of the index and capsule of its metacarpophalangeal joint. The *second* and *third* pass to the radial and ulnar sides of the medius; the second usually reaches the digital expansion and proximal phalanx, the third only the digital expansion (5.71). The *fourth* may be also wholly attached to the expansion but often also sends a slip to its proximal phalanx.

Palmar interossei (5.83B) are smaller and palmar to their metacarpal bones (1,2,4 and 5). Except the first, each arises from the entire length of its metacarpal bone, both arising and passing to the appropriate (adductor) side of its dorsal digital expansion (Salsbury 1937, Landsmeer 1949). (The medius has no palmar interosseous; the remaining digits have palmar interossei on their aspects *facing the medius*.) Thus, the *first* arises from the ulnar side of the palmar surface of the first metacarpal base and passes to a



sesamoid bone on the ulnar side of the proximal phalanx, and thence to the phalanx and usually also to the dorsal digital expansion (Lewis 1965). It is ventral to the lateral head of the first dorsal interosseous and is overlapped ventrally by the oblique head of adductor pollicis (5.81A). (Some have preferred to regard this first muscle as a deep stratum of flexor pollicis brevis, a view now largely forgotten.) The *second* arises from the ulnar side of the second metacarpal and is attached to the ulnar edge of the dorsal digital expansion in the index. The *third* arises from the radial side of the fourth metacarpal and is attached in common with the third lumbrical. The *fourth* arises from the radial side of the fifth metacarpal and is attached in common with the fourth lumbrical (vide supra) and additionally to the base of its proximal phalanx. These attachments to the dorsal digital expansions (5.71) stabilize extensor tendons on the convex heads of metacarpal bones during movements at metacarpophalangeal joints.

Interossei do not vary much; they are occasionally reduplicated, perhaps due to the derivation of the palmar interossei from paired short flexors (Lewis 1965).

Stack (1962) and others prefer to classify interossei as 'proximal' and 'distal'. The former, chiefly dorsal interossei, are attached to the proximal parts of extensor expansions ('*hood*' or '*dorsiere*') forming the *proximal wing tendons* and separately to the phalangeal tubercle of bases of proximal phalanges (5.70,71). The palmar or 'distal' interossei, apart from the first, are attached only to extensor expansions, distal to the 'hood' and usually opposite a lumbrical, both attachments forming the *distal wing tendons* (p. 623).

5.83A The dorsal interosseous muscles of the left hand: palmar aspect.

5.83B The palmar interosseous muscles of the left hand: palmar aspect.

Nerve supply: the deep branch of the ulnar nerve, C.8 and T.1. Rarely, the first dorsal interosseous is supplied only by the median nerve (Sunderland 1946).

Actions. Dorsal interossei abduct digits from an arbitrary longitudinal line through the centre of the medius; palmar interossei adduct towards this line (p. 634). With the lumbricals they flex the proximal phalanges; by their attachments to the dorsal digital expansions they are able, in certain conditions (p. 634), to extend the middle and distal phalanges. The first palmar interosseous flexes and adducts the pollicial proximal phalanx.

THE NATURE OF MANUAL DEXTERITY

Human upper limbs, with a mobile, basal shoulder girdle, an extensible, folding arm and forearm and a terminal working tool, the hand, have an extraordinary range and versatility of movement. One has but to watch the limited performance of the most complex mechanical and electronic manipulators elaborated by human ingenuity to recognize the immensely greater skill and repertoire of the human hand. Pre-eminently adapted for reaching, grasping and manipulating, it has also much potentiality for other activities: pushing and adjusting objects without grasping, striking blows and supporting the body in endless positions. When transmitting thrust or supporting weight, the whole upper limb may become a rigid pillar, like the leg, with joints in their close-packed positions; or it may absorb forces by appropriately controlled resilient flexion. The hand may be used as a fist, or forces may be transmitted through fingers extended in close-packed positions at the digital joints and carpus, sometimes with the proximal interphalangeal joints slightly flexed, as in the toes at take-off (p. 658).

But especially in grasping activities has the human hand enabled development of great skills. Despite this, the hand is in many ways primitive and physically capable only of a limited range of movements, though with much skill and versatility. Human hands are not specialized in movement beyond those of some other primates. Some, like the gibbon, have specialized, hook-like hands in which opposition is lost; but the chimpanzee, gorilla and many monkeys have much the same repertoire of hand movements. The difference lies in the range of uses to which they are put (Jones 1941). Mankind incomparably excels in endlessly variable application of manipulative skills, the hands being responsive tools commanded by unrivalled mental development. A note of caution is needed in the use of the terms 'primitive' and 'specialized', which may lead to a semantic morass. Such terms are used by morphologists with little reference to function. In the structural sense the human hand is obviously more generalized than most mammalian extremities, though in many minor details more highly adapted to intricate functions; it is from this point of view extremely 'specialized' (Bishop 1964).

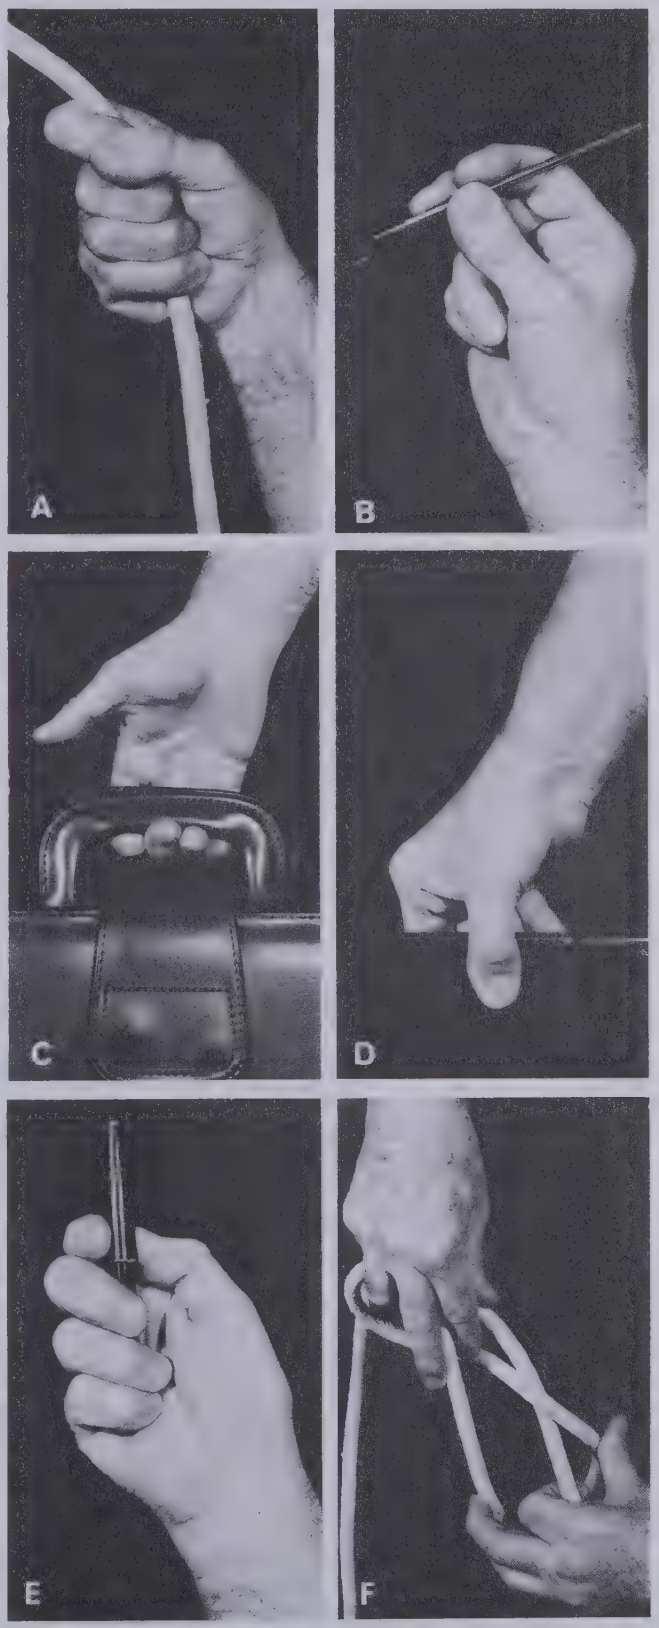
Prehensile activities have been variously analysed, e.g. as cylinder, ball, ring, pliers and pincer grips (Griffiths 1943); but a simpler view is possible, all such grips being variants of *power* and *precision grips* (Napier 1956). Combinations occur in some activities, and a *hook grip* is in some features distinct.

In the **power grip** (5.84) the fingers are flexed round an object, with counter pressure from the pollex, positioned to bring either its pulp or medial border against the object held. The purpose is to hold an object firmly, either as a tool or weapon, or to be worked upon by the other hand. Once grip is made, the hand is held still or moved with the rest of the limb; any skill is due to the limb, including the carpus; relative movements of thumb and fingers are not involved.

In the **precision grip** (5.84), in contrast, not only is grasp more precise but small digital movements are usually the main source of adroit activity. The object is gripped between the tips of the fingers and thumb, sometimes by all, more often by the thumb and index, with the middle finger frequently involved, as in grasping a pen, pencil or the handle of any small tool. The position may be adjusted at the wrist or involve supination, pronation and small adjustments at the elbow and shoulder. In the finest work, however, most skilled manipulations employ the lumbricals and interossei, with metacarpophalangeal flexion and interphalangeal extension, and vice versa. These are characteristically utilized in

the motions of advancing and withdrawing any small objects to or from another (e.g. a thread to the eye of a needle), one held still in a power grip, the other manipulated to and fro in a precision grip. Such activities are commonplace in inspecting or manipulating any small object. Flexor-extensor musculature of digits is highly organized for this; individual contributions have been described and investigated in considerable detail (Long 1968, MacConaill & Basmajian 1969, Kapandji 1970).

Relatively small objects may be held steady in a power grip by flexion of the medial three digits against the palm, while the index and thumb carry out manipulations upon them by a precision grip, e.g. a fountain pen may be thus held while its cap is screwed off or on. A single hand may thus be used simultaneously in power and precision grip.



The **hook grip** (5.84) is used to suspend or pull; it may be used like the power grip, to suspend or elevate the body in climbing. Fingers may loop around handles, straps, cords, branches, rocks, etc. and flex towards the palm, to a degree depending upon the dimensions of whatever is grasped. The thumb may or may not be involved. It is a grip for the transmission of forces, not for fine manipulation.

Thus, by flexion and extension of the wrist and digits, adduction and abduction of digits, and the opposition of the pollex, a relatively small repertoire of manual movement is possible. Accessory to this, it is to be noted, are minor degrees of rotation in the fingers and a freer range in the pollex. Though the repertoire is limited, the scope of movements and nicety of control with which they can be varied, especially with practice, are the unequalled prerequisites of mankind. This manual skill, guided by discriminative vision and directed by a highly imaginative and inquisitive mentality into a seemingly endless range of activities, has enabled mankind to master much of the natural environment and to create a culture of art, science and technology without peer. The ever-increasing complexity of the artificial environment thus created has carried us far beyond any other form of life of which we are aware—perhaps in some respects already too far.

Mechanical Analysis of Manual Movements

Mechanics of manual movements involve many factors and not least are the effects of external resistance from objects manipulated. These initiate a continuous feedback, to which the motor apparatus responds in intricate nuances of adaptive adjustment in a complex chain of articulations. Ignoring the carpus, each digit has four joints (three in the thumb), whose individual changes must be concerted, each digit actuated by not less than six muscles (medius and annularis) and as many as nine (minimus), a total of 36. It is scarcely practicable to attempt to deal exhaustively with the myokinetics of manual movements, even if fully supported by experiment or direct observation. In fact, most detailed accounts (Wood Jones 1941, Napier 1966, Kaplan 1965, Stack 1973, Landsmeer 1976) are a mixture of theorization and factual data. Such interpretations of anatomical facts are, however, often plausible and experimental data available are sometimes confirmatory. The following account is necessarily based upon this mixture of real data and derived interpretation.

The hand is a flexor–extensor mechanism, complicated by adduction–abduction and small rotations, the latter usually conjunct. To be added is opposition. The grasping, flexor aspect, the palm, is necessarily hollowed, dynamic palmar arching being carried proximally into a rigid carpal concavity. Analogies between this arched form and that in the foot have been mooted; but the hand is not habitually weight-bearing and such comparison will not be pursued. In a prehensile apparatus flexors would naturally exceed extensors in available power. Electromyography shows that in slow and moderate flexion of digits only flexor digitorum profundus is active, flexor digitorum superficialis assisting in more powerful and rapid gripping. Extension, mainly with digital abduction, is usually preliminary to grasping. But digital manipulation demands more than simple extension and flexion; as already emphasized, it is the dissocation of events at metacarpophalangeal and interphalangeal joints which converts the hand from a grasping organ to a skilled manipulator. Separate flexors and extensors, operating in opponent pairs at each joint in a digital articular chain, might serve independent flexor–extensor adjustments, as they do in the thumb. But the latter has only two

5.84 A few of the many varieties of functional postures which may be adopted by the human hand: A. power grip; B. precision grip; C. hook grip; D. pincers grip; E. simultaneous power and precision grip; F. complex manipulation.

phalanges; the triple phalangeal series of other digits might be difficult, perhaps even impossible, to control completely even with such a multiplicity of long extrinsic tendons. However, only one long extensor is available; and this, through attachment to proximal phalanx and transverse metacarpal ligament (p. 515 and 5.70B), is limited to extension at the metacarpophalangeal joints, at which point retraction of the extensor 'hood' is arrested. This entails that the extensor tendon distal to this must be long enough to allow full interphalangeal flexion, even when the metacarpophalangeal joint is fully extended. In full flexion of an average digit its extensor aspect increases by 2–3 cm. Therefore there must exist some means by which the digital parts of long extensor tendons can be varied in effective length. Mere elasticity might suffice but elongation, to this extent, of largely collagenous structures is impossible. In fact, the extensor apparatus (it is far more than a simple tendon) is arranged to exploit this apparent difficulty (5.70A–C, 5.71A–D). The lateral bands of each tendon, ending at a terminal phalangeal base, can be drawn proximally by the intrinsic muscles attached to them and can also be spread apart by these forces, shortening the distal part of the tendon. The arrangement resembles a diamond (5.71C), with forces applied at its four angles. An increase in width by traction at the lateral angles (by intrinsic muscles) shortens the length of the extensor apparatus. Theoretically this would permit flexion or extension at the interphalangeal joints whatever the state of the metacarpophalangeal; this is precisely what occurs in digital movements. Moreover, proximal *and* distal attachments of the intrinsic muscles provide for separate extension at both interphalangeal joints.

Interosseous and lumbrical muscles thus supply the third and balancing force between extrinsic digital flexors and extensors. Independent control of movements at three digital articulations would otherwise be impossible. This can be stated with confidence; the effects of paralysis of intrinsic muscles are well known, the data of electromyography are also convincing, though limited.

More must be added with regard to the lumbrical muscles. Like interossei, their tractive effect is aligned ventral to the metacarpophalangeal joints; they are therefore somewhat inefficient flexors. Again like interossei, they pull on extensor expansions at their distal wings and exclusively so. Unlike interossei they do not act from a static proximal attachment, but from adjustable bases of deep flexor tendons. It is difficult to envisage precise changes in the length of these muscles which must occur in different states of flexor–extensor balance, nor are direct observations available. However, Stack (1962) has essayed a detailed analysis of such changes in the length of lumbrical (and interosseous) muscles in different digital positions, estimating the proximal positioning of lumbricals from the excursions of deep flexor tendons. Excursions have been assessed at 5–20 mm by Bunnell (1949), Kaplan (1965) and Landsmeer (1955). As will be appreciated from the diagram in 5.71, the lumbrical muscles are shown as most contracted and distal in position in full digital extension; in contrast they appear most elongated and proximal in full flexion. Stack interprets these reconstructions (which cannot be far from reality) as indicating that intrinsic muscles, especially the lumbricals, act as servo-mechanisms, the main power of extension derived from the long extensor tendons, while precise points of application of power at interphalangeal joints is determined and transmitted by the intrinsic muscles. (It is perhaps reasonable, therefore, to enquire whether *extensor* forces cannot equally be exerted by deep digital *flexors* via lumbricals.) Whatever the real activities of lumbrical muscles, theirs is undeniably a key role in digital movements. It has been suggested that their stretch receptors are of special importance, apparently a reasonable assumption, though it is unwise to emphasize any single factor in the complex mechanics of digital movement.

The contribution of the *digital retinacular ligaments* (p. 630) is considered an integration between interphalangeal joints. Flexion at the distal appears to tauten ligaments on each side of the digit and to pull proximal joints into flexion. It is observable that when flexion at a proximal joint is prevented, flexion at the distal is resisted, probably by retinacular ligaments. The two joints are similarly linked in extension. Passive flexion of a distal joint automatically produces a similar movement at the proximal. Stack (1962) has constructed an interesting model to illustrate these and other digital mechanics.

Nothing has yet been said of slight rotations at digital joints. Interphalangeal joints are often regarded as uni-axial, but slight conjunct rotation occurs (p. 515); more obvious rotation is visible at the metacarpophalangeal joints and the rotational movement of metacarpals at carpometacarpal junctions also contribute to digital movements. When digits are opposed in precise manipulations all except the medius show slight metacarpal rotation; in the fingers these rotations are held to be effected by the appropriate interossei (Braithwaite et al 1948), necessary to approximate the tips of fingers and thumb in various forms of precision grip (vide supra), which can involve more than the pollex and index. These two provide a '*pliers*' or '*pincer*' grip; any or all of the others may be added to produce varieties of '*chuck*' grip (5.84). In these and other flexor actions, the metacarpal movements, though small (except in the pollex), are easily observed. In gripping any object powerfully with the whole hand, the more mobile metacarpals (5th, 4th, 2nd) are flexed to relative extents indicated at the carpometacarpal joints and the fifth at least may also rotate. These movements depend on shape, dimensions and the malleability of the objects grasped, e.g. in grasping a long cylinder across the whole palm metacarpal rotation is unnecessary, unless it is of small diameter or yielding substance, such as a thin rope; in which case flexion and rotation of the fifth metacarpal in particular contribute to the well-known effectiveness of the minimus in gripping small, long objects. In all grasping movements the ultimate events at the articulations involved depend upon the size, contours and resistances presented by an object, as much as upon deployment of muscular forces. For such reciprocally adaptive adjustment the multiplicity of skeletal components, and hence articulations, in the hand appears extremely apt.

The pollex, more accessible to direct observation, presents less difficulty in the description of its activities; but there is more controversy over the definition of its *cardinal* movements (compare Haines 1944, Napier 1955 and Pieron 1973) and especially over how these contribute to the *customary* pollicial activities which are not the selected actions of formal analysis: i.e., flexion, extension, abduction, adduction and circumduction. These activities have, in their turn, dictated the names of the muscles involved, despite the fact that these do not have the 'pure' or cardinal effects indicated by their names. For example, abductor pollicis brevis is not a simple abductor, for it also assists in medial rotation, a combination clearly adapted to opposition; 'pure' abduction is an abstraction, while slightly 'impure' abduction with minimal spin is infrequently required.

It is hence necessary to consider these cardinal movements. Since the pollicial carpometacarpal joint is sellar, planes of its two cardinal 'swings'—flexion–extension and adduction–abduction—must be approximately at right angles; but orientation of these planes relative to the rest of the hand is variably defined in different accounts, perhaps the source of controversies in naming the movements. Commonly the plane of adduction–abduction is regarded as approximately orthogonal to that of the palm, entailing that flexion–extension is parallel to the latter. Inspection clearly shows that the major axes of this sellar joint are not so orientated: the ridge on the trapezial articular surface (along which the metacarpal base slides in adduction–abduction) is inclined at an angle nearer to 60° than 90° relative to the 'palmar' plane. Hence abduction is not only 'away' from the palm but also somewhat lateral. Doubtless this plane varies individually; even to regard it as a plane is probably a simplification. Sellar surfaces at this joint are not perfectly symmetrical; Kuczynski (1974) has examined a short series (15 hands) in great detail, showing that contours of the surfaces are such that pure swings are improbable, being accompanied in fact by slight rotation. He also considers that rotations are even greater in flexion–extension. This is perhaps to be expected in a digit constantly moving from positions of opposition to open grasp, with the pollex somewhere between extension and abduction. Both Kapandji (1970) and Kuczynski (1974) emphasize that pollicial movements depend on what is occurring at all joints simultaneously. Medial metacarpal rotation, accompanying flexion and adduction during opposition, is combined with a similar rotation at the metacarpophalangeal joint. Medial

rotation at the latter is usually compounded with some abduction of the proximal phalanx, as when opposing the tips of pollex and minimus. Movements at both ends of the pollicial metacarpal could be integrated by thenar muscles, all of which, except opponens, act on the carpometacarpal *and* metacarpophalangeal joints. Pollicial muscles, intrinsic (thenar) and extrinsic, have been likened to an array of stays or guy-ropes, alterable in length to adjust either joint to a new position from which the rest of the digit can then be moved. Movements of the terminal phalanx at the interphalangeal joint are controlled by the long flexor and extensor. Having only two phalanges the pollex does not present the same extensor problems as do other digits; no complex extensor expansion is required.

At rest the thumb is in contact with or near to the lateral palmar border and index finger. Other digits are slightly flexed, to a degree increasing from the second to the fifth. Metacarpal heads form an arch, corresponding in palmar concavity to that of the carpus, at which the hand is about half extended. The whole apparatus, though 'open', is semi-flexed or 'cupped', ready for grasping or oppositional effort as required. For larger objects the initial extensor 'spread' may be a preliminary to active progress to some form of power or precision grip. If the latter involves all digits, as in holding a ball between their tips, the variable mobility of metacarpals is particularly noticeable, allowing the fingertips to turn towards the pollex and to space themselves at different angles around such an object. Opponens minimi digiti enables its more mobile metacarpal to bring the fifth digit in complete opposition to the pollex across the diameter of large or small objects. The influence of ligaments in pollicial activity, especially at the carpometacarpal joint, has attracted little interest. The intermetacarpal ligament, between the first and second metacarpal bases (Haines 1944), has been re-examined by Bojsen-Møller (p. 514), who regards it as much involved in such movements.

All movements so far described concern prehension; but the hand can also be used in transmitting force, as in pushing objects or pressing upon surfaces. The resistance to be overcome may be great, amounting to body weight and more. In dynamic situations, where the hand fends off moving bodies or to avoid collision with static obstructions, the forces transmitted through the outstretched, extended hand may be even greater. Most joints in the hand and wrist are then in the close-packed position, and flexor structures, tendons, ligaments and fasciae, are tensed to produce maximal resistance to further extension.

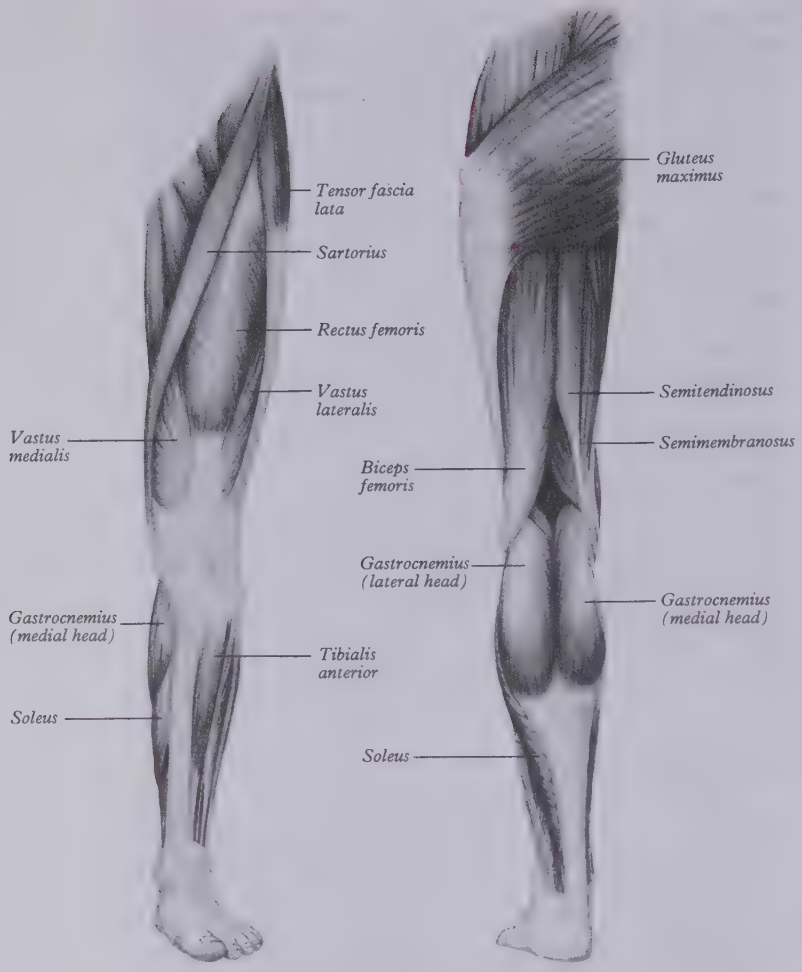
The great variety and skill of manual movements is mediated by a most complex motor equipment and sensory apparatus, cutaneous and neuromuscular. It is not surprising that the hand monopolizes a greater area of motor and sensory cortex (7.1049) than the rest of the arm or the whole of the leg. The thumb's importance is manifest in the allocation to it of about half the cortical 'areas' for the hand.

MUSCLES OF THE LOWER LIMB

Muscles of the lower limb may be grouped as follows:
1. Muscles of the iliac region.
2. Muscles of the femoral and gluteal regions.
3. Muscles of the leg.
4. Muscles of the foot.

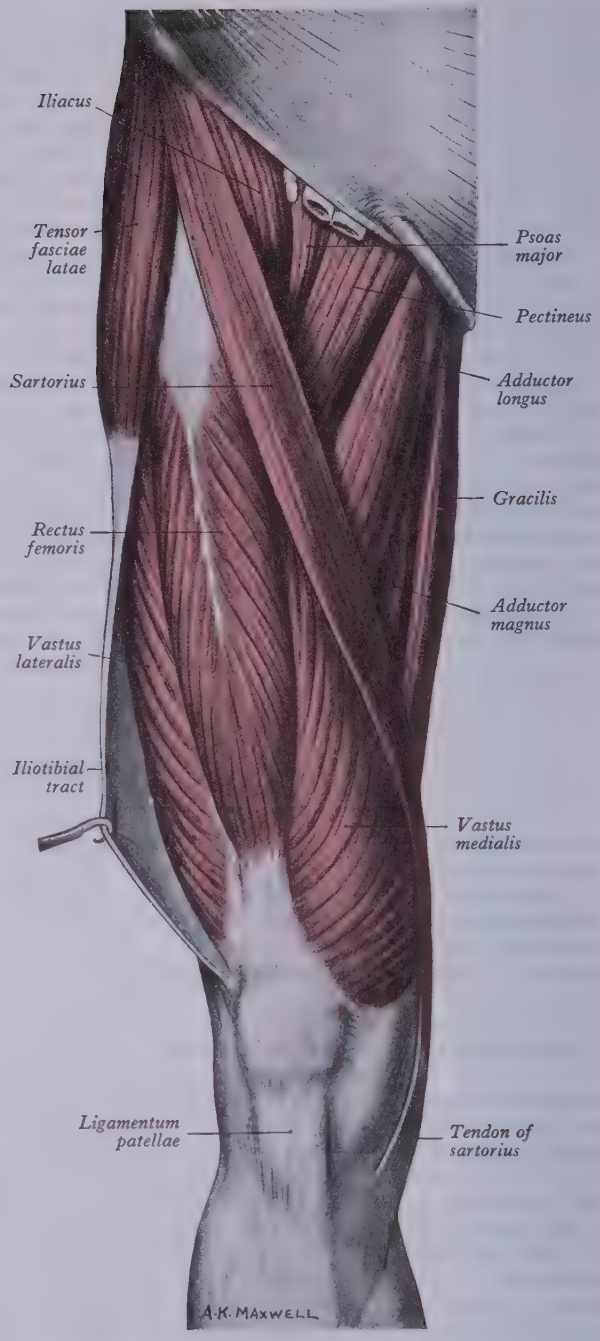
For a general survey consult 5.85A.

1. Muscles of the Iliac Region



These three muscles arise from the lumbar vertebral column (psoas major and minor) and iliac bone (iliacus), and two are attached together as femoral flexors. Psoas minor falls short of this and acts on the vertebral spine and sacro-iliac joints.

Iliac fascia covers the psoas and iliacus; thin above, it gradually thickens towards the inguinal ligament. The *part covering psoas* is thickened above as the *medial arcuate ligament* (p. 592). Medially it is attached by a series of fibrous arches with their intervening columns blending with the intervertebral discs, the margins of adjacent vertebral bodies and to the upper sacrum. Laterally, above the iliac crest, it blends with the fascia on quadratus lumborum (p. 604), below the crest, with the fascia covering the iliacus. The *iliac part* is attached to the inner lip of all the ventral segment of the iliac crest to the pelvic brim, blending with the periosteum, and to the iliopectineal eminence, receiving a slip from the tendon of psoas minor. External iliac vessels are *anterior* to it but branches of the lumbar plexus *posterior*; it is separated from the peritoneum by loose areolar tissue. Lateral to the femoral vessels the fascia is continuous with the posterior margin of both the inguinal ligament and the transversalis fascia. Medially it passes behind the femoral vessels to become the pectineal fascia, attached to the pecten pubis. Between the lateral and medial regions it is attached to the iliopectineal eminence and capsule of the hip joint, forming a septum between the inguinal ligament and the innominate bone and separating the large osteoligamentous interval into a lateral *lacuna musculorum*, containing the psoas major, iliacus and femoral nerve, from a medial *lacuna vasorum*, transmitting the femoral vessels and lymphatics. Distally the fascia becomes the posterior part of the femoral sheath (p. 638).



The segmental values of the nerves to the muscles in the lower limb are those given by Sharrard (1955).

Psoas major (5.85), a long fusiform muscle lateral to the lumbar vertebral column and pelvic brim, arises: (1) from the anterior surfaces and lower borders of all lumbar transverse processes; (2) by five digitations, each from the localized parts of the bodies of adjoining vertebrae and their intervertebral discs, the highest from the lower margin of the twelfth thoracic body and upper margin of the first lumbar and the interposed thoracolumbar disc, the lowest slip from adjacent margins of the fourth and fifth lumbar bodies and their disc; and (3) from the tendinous arches extending across the concave lumbar bodies between, and blended with, the digitations. Lumbar arteries and veins and rami of the sympathetic trunk pass medial to these arches. The upper four *lumbar intervertebral foramina* bear important relations to these two principal 'lines' or planes of superior attachment of the muscle. The foramina lie *anterior* to the transverse processes and *posterior* to the attachments to vertebral bodies, discs and tendinous arches. Thus, the roots of the lumbar plexus directly *enter* the muscle, the plexus is lodged *within it* and its branches *emerge* from its borders and surfaces. The psoas major muscle descends along the pelvic brim, posterior to the centre of the inguinal ligament, anterior to the capsule of the hip joint (over the acetabulum and femoral head), and converges into a tendon which receives laterally almost all the iliacus and is attached to the lesser trochanter. A large subtendinous iliac bursa, occasionally communicating with the hip joint, separates the tendon from the pubis and articular capsule. These complex attachments display minor variations.

Relations: *above*, the superior tip of the psoas is posterior to the diaphragm (i.e. in the posterior mediastinum) and may contact the pleural sac. In the abdomen its *anterolateral surface* is related to the medial arcuate ligament, which is a superior arched thickening in the general psoas fascia, extraperitoneal tissue and peritoneum, kidney, psoas minor, renal vessels, ureter, testicular (or ovarian) vessels and genitofemoral nerve. The right psoas is overlapped by the inferior vena cava and crossed by the terminal ileum; the left is crossed by the colon. *Posterior* are the transverse processes of the lumbar vertebrae and medial edge of the quadratus lumborum. The lumbar plexus is, as noted, embedded posteriorly between the planes of the muscle (p. 1140). *Medial* are the lumbar vertebral bodies and lumbar vessels. Along its *anteromedial margin* it is in contact with a sympathetic trunk, aortic lymph nodes and, along the pelvic brim, the external iliac artery;

5.85A Muscles of the leg (superficial view): (left) anterior aspect; (right) posterior aspect.

5.85B Superficial muscles of the thigh: extensor aspect (from Quain's *Anatomy*, 11th edn).

this anteromedial margin is, as noted, covered by the inferior vena cava on the right, whereas on the left it is posterolateral to the abdominal aorta. In the thigh the fascia lata and femoral artery are *in front; behind* is the capsule of the hip joint separated by a bursa; at its *medial border* are the pectineus, medial circumflex femoral artery and the femoral vein, which may overlap it slightly; at its *lateral border* are the femoral nerve and iliacus; the nerve descends at first through its fibres, then between it and the iliacus.

As indicated, branches of the lumbar plexus diverge from the abdominal part of the psoas. From the lateral border of the psoas emerge, from above downwards: the iliohypogastric, ilio-inguinal and lateral femoral cutaneous and femoral nerves; from the anterolateral surface, the genitofemoral nerve; from the medial border, the obturator and accessory obturator nerves and the upper root of the lumbosacral trunk.

Nerve supply: the ventral rami of the lumbar spinal nerves, L.**1, 2** and 3.

Actions: the psoas major acts largely with the iliacus (vide infra).

The **psoas minor** lies anterior to the psoas major and is confined to the abdomen; it arises from the sides of the twelfth thoracic and first lumbar vertebral bodies and the disc between them. It ends in a long, flat tendon attached to the pecten pubis, iliopectineal eminence and iliac fascia. It is absent in about 40% of subjects.

Nerve supply: a branch from the first lumbar spinal nerve.

Action. It is probably a weak flexor of the trunk.

Iliacus (5.85) is a triangular sheet of muscle attached to the superior two-thirds of the iliac fossa, inner lip of iliac crest, ventral sacro-iliac and iliolumbar ligaments, and upper surface of the sacral ala (3.43); this attachment reaches the anterior superior and inferior iliac spines, receiving a few fibres from the capsule of the hip joint. Most of the muscle converges into the lateral side of its conjoined strong tendon with psoas major, and together they are attached to the lesser trochanter, but some iliac fibres are attached directly to the femur for about 2.5 cm antero-inferior to this.

Relations. In the abdomen, *anterior* are the iliac fascia, separating it from extraperitoneal tissue and the peritoneum and lateral femoral cutaneous nerve; on the right, the caecum, on the left, the iliac part of the descending colon; *posterior* is the iliac fossa; *medial* are the psoas major and femoral nerve. In the thigh, its *anterior surface* is in contact with the fascia lata, rectus femoris, sartorius and arteria profunda femoris, its *posterior surface* with the capsule of the hip joint, a bursa common to it and with psoas major interposed.

Nerve supply: branches of the femoral nerve, L.**2** and 3.

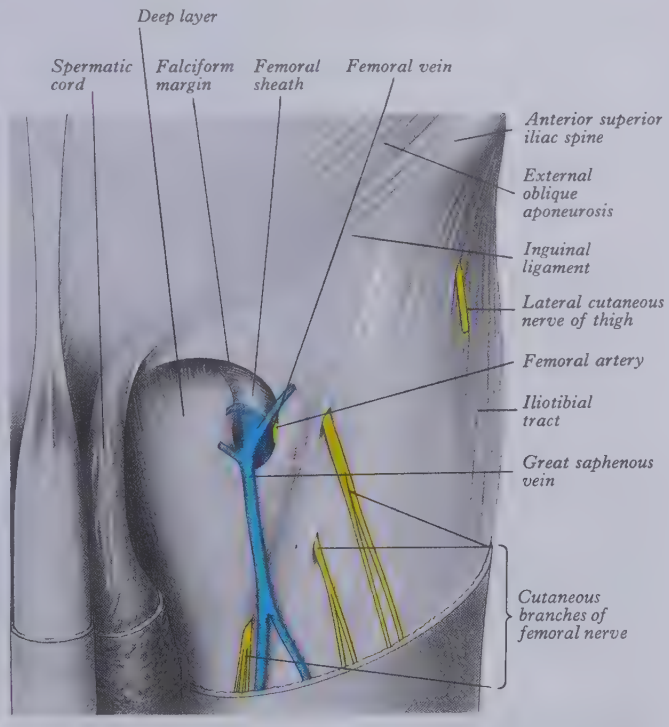
Actions. Acting from above, the psoas major flexes the thigh on the pelvis, assisted by the iliacus. Electromyography does not support the common view that psoas major is a medial rotator at

the hip joint, but it *is* active in *lateral* rotation, particularly in the young, a view supported by dissections in infants (McKibbin 1968). Conflicting views expressed for many years demand further investigation. When the psoas major and iliacus act from below, they are powerful vertebral flexors against resistance, as in raising the trunk from the recumbent posture. Geometrical reasoning suggests that, with the body erect and lower limb fixed, the psoas major might flex the trunk anterolaterally; but electromyography does not support this, indicating maximum activity when the lumbar curvature is increased. However, direct recording during operations suggests that in addition to being a hip flexor, the muscle is active in balancing the trunk in sitting (Keagy et al 1966).

In symmetrical standing recordings from iliopsoas vary from electrical silence to *slight* intermittent or continuous activity, perhaps reflecting differences between individuals and the techniques of investigation. But most are agreed that the low level of activity correlates with the fact that the line of body weight is behind the transverse coxal axis and that hip joints are near their close-packed position, with spiralization of the ligaments (especially iliofemoral) and marked compression and congruence of articular surfaces, these passive forces largely counterbalancing extending torque of the body weight. However, prolonged symmetrical standing is rare (in non-military personnel).

Applied Anatomy. When the femoral neck is fractured the psoas major acts as a lateral rotator, accounting for the characteristic posture of the lower limb. Occasionally pus from disease of the thoracic and lumbar vertebrae tracks into the thigh within the muscle's fascial sheath, but this is quite uncommon with the use of modern therapeutics.

2. Muscles of Femoral and Gluteal Regions



Muscles of the thigh and hip could be divided into flexors and extensors; but due to rotation of the limb into a new working position in land vertebrates (p. 398), the primitive dorsal, extensor surface of the thigh has become anterior; the original ventral aspect containing the flexor muscles is now posterior. This has not affected the 'girdle' muscles; iliopsoas, a flexor already described, is still ventral and the gluteal muscles, primitive extensors, have remained dorsal. Moreover, development of multiaxial function at the hip has been coupled with the appearance of adductors and abductors, the joint becoming surrounded by muscle forces capable of moving the femur in any direction or maintaining static postures, especially the erect position. These activities are complicated by gravity, aiding some movements, opposing others. Hence muscle groups are unequal in power.

(a) Anterior Femoral Muscles

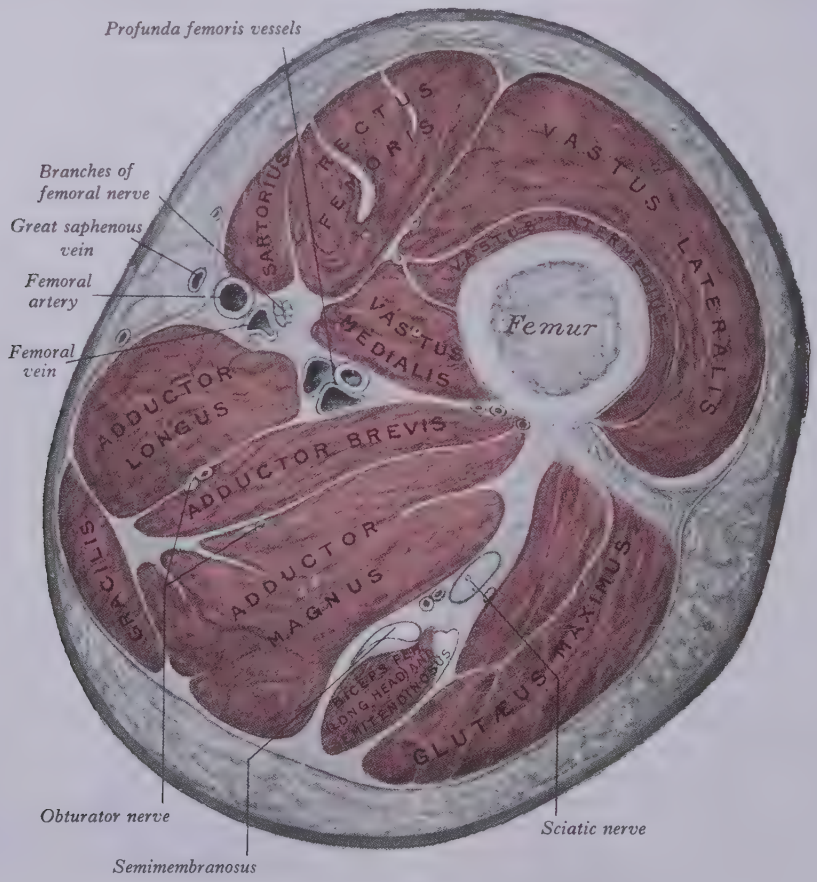
Included in this group (5.85B) are the tensor fasciae latae, sartorius and rectus femoris, all acting on hip and knee joints, and vasti medialis, lateralis, and intermedius acting only at the knee. The articularis genus, a derivative of vastus intermedius, completes the group. Rectus femoris and the vasti extend the knee by a common tendon and are hence grouped as *quadriceps femoris*.

The **superficial fascia** of the thigh is loose areolar tissue containing variable amounts of fat and in some regions, particularly near the inguinal ligament, it splits into recognizable layers, between which ramify superficial vessels and nerves. In the inguinal region it is thick and between its two layers are superficial inguinal lymph nodes, the great saphenous vein and smaller vessels. The *superficial* layer is continuous with that of the abdominal wall; the *deep* layer, a thin fibro-elastic stratum, is best differentiated medial to the great saphenous vein and inferior to the inguinal ligament, extending between subcutaneous vessels and nerves and the deep fascia, with which it fuses distal to the ligament. (This line of fusion lies in the floor of the *ventral flexure line* or *groove* associated with the hip joint.) The membranous fibro-elastic fascia completes the saphenous opening, blending with its spiral circumference and the femoral sheath (p. 781). Over the opening it is perforated by the great saphenous vein and other vessels, hence the term *cribriform fascia*. Anterior to the patella the superficial fascia contains a subcutaneous prepatellar bursa.

The **fascia lata,** the **deep fascia** of the region, is thicker in proximal and lateral parts of the thigh where tensor fasciae latae and an expansion from gluteus maximus fuse with it. It is thin posteriorly and over adductor muscles but thicker around the knee, strengthened by expansions from the tendon of biceps femoris laterally, the sartorius medially and the quadriceps femoris in front. The fascia lata is attached proximally to the back of the sacrum and coccyx, the iliac crest, inguinal ligament, superior and inferior pubic rami, the ischial ramus and tuberosity and the lower border of the sacrotuberus ligament. From the iliac crest it descends densely over gluteus medius to the upper border of gluteus maximus, splitting into two layers, superficial and deep to this muscle; at its lower border they reunite. Over the lateral femoral aspect fascia lata is compacted into a strong *iliotibial tract*, which splits at its proximal end, where tensor fasciae latae is attached to and enclosed in it, and posteriorly where it receives most of the tendon of gluteus maximus. The superficial layer ascends lateral to tensor fasciae latae to the iliac crest, the deeper ascends medially, deep to the muscle, to blend with the capsule of the hip joint. Distally, the iliotibial tract is attached to a smooth, triangular, anterolateral facet on the lateral tibial condyle, superficial to and blended with an aponeurotic expansion from vastus lateralis. It makes a subcutaneous visible ridge on the anterolateral aspect of the knee, when it is *extended* (Kaplan 1958). Distally the fascia lata is attached to all exposed bony points around the knee, such as the condyles of the femur and tibia and fibular head. These remarks apply particularly to the iliotibial tract (Evans 1977). On each side of the patella, the deep fascia is reinforced by transverse fibres from the vasti, which are thus attached to it; the lateral fibres are continuous with the iliotibial tract. The fascia lata is continuous with two powerful intermuscular septa, attached to the whole linea aspera and its prolongations; the lateral, stronger septum, extending from the attachment of gluteus maximus to the lateral condyle, is between vastus lateralis in front and the short head of biceps femoris behind, providing partial attachment for them; the medial, thinner septum is between the vastus medialis and the adductors and pectineus. Smaller septa pass between individual muscles ensheathing them and sometimes providing attachments.

5.86 The left saphenous opening, after the removal of the cribriform fascia. Note the superficial and deep layers of the deep fascia (see text).

Evans (1977) has emphasized the ligamentous nature of the iliotibial tract, regarding it as more substantial than appears necessary for tensor fasciae latae and gluteus maximus. He regards it as a ligament between ilium and tibia, intimately concerned in the standing posture (Evans 1983) (vide infra). This, however, appears to disregard the attachment of these muscles to substantial lengths of the femur through the iliotibial tract and its deep extension, the strong lateral intermuscular septum.



The saphenous opening (5.86) is in the deep fascia lateral and a little distal to the medial part of the inguinal ligament; through it pass the great saphenous vein and other vessels. (Its approximate 'centre' is, in adults, deep to a point 3 cm inferior and lateral to the pubic tubercle.) The cribriform fascia, pierced by these vessels, fills the aperture and must be removed to reveal it. The fascia lata in this region displays the superficial and deep parts (not to be confused with the layers of superficial fascia described above). The *superficial stratum*, lateral to the saphenous opening, is attached to the iliac crest and anterior superior iliac spine, inguinal ligament and pecten pubis (with the lacunar ligament) (p. 596). From the pubic tubercle it turns inferolaterally as an arched *falciform margin*, forming the superior, lateral and inferior boundaries of the saphenous opening (5.86), and is adherent to the anterior aspect of the femoral sheath; the cribriform fascia is attached to it. This margin is described as having *superior* and *inferior cornua*, the latter well defined and continuous behind the great saphenous vein with the *deep stratum* of the fascia lata, which is medial to the saphenous opening and continuous with the superficial stratum at its lower margin. It ascends over the pectineus, adductor longus and gracilis, passes *behind* the femoral sheath and then, united to it, continues to the pecten pubis. The superficial and deep strata are respectively anterior and posterior to the femoral sheath; the saphenous opening, is somewhat spiral and formed by their continuity. The opening varies much, its height from 1.5–8 or 9 cm, its width from 1–3 or 4 cm. Adjacent *subsidiary openings* may occur, transmitting venous tributaries, but are more often in the floor of the fossa.

The **tensor fasciae latae** (5.85) is attached to the anterior 5 cm of outer lip of the iliac crest, to the lateral aspect of the anterior superior iliac spine and part of the notch below it between gluteus medius and sartorius, and to the deep surface of the fascia lata. It descends between, and is attached to, the layers of the iliotibial tract and blends with it near the junction of the middle and upper thirds of the thigh; but the belly is variable in length and some of its fibres may, like the tract, even reach the lateral femoral condyle. Its proximal attachment may spread to the aponeurosis superficial to gluteus medius.

Nerve supply: superior gluteal nerve, L.4 and 5.

Actions. Acting through the iliotibial tract the muscle extends the knee with lateral rotation of the leg; it may assist in abduction and medial rotation of the thigh, but its abductor role has been denied (Kaplan 1958). In erect posture, acting from below, it helps to steady the pelvis on the head of the femur. Through the tract it steadies the femoral on the tibial condyles. When the thigh flexes against gravity, with the knee extended, an angular depression appears distal to the anterior superior iliac spine; its lateral boundary is the tensor fasciae latae, active in flexion. The muscle aids gluteus medius in postural abduction at the hip (p. 642). Kaplan (1958) and Evans (1977) regard the iliotibial tract as more effective in ligamentous steadying of the pelvis than the muscle control mediated (but vide supra, and p. 637).

Sartorius (5.85,87,89), a narrow strap muscle (and incidentally the longest in the body) arises by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it, crosses the thigh obliquely to its medial side and descends more vertically medial to the knee, where a thin, flat tendon replaces the muscle fibres and curves obliquely forwards, expanding into a broad aponeurosis attached in front of gracilis and semitendinosus to the medial tibial surface (5.98). The proximal part of this aponeurosis curves back over the proximal, curved edge of the preterminal tendon of gracilis to attach behind it. A slip from its upper margin blends with the articular capsule and another, from its distal border, with medial fascia of the leg. The muscle

5.87 Transverse section through the right thigh at the level of the apex of the femoral triangle: proximal (superior) aspect.

varies little but is sometimes bicipital at its proximal end, the extra head being attached to the pectineal line or femoral sheath; it is occasionally absent.

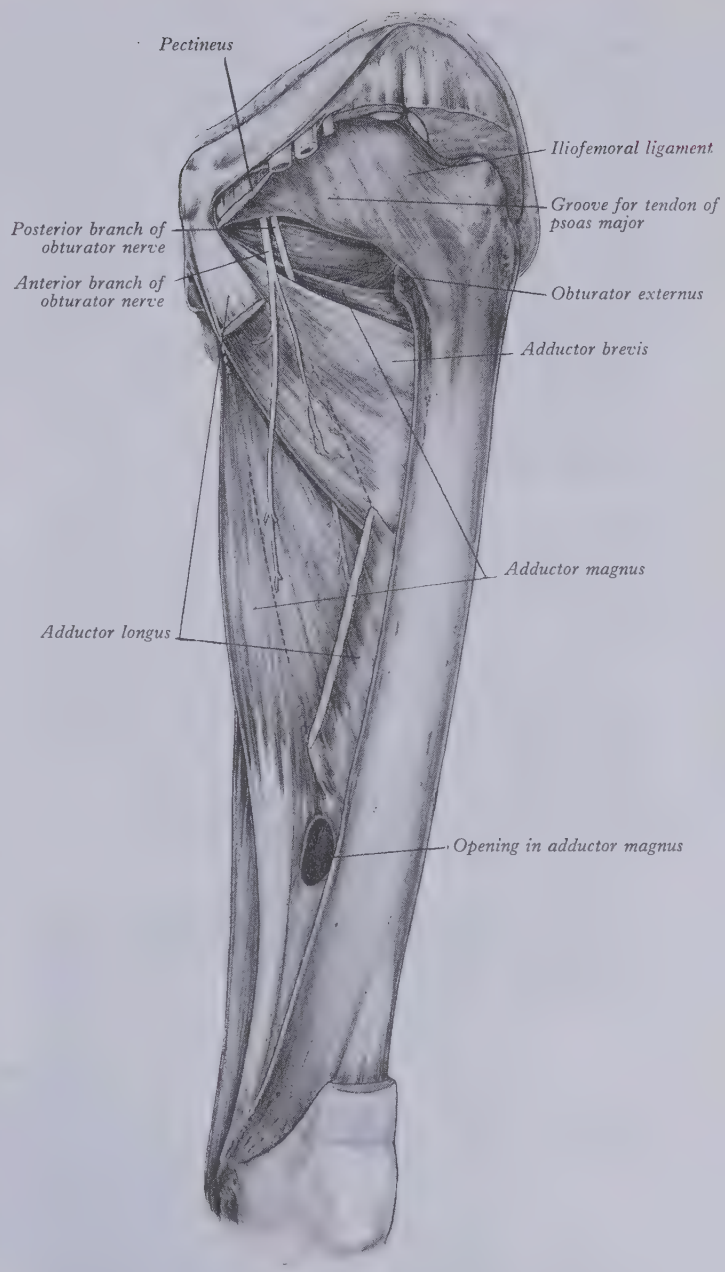
Relations. In the thigh's proximal third the muscle's medial border is the lateral edge of the *femoral triangle*, the medial being the medial border of adductor longus, and its base the inguinal ligament. The femoral artery descends from the centre of the base to the apex of the triangle. In the thigh's middle third the femoral artery is in the adductor (subsartorial) canal, with a stratum of deep fascia and sartorius anterior to it (5.89). This strong fascial layer bridges the interval between adductors and quadriceps; it must be incised to expose the vessels. (For the changing mutual relationships of femoral artery and veins see pp. 782, 814.)

Nerve supply: femoral nerve, L.2 and 3.

Actions. Sartorius assists in flexing the leg at the knee and the thigh on the pelvis, particularly when these movements are combined. It also helps to abduct the thigh and rotate it laterally. These movements, combined with inversion of the foot, bring its sole into direct view. Acting against gravity, as it usually is, the muscle can be seen and felt.

Quadriceps femoris (5.85,87,89), the great extensor of the leg, covers almost all the front and sides of the femur. It can be divided into four parts: one in the middle of the thigh, arising from the ilium, named from its straight course, *rectus femoris*; the other three are attached to the femoral shaft, which they surround, apart from the linea aspera, from trochanters to condyles; lateral is *vastus lateralis*, medial is *vastus medialis* and between them *vastus intermedius*.

Rectus femoris (5.85,87,89) is fusiform, its superficial fibres bipennate, the deep parallel. Its straight tendinous head is attached to the anterior inferior iliac spine and by a reflected tendon to a groove above the acetabulum and the fibrous capsule of the hip joint. These tendons unite at an acute angle and spread as an aponeurosis prolonged distally on the muscle's *anterior* aspect; from this the muscular fibres extend to a broad aponeurosis on the *posterior* aspect of its distal two-thirds, tapering to a flattened tendon attached to the base of the patella as the *superficial central* part of the tendon of quadriceps.



Vastus lateralis (5.85,87,89), the largest component of quadriceps femoris is attached by a broad aponeurosis to the intertrochanteric line, the anterior and inferior borders of the greater trochanter, lateral lip of gluteal tuberosity, and proximal half of the lateral lip of linea aspera (3.185,5.89). This aponeurosis covers the muscle's proximal three-quarters; from its deep aponeurotic surface many additional fibres arise, a few also from both the tendon of gluteus maximus and the lateral intermuscular septum, between vastus lateralis and the short head of biceps femoris. This mass is attached to a strong aponeurosis on the deep aspect of the muscle's distal part; this narrows to a flat tendon, attached to the patella's base and lateral border, blending in the compound tendon of quadriceps (vide infra). It gives to the knee joint's capsule an expansion descending to the lateral tibial condyle and blending with the iliotibial tract.

Vasti medialis and intermedius appear united but when rectus femoris is displaced a cleft appears ascending from the medial patellar border between them, sometimes as far as the lower part of the intertrochanteric line, where they often fuse.

Vastus medialis (5.85,87,89) is attached to the distal part of the intertrochanteric line, spiral line, medial lip of the linea aspera, proximal part of the medial supracondylar line, tendons of adductor longus and magnus and the medial intermuscular septum (p. 637). Its fibres descend forwards mainly to an aponeurosis on the muscle's deep surface which reaches the medial patellar border and tendon of quadriceps (vide infra). An expansion reinforces the knee joint's capsule attached below to the medial tibial condyle. Most distal fibres are almost horizontal, bulging superficially superomedial to the patella.

Vastus intermedius (5.87,89) is attached to the proximal two-thirds of the anterior and lateral surfaces of the femoral shaft and distal part of the lateral intermuscular septum. Its fibres end in an anterior aponeurosis which forms the *deep part* of the tendon of quadriceps, attached to both the lateral patellar border and the lateral tibial condyle.

Tendons of the four components of quadriceps unite distally as a strong tendon attached to the patellar base, some fibres continuing over this into the ligamentum patellae. The patella is a sesamoid bone in the tendon; the 'ligamentum' patellae, extending from the patellar apex to the tibial tubercle, is the continuation of this tendon, medial and lateral *patellar retinacula* (p. 527) being expansions from its borders. The supra-patellar bursa (a synovial extension of the knee joint) is between the femur and suprapatellar part of the tendon; the deep infrapatellar bursa is between the ligamentum patellae and proximal end of the tibia (4.75). Quadriceps varies little; rectus femoris may arise from the anterior *superior* iliac spine and its reflected head may be absent.

5.88 The adductor muscles of the left thigh: anterior aspect. Most of the adductor longus has been excised; dashed lines indicate its borders.

Articularis genus, a small muscle, usually distinct from vastus intermedius but sometimes blended with it, consists of several muscular bundles arising from the distal anterior surface of the femoral shaft and attached to a proximal reflexion of the synovial membrane of the knee joint (DiDio et al 1967).

Nerve supply: femoral nerve, L.2, 3 and 4.

Actions. The whole muscle extends the knee. Rectus femoris also helps to flex the thigh or, if the thigh is fixed, to flex the pelvis. It is remarkably quiescent in standing (Joseph & Williams 1957).

Rectus femoris may flex the hip and extend the knee simultaneously. The lower fibres of vastus medialis contract late in genual extension to retain the patella in its groove, counteracting its tendency to lateral displacement, due to lateral inclination of the long axis of the thigh relative to that of the leg (Lieb & Perry 1968). The lower fibres of vasti medialis and lateralis may be involved in stabilizing the knee. Electromyography indicates that the vasti are not equally or synchronously active in different phases of extension or rotation, but this awaits confirmation. The muscle's complex architecture offers a wide field for myokinetic analysis; perhaps its complexity explains the paucity of information.

Articularis genus retracts the synovial supra-patellar 'bursa' during extension, presumably preventing the interposition of synovial folds between the patella and femur (cf articularis cubiti, p. 616).

(b) Medial Femoral Muscles

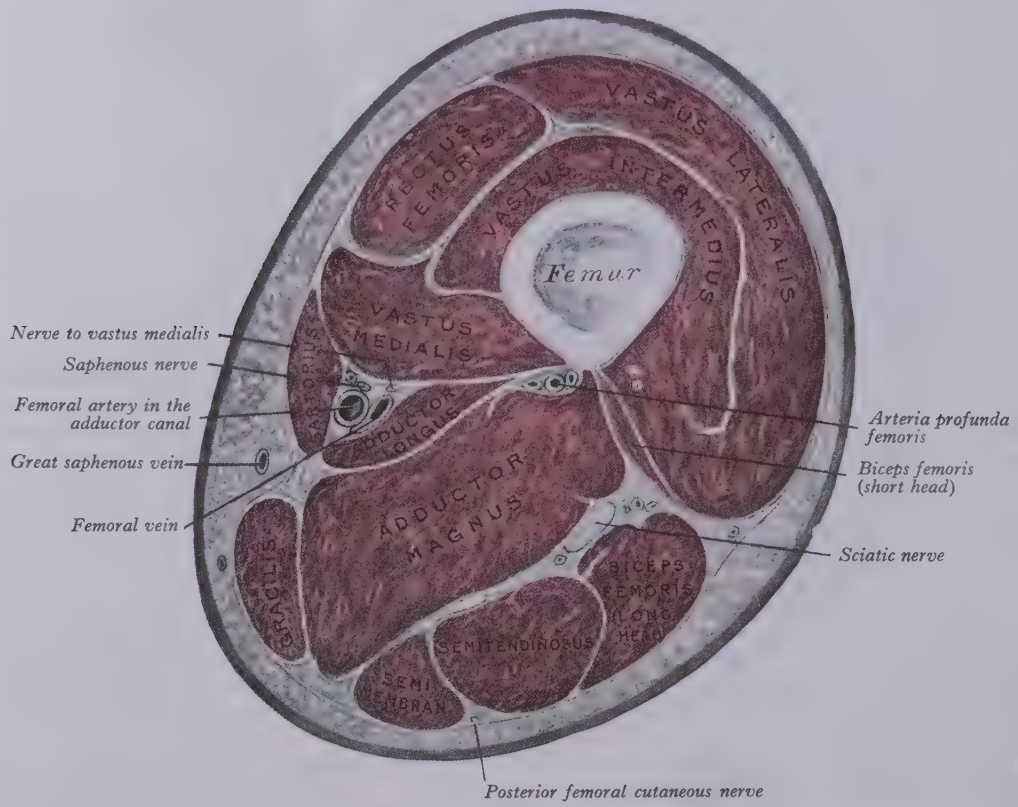
This group is derived, as the nerve supply suggests, from both the flexors and extensors between which it lies. All five muscles, gracilis, pectineus and adductores longus, brevis and magnus, cross the hip joint; only gracilis descends beyond the knee. Often named adductors of the thigh, they are more complex than this.

Gracilis (5.85,87,89), the most superficial, is thin and flat, proximally broad, distally narrow and tapering. Attached proximally by a thin aponeurosis from the medial margins of the lower half of the body of the pubis, the inferior pubic ramus and adjoining part of the ischial ramus (3.171), it descends vertically to a rounded tendon crossing the medial femoral condyle posterior to the tendon of sartorius; it curves round the medial tibial condyle and fans out proximally on the tibial medial metaphysial surface, just distal to its condyle. A few distal fibres continue into the crural deep fascia. The attachment is immediately proximal to that of semitendinosus, its upper edge overlapped by the tendon of sartorius, with which it is partly blended. It is separated from the tibial collateral genual ligament by a tibial intertendinous bursa (p. 530).

Nerve supply: obturator nerve, L.2 and 3.

Actions. Gracilis flexes the leg and rotates it medially; it may also act as a femoral adductor.

Pectineus (5.85), a flat, quadrangular muscle in the femoral triangle, arises from the pecten pubis and the bone in front of it between the iliopectineal eminence and pubic tubercle and from the fascia on its anterior surface; it descends, posterolaterally, to a line from the lesser trochanter to the linea aspera. It may be bilaminar, as in other mammals, layers receiving separate nerve supplies (vide infra). Proximally it may be partially or wholly attached to the coxal capsule.



Relations. *Anterior* is the fascia lata, separating the muscle from the femoral vessels and great saphenous vein; *posterior* are the coxal capsule, adductor brevis, obturator externus and anterior branch of the obturator nerve; *lateral* are the psoas major and medial circumflex femoral vessels; *medial* is the lateral margin of adductor longus.

Nerve supply. Pectineus is supplied by the femoral nerve, L.2 and 3; and the accessory obturator, L.3, when present, occasionally by a branch from the obturator nerve. It may be partly divided into dorsal and ventral strata, supplied respectively by the obturator and femoral (or accessory obturator) nerves. In a total of 800 cases, only 69 displayed a partial supply by an accessory obturator nerve (Woodburne 1960).

Actions: adduction of the thigh; flexion of the pelvis.

Adductor longus (5.88,89), the most anterior adductor, is triangular and in the plane of the pectineus. It has a flat, narrow tendon (but sometimes C-shaped in section) attached to the pubic body, in the angle between the pubic crest and the sheath enclosing rectus abdominis and pyramidalis lateral to the symphysis. This expands to a broad belly, descending posterolaterally to an aponeurosis attached to the linea aspera in the middle femoral third between the vastus medialis and adductores magnus and brevis, usually blending with each. It is occasionally double.

Relations. *Anterior* are the spermatic cord and fascia lata, separating it from the great saphenous vein and distally femoral vessels and sartorius. *Posterior* are the adductores brevis and magnus, the anterior branch of the obturator nerve and distally the profunda femoris vessels. *Lateral* is pectineus, *medial* is gracilis.

640 5.89 Transverse section through the middle of the right thigh: proximal (superior) aspect.

Nerve supply: the anterior division of the obturator nerve, L.2, 3 and 4.

Adductor brevis (5.87,88), posterior to pectineus and adductor longus, is also somewhat triangular (but truncated proximally) with a narrow linear (horizontal) attachment to the external aspect of the pubic body and its inferior ramus between gracilis and obturator externus, descending posterolaterally to a vertical aponeurosis attached to the femur along a line from the lesser trochanter to the linea aspera and to the proximal part of the line behind pectineus and adductor longus. It often has two or three parts or may be integrated into the adductor magnus.

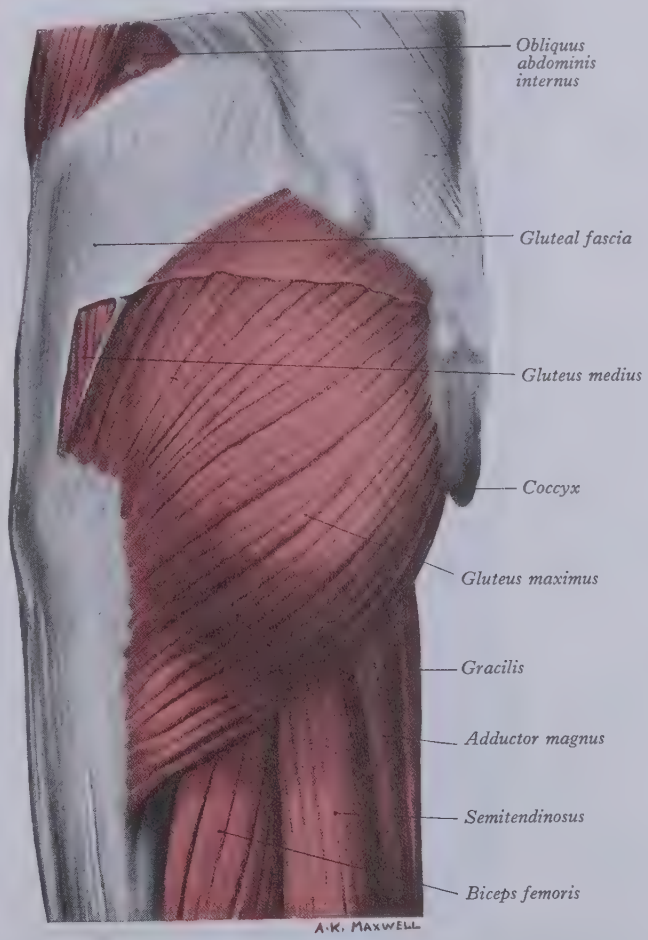
Relations. *Anterior* are pectineus, adductor longus, arteria profunda femoris and the anterior branch of the obturator nerve; *posterior* are adductor magnus and the posterior branch of the obturator nerve; at the muscle's *proximal border* are the medial circumflex femoral artery, obturator externus, and the conjoined tendon of psoas major and iliacus; at its *distal border* are gracilis and adductor magnus. Near its femoral attachment the second and sometimes first perforating arteries pierce it.

Adductor magnus (5.87,88,89), a massive triangular muscle, starts from a small part of the inferior pubic ramus, the conjoined ischial ramus, and the inferolateral aspect of the ischial tuberosity. Fibres from the pubic ramus are short, *horizontal* and attached to the medial margin of the gluteal tuberosity, medial to gluteus maximus; this part, anterior to the rest, is sometimes termed the *adductor minimus*. Fibres from the ischial ramus fan out inferolaterally to a broad aponeurosis attached to the linea aspera and proximal part of the medial supracondylar line. The muscle's medial part, mainly fibres from the ischial tuberosity, is a thick mass descending *almost vertically* to a rounded tendon in the distal third of the thigh, which is palpable proximal to its attachment to the adductor tubercle (p. 438) on the medial femoral condyle. This tendon is connected by a fibrous expansion to the medial supracondylar line. This long attachment is interrupted by osseo-aponeurotic openings, bridged by *tendinous arches* attached to the bone. The proximal four are small and transmit perforating branches and the termination of arteria profunda femoris; the distal one is large and admits the femoral vessels to the popliteal fossa. The muscle's vertical, ischiocondylar part is variably separate. The proximal border may be fused with quadratus femoris.

Relations. *Anterior* are pectineus, the adductores brevis and longus, femoral and profunda vessels and the posterior branch of the obturator nerve; a bursa separates the proximal part of the muscle from the lesser trochanter. *Posterior* are the sciatic nerve, gluteus maximus, biceps femoris, semitendinosus and semimembranosus. The *proximal border* is parallel with quadratus femoris, the transverse branch of the medial circumflex femoral artery passing between them. The *medial border* is related to gracilis, sartorius and the fascia lata.

Nerve supply. The adductor magnus is *composite* and doubly innervated by the obturator nerve and by the tibial division of the sciatic, L.2, 3 and 4. The latter supplies the ischiocondylar part. Both nerves are from *anterior* divisions of the lumbosacral plexus, indicating a primitive 'flexor' origin for both parts.

Actions. Extensive or forcible femoral adduction is not a common action and, though adductors can so act when required, they are more commonly synergists in the complex patterns of gait and partly controllers of posture. They are active in flexion and extension of the *knee* (Janda & Stara 1965). Magnus and longus are probably *medial* rotators of the thigh, according to de Sousa & Vitti (1966), who also observed that, while adductors are *inactive* during adduction of the *abducted* thigh in erect posture (where gravity assists), they *are* active in the supine position, or during adduction of the flexed thigh in standing. Adductors are also active at the *hip joint* during flexion (longus) and extension (magnus). In symmetrical easy standing their activity is minimal.



(c) Muscles of the Gluteal Region

Glutei maximus, medius and minimus (5.90,91) are extensors and abductors at the hip joint; a deeper group of smaller muscles, lateral rotators, includes piriformis, obturatores internus and externus, gemelli superior and inferior and quadratus femoris. (These actions are, however, enhanced, diminished or altered when the thigh is in different *initial positions*.)

Gluteus maximus (5.90), largest and superficial, is a broad, thick quadrilateral mass, forming with thick superficial adipose fascia the familiar buttock. (However, the borders and extent of the muscle do *not* correspond with those of the adipose tissue; vide infra.) The large size of gluteus maximus is a special feature of the human hip, associated with bringing and keeping the trunk upright. It is coarsely fascicular, its fibres in large bundles separated by fibrous septa. It is attached to the ilium's posterior gluteal line and to the rough bone (including the crest) posterosuperior to it, to the aponeurosis of erector spinae, dorsal surface of lower sacrum and side of the coccyx, sacrotuberous ligament, and fascia (gluteal aponeurosis) covering gluteus medius. Its fasciculi *descend laterally*, the upper, larger part and a distal superficial stratum ending in a tendinous lamina lateral to the greater trochanter and continued into the iliotibial tract. Its deeper distal stratum is attached to the femoral gluteal tuberosity between the vastus lateralis and adductor magnus.

A large, usually multilocular *trochanteric bursa of gluteus maximus* separates it from the greater trochanter; a *gluteofemoral bursa* is between its tendon and that of vastus lateralis; an *ischial bursa of gluteus maximus*, often absent, separates it from the ischial tuberosity. Additional slips from the lumbar aponeurosis or ischial tuberosity occur. The muscle may be bilaminar.

Relations. *Superficial*: a thin deep fascia and overlying thick adipose subcutaneous tissue; *deep*: ilium, sacrum, coccyx and sacrotuberous ligament, gluteus medius, piriformis, gemelli, obturator internus, quadratus femoris, ischial tuberosity, greater trochanter, attachments of biceps femoris, semitendinosus, semimembranosus and adductor magnus. The superior gluteal artery (superficial part) passes deep to the gluteus maximus

5.90 The left gluteus maximus. Some of the gluteal fascia has been removed to expose part of the gluteus medius.

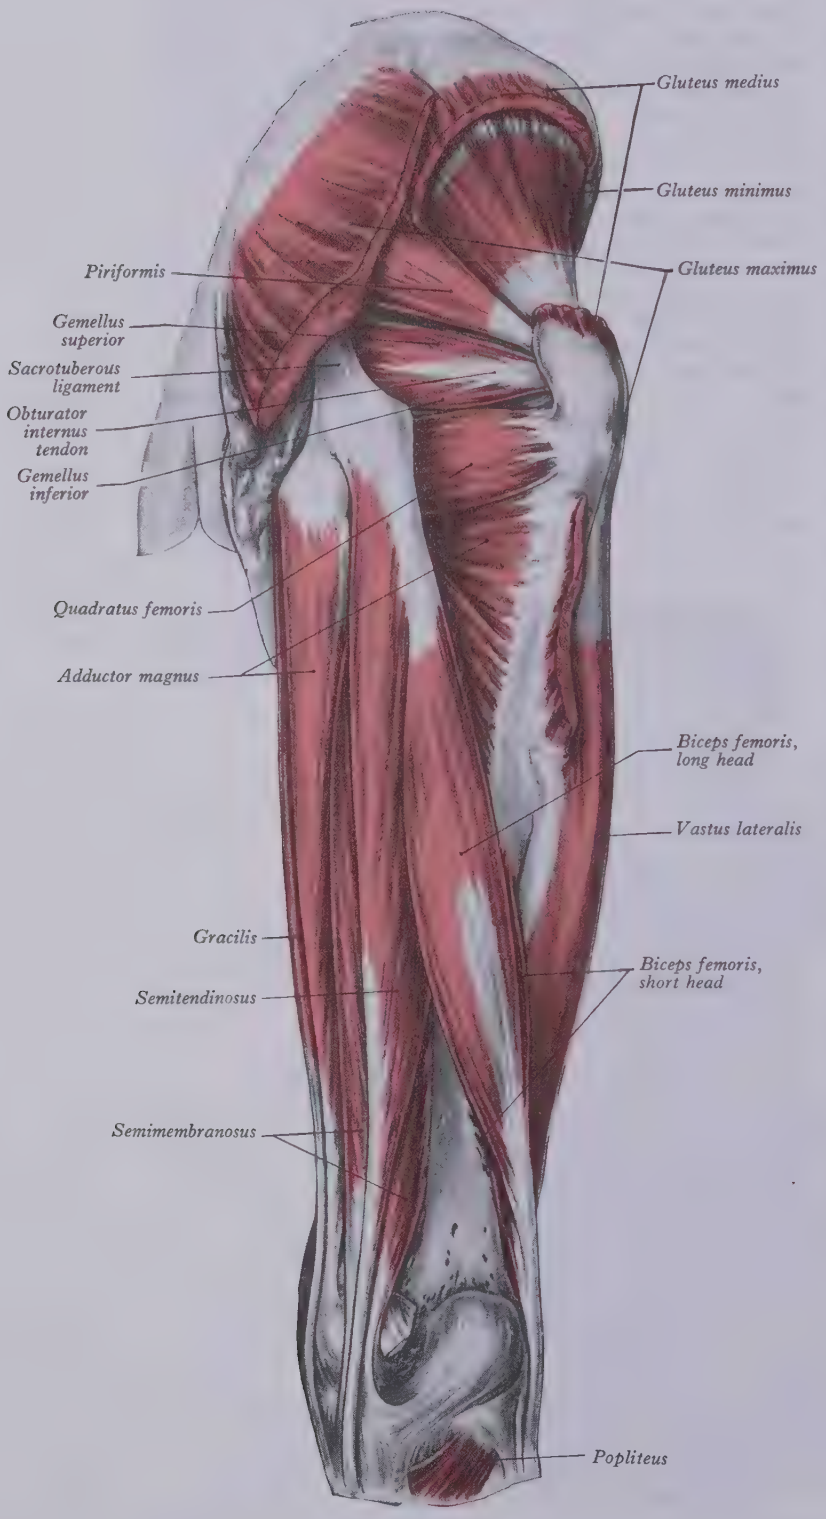
between the piriformis and gluteus medius; the inferior gluteal and internal pudendal vessels, sciatic, pudendal and posterior femoral cutaneous nerves and muscular branches from the sacral plexus leave the pelvis below the piriformis. The first perforating artery and terminal branches of the medial circumflex femoral are deep to the lower part of gluteus maximus, whose thin oblique *proximal border* is superficial to gluteus medius. Its prominent *distal border*, sloping down and laterally, is *crossed* by the *horizontal gluteal fold* (the *posterior flexure line* of the hip joint), the latter marking the site of condensed fascial adhesion and indicating the junction of the thigh and the buttock (5.39). (The *anterior flexure line* corresponds to the fusion between the membranous superficial fascia and the deep fascia distal to the inguinal ligament.)

Nerve supply: inferior gluteal nerve, L.5 and S.1 and 2. Menning et al (1974) have detailed intramuscular distribution.

Actions. Acting from the pelvis, gluteus maximus extends the flexed thigh in line with the trunk. From its distal attachments it may prevent forward momentum of the trunk flexing at the supporting hip during bipedal gait. It is inactive in standing, forward swaying, and downward bending at the hip. With femoral flexors, however, it raises the trunk from stooping, rotating the pelvis back on the femoral head (Joseph & Williams 1957). It is intermittently active in the walking cycle and in climbing, continuously so in strong lateral rotation. Its upper fibres are involved in powerful abduction; it tenses the fascia lata, stabilizing the femur on the tibia, when the femoral extensors of the knee relax.

Gluteus medius is a broad, thick muscle; its posterior third is deep to gluteus maximus and it is covered in its anterior two-thirds only by deep fascia (5.90). Attached to the external iliac surface between the iliac crest and the posterior gluteal line above, the anterior gluteal line below and to deep fascia superficial to its upper part, it converges to a flat tendon, attached below to a ridge slanting down and forwards on the lateral aspect of the greater trochanter; but it is separated anterosuperiorly from the bone by a *trochanteric bursa of gluteus medius*. A deep slip of the muscle may be attached on the upper border of the trochanter; the muscle is sometimes blended posteriorly with the piriformis.

Gluteus minimus (5.91), smallest of the group and deep to medius, is fan-shaped, attached above to the ilium between the anterior and inferior gluteal lines and behind from the margin of the greater sciatic notch; it converges below to the deep surface of an aponeurosis tapering to a tendon attached to an anterolateral ridge on the greater trochanter, with an expansion to the coxal capsule. A *trochanteric bursa of gluteus minimus* separates the tendon from the medial part of the anterior trochanteric surface. The muscle may show anterior and posterior parts. Separate slips may pass to the piriformis, gemellus superior or vastus lateralis.



Relations. Between the gluteus medius and minimus are deep branches of the superior gluteal vessels and nerve. The reflected tendon of rectus femoris and the articular capsule are deep to the minimus.

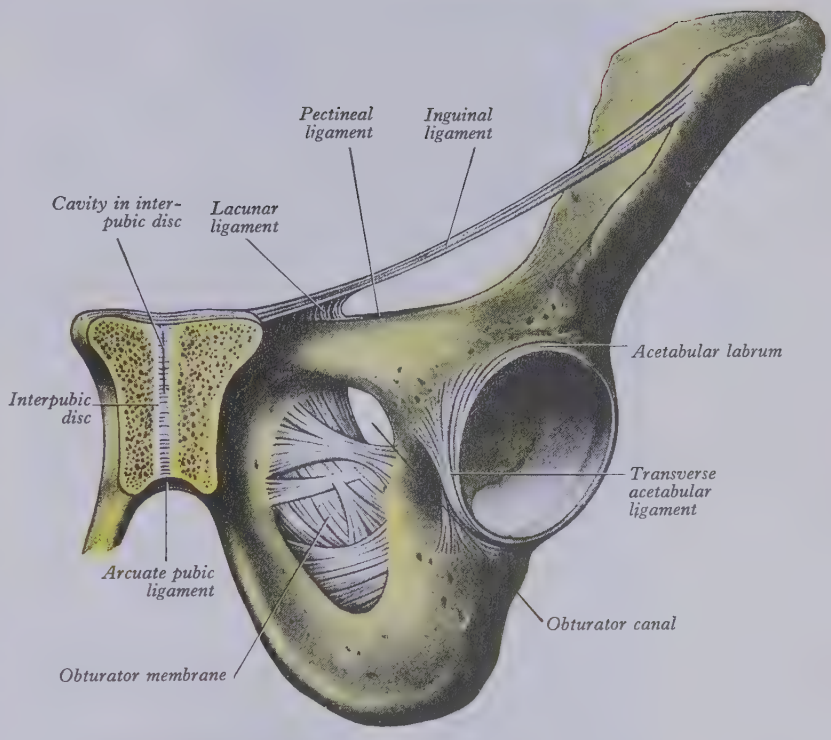
Nerve supply. Gluteus medius and minimus are supplied by the superior gluteal nerve, L.5 and S.1.

Actions. Gluteus medius and minimus, acting from the pelvis, abduct the thigh, their anterior fibres rotating it medially. They are essential for keeping the trunk upright when the opposite foot is raised in walking and running, the body weight tending to depress the pelvis on the unsupported side unless counteracted by the gluteus medius and minimus of the supporting limb. They exert such powerful traction that the pelvis actually *rises* on the unsupported side. The muscles are inactive or variably active in varieties of symmetrical standing; in standing 'at ease' with feet separated, abductor muscles are usually electromyographically 'silent'. According to Jonsson & Steen (1962) they *are* active in the position for Romberg's test—feet parallel and close together. Evans (1977) considered the iliotibial tract the major factor in preventing pelvic sag on the unsupported side. (Unmodified, this view must be considered with caution.)

Applied Anatomy. The supportive effect of glutei medius and minimus when the contralateral foot is raised depends on the following: (1) muscles and innervation must be normal, (2) components of hip joint, the fulcrum, must be normal; (3) the femoral neck must be intact and normally angulated. When any one condition is not fulfilled, e.g. (1) paralysis of the glutei, (2) congenital dislocation of the hip, (3) non-united fracture of the femoral neck or coxa vara, the supporting mechanism is deficient, the pelvis sinks in attempts to stand on the affected limb. This constitutes *Trendelenberg's sign*. Paralysis of the gluteus medius and minimus is the most serious coxal muscular disability; sufferers have a peculiar lurching gait. Conversely, when these muscles remain intact, with many others paralysed, walking, even running, is much less affected.

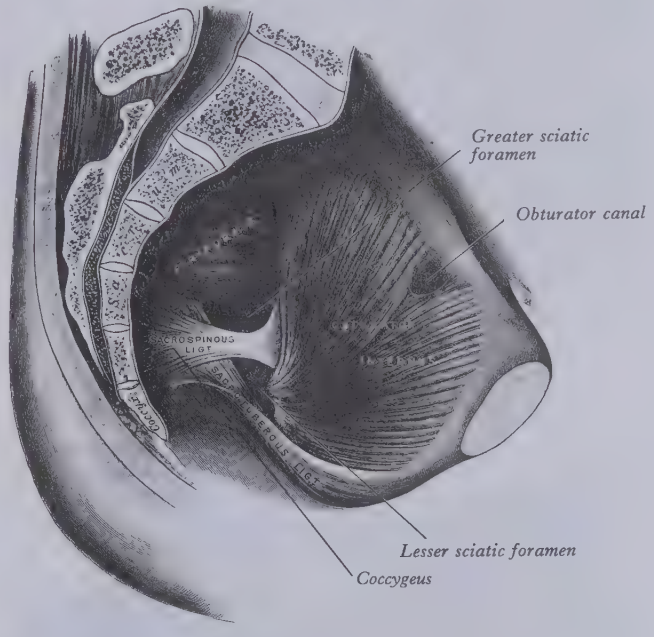
Piriformis (5.91), almost parallel with the posterior margin of gluteus medius, is partly internal to the osteoligamentous pelvis

5.91 The muscles of the gluteal region and flexor aspect of the right thigh: posterior aspect (e.g. flexor with respect to the *knee*, they are extensors, abductors and lateral rotators of the *hip*).



and partly external, posterior to the hip joint. Its three digitations are attached anteriorly between the pelvic sacral foramina, to the floor and margins of the grooves leading from them (3.43), from the iliac gluteal surface near the posterior inferior iliac spine, capsule of the sacro-iliac joint, and sometimes the upper pelvic surface of the sacrotuberous ligament. The muscle exits through the greater sciatic foramen, to be attached by a round tendon to the upper border of the greater trochanter, posterosuperior to the trochanteric fossa and often partly blended with the common tendon of obturator internus and gemelli. It may also be blended with gluteus medius.

Relations. *In the pelvis, anterior* are the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels; *posterior* is the sacrum. *Outside the pelvis, anterior* are the posterior ischial surface and capsule of the hip joint; *posterior* is gluteus maximus. Its *upper border* is in contact with gluteus medius and the superior gluteal vessels and nerve, its *lower border* with the coccygeus and gemellus superior. The inferior gluteal and internal pudendal vessels, sciatic, posterior femoral cutaneous and pudendal nerves and muscular branches from the sacral plexus appear between the piriformis and gemellus superior. The muscle is frequently traversed by the common peroneal nerve, which may divide it. The sciatic nerve often varies in relation to the piriformis; in 168 dissections Lee & Tsai (1974) observed variation in almost 30%; the nerve emerged *above* the muscle in 2.98%, *through* it in 1.8%, with its divisions above and below in 4.2%, one division between heads of a divided muscle and one division above (1.2%) or below (19.6%), the last being the commonest variation. In a larger series (2250 specimens) reported by Anson (1963), incidence of variation was only 10.7% (242 specimens); in 10% (222) the common peroneal division separately traversed the muscle, the whole nerve in 0.2% (5) and divisions appeared above and below in 0.7% (15); in this series the entire nerve never appeared at the upper border.



Nerve supply: branches from L.5,S.1 and 2.

Actions: lateral rotation of the extended thigh, abduction of the flexed thigh.

The obturator membrane (5.92) is a thin aponeurosis almost closing its foramen. Its fibres interlace, with many oblique bundles but the majority roughly transverse; some form an uppermost bundle between the obturator tubercles, completing the obturator canal for the obturator vessels and nerve. The membrane is attached to the obturator foramen's sharp margin except at its inferolateral angle, where it invades the pelvic surface of the ischial ramus, internal to the foramen. Obturator muscles are attached to its two surfaces; externally some fibres of the pubofemoral ligament are attached to it. It *obturates* its foramen.

5.92 The left obturator membrane: ventral aspect.

5.93 The left obturator internus: pelvic aspect. Note that the muscle fibres of the coccygeus are blended and coextensive with the sacrospinous ligament (on their gluteal aspect).

Obturator internus (5.93) is partly internal in the osteoligamentous pelvis and partly external, behind the hip joint. It is attached to the anterolateral wall of the lesser pelvic cavity, around most of the obturator foramen; to the inferior pubic ramus, ischial ramus and an extensive pelvic periosteal surface postero-inferior to the pelvic brim from the upper greater sciatic foramen posterosuperiorly; to the obturator foramen anteroinferiorly (3.172), and also from the obturator membrane's internal surface, the tendinous arch at its upper border and the obturator fascia. Fibres converge acutely towards the lesser sciatic foramen to end in four or five tendinous bands on the muscle's deep surface, which bend abruptly round the grooved surface between the ischial spine and tuberosity; this is covered by hyaline cartilage and is separated from the tendon by a bursa; it is also ridged in adaptation to grooves in the tendon, whose intervening bands traverse the lesser sciatic foramen to unite into a flat tendon, passing horizontally across the hip joint's articular capsule; fusing with the gemelli it is then attached to an anterior impression on the medial surface of the greater trochanter anterosuperior to its fossa. A long bursa usually exists between the tendon and the coxal capsule, sometimes communicating with the bursa between the tendon and the ischium.

Relations. *Within the pelvis, anterolateral* are the obturator membrane and lateral pelvic wall; *posteromedial* are the obturator fascia, levator ani and the sheath of internal pudendal vessels and pudendal nerve (p. 1149), forming the lateral wall of the ischiorectal fossa. *Outside the pelvis* the muscle is covered by gluteus maximus, crossed posteriorly by the sciatic nerve, and passes behind the hip joint. As its tendon emerges it is overlapped above and below by the gemelli; near its attachment the gemelli pass anterior to the tendon and form a groove in which it lies.

Nerve supply: nerve to the obturator internus, L.5 and S.1.

Gemellus superior (5.91), the smaller, passes from the dorsal aspect of the ischial spine to blend with the upper part of the obturator tendon, attached with it to the medial aspect of the greater trochanter. It is sometimes absent.

Nerve supply: nerve to the obturator internus, L.5 and S.1.

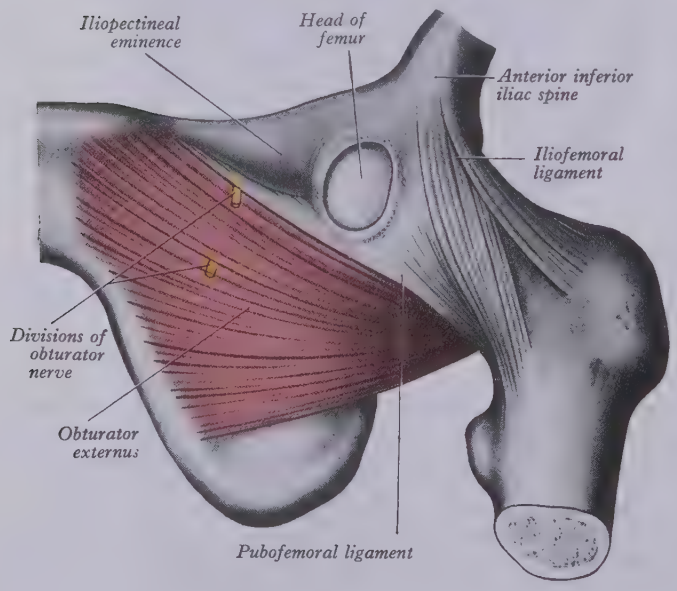
Gemellus inferior (5.91) is attached to the ischial tuberosity below the groove for the obturator internus tendon, then blends

with the tendon's lower part and is attached with it to the medial aspect of the greater trochanter.

Nerve supply: nerve to the quadratus femoris, L.5 and S.1.

Action. Obturator internus and the gemelli rotate the extended thigh laterally but they abduct it when it is flexed.

Quadratus femoris (5.91) is a flat, quadrilateral muscle between the gemellus inferior and the proximal margin of adductor magnus, separated from the latter by the transverse branch of the medial circumflex femoral artery. From the upper external aspect of the ischial tuberosity it passes to the low rounded quadrate tubercle a little above the middle of the trochanteric crest and to the bone a short distance distal to it. It passes transversely, posterior to the hip joint and femoral neck, but separated by the tendon of obturator externus and the ascending branch of the medial circumflex femoral artery. A bursa often exists between the muscle and the lesser trochanter. The muscle may be absent.



Nerve supply: nerve to the quadratus femoris, L.5 and S.1. The arterial supply is chiefly from the medial circumflex and first perforating arteries (Leborgne et al 1973).

Action: lateral rotation of the femur.

Obturator externus (5.94), flat and triangular, covers the external aspect of the anterior pelvic wall. Its fibres converge and ascend posterolaterally to a tendon crossing behind the femoral neck and capsule of the hip joint to end in the trochanteric fossa. (The whole muscle and its tendon *spiral* towards their lateral attachment.) It is attached to the external surface of the obturator membrane (medial two-thirds), the adjacent bone of the pubic and ischial rami and the lip of their *pelvic* aspects between the foraminal margin and the obturator membrane (p. 643). A bursa, communicating with the hip joint, may exist between the tendon, articular capsule and femoral neck. The obturator vessels are between the obturator muscle and the membrane; the obturator nerve's anterior branch enters the thigh in front of the muscle; its posterior branch enters by piercing it (5.94).

Nerve supply.: the posterior branch of the obturator nerve, L.3 and 4.

Action. The muscle is a lateral rotator. The short muscles around the hip joint—pectineus, piriformis, obturators, gemelli and quadratus femoris—are possibly more postural than prime movers. They may act as adjustable ligaments for all positions, but, being largely inaccessible to direct observation, views about their actions are necessarily speculative.

5.94 The left obturator externus: antero-inferior aspect. The bursa of psoas major tendon, which in this specimen communicated with the synovial cavity of the hip joint, has been opened to expose the head of the femur.

(d) Posterior Femoral Muscles

This group includes (5.91) biceps femoris, semitendinosus, and semimembranosus, often familiarly termed the '*hamstrings*', which span the hip and knee joints, integrating coxal extension with genuflexion.

Biceps femoris (5.87,89,91,95A,B), the posterolateral 'hamstring', has two proximal attachments: a *long head*, attached to an *inferomedial* impression on the proximal area of the ischial tuberosity (3.173) by a tendon common to it and semitendinosus, which blends with the lower part of the sacrotuberous ligament; and a *short head* attached to the lateral lip of the linea aspera between adductor magnus and vastus lateralis and extending proximally almost to gluteus maximus and distally along the lateral supracondylar line to within 5 cm of the lateral femoral condyle and also to the lateral intermuscular septum. Fibres of the long head form a fusiform belly descending laterally across the sciatic nerve to an aponeurosis covering the muscle's posterior surface and receiving fibres of the short head on its anterior aspect; this mass gradually narrows into a tendon (lateral hamstring), most of which splits round the fibular collateral ligament and is attached to the fibular head; the rest splits into three laminae, an intermediate fusing with fibular collateral ligament, the others passing superficial and deep to it to the lateral *tibial* condyle (Sneath 1955). The common peroneal nerve descends along the tendon's medial border, separating it distally from the lateral head of gastrocnemius. The short head may be absent. Additional slips may arise from the ischial tuberosity, linea aspera, or medial supracondylar line.

Nerve supply: sciatic nerve, long head through its tibial part, short head through the common peroneal, L.5, S.1 and 2, which accords with their derivation from both flexor and extensor musculature (cf. the nerve supply of semimembranosus).

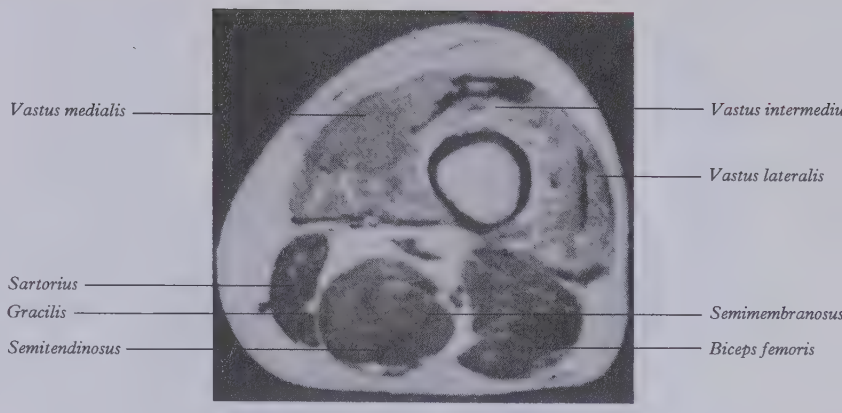
Semitendinosus (5.89,91,95A,B), remarkable for its lengthy tendon, is posteromedial and is attached proximally to an inferomedial impression on the upper area of the ischial tuberosity by a tendon shared with the long head of biceps femoris and to an aponeurosis connecting their adjacent surfaces for about 7.5 cm. Its belly is fusiform and ends a little distal to mid-thigh in a long, round tendon, which runs on the surface of semimembranosus and then curves around the medial tibial condyle, skirts the tibial collateral ligament, separated from it by a bursa, to be attached proximally on the medial metaphysial tibial surface behind the attachment of sartorius, distal to that of gracilis. Terminally it is united with the tendon of gracilis, with a prolongation to the adjacent deep fascia. A tendinous interruption usually exists near its midpoint; it may receive a muscular slip from the long head of biceps femoris.

Nerve supply: sciatic nerve through its tibial division, L.5, S.1 and 2 (cf. the nerve supply of semimembranosus).

Semimembranosus (5.89,91,95A,B), so termed from the flat, membranous form of its proximal attachment, is also posteromedial, attached by a tendon to a *superolateral* impression on the ischial tuberosity (3.173). Its fibres are partly interwoven with those of biceps femoris and semitendinosus and its tendon also receives, from the ischial tuberosity and ramus, two fibrous expansions flanking the adductor magnus. This complex proximal tendon expands into an aponeurosis, descending anterior to semitendinosus and the long head of biceps; from this, muscular fibres start and converge to a second aponeurosis on the muscle's distal posterior aspect which tapers into the tendon of the distal attachment. The tendon divides at knee level into five components, the chief being attached to a *tuberculum tendinis* on the posterior aspect of the medial tibial condyle (Cave & Porteous 1958); other slips are attached to the medial tibial margin behind the tibial collateral ligament, to the fascia over the popliteus, as a cord-like tendon to the inferior lip and adjacent groove behind the medial tibial condyle deep to this ligament and a variable fasciculus ascending laterally to the femoral intercondylar line and lateral femoral condyle (oblique popliteal ligament of knee joint). The muscle overlaps the popliteal vessels and is partly overlapped by semitendinosus throughout its extent (5.91). (Distal tendons of semitendinosus and semimembranosus form the medial 'hamstring'.)

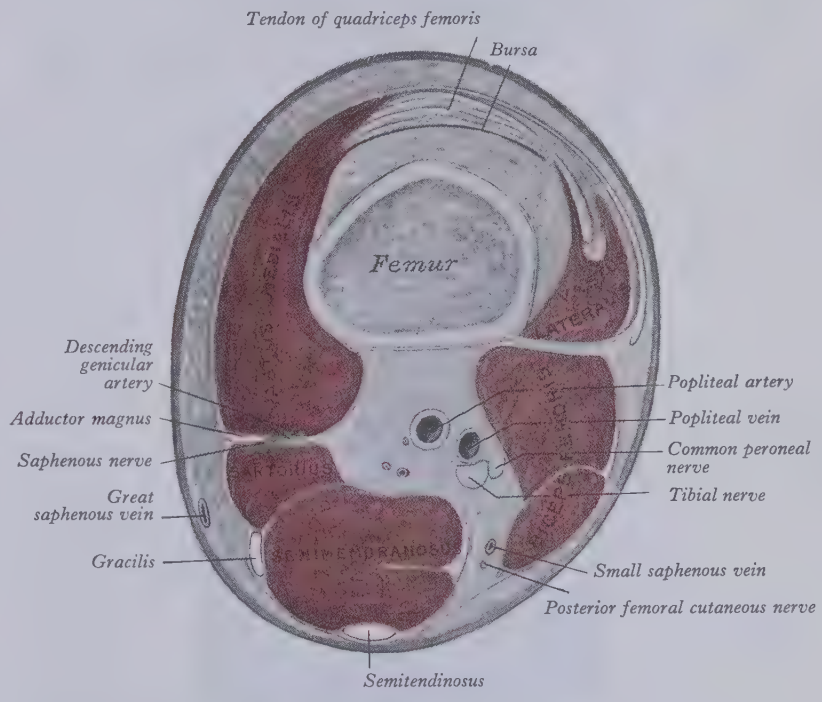
Semimembranosus varies much in size and may be absent. It may be double, arising mainly from the sacrotuberous ligament. Slips to the femur or adductor magnus may occur.

Nerve supply: sciatic nerve, tibial division, L.5, S.1 and 2. Intramuscular distributions of nerves supplying posterior femoral muscles have been detailed by Himstedt et al (1974).



Actions. Posterior femoral muscles, acting from above, flex the knee; from below they extend the hip; they pull the trunk upright against gravity, the biceps being the most active. With the knee semi-flexed, biceps femoris is a lateral rotator (of leg on thigh at the knee). Semimembranosus and semitendinosus are medial rotators. The biceps also laterally rotates the *thigh* when the hip and knee are extended, semimembranosus and semitendinosus being then medial rotators. Like quadriceps femoris, the adductors and gluteus maximus, the flexors are quiescent in symmetrical standing; but any action which carries the relevant centre of gravity in front of the transverse coxal axis, e.g. forward reaching, swaying, or bending, evokes an immediate strong contraction in them.

(Gluteus maximus, however, only contracts when powerful extension at the hip joint is required.)



In flexion of the knee against resistance the tendon of biceps is palpable lateral to popliteal fossa, medial to which the tendons of gracilis and semitendinosus are prominent; between them (and also by deep pressure from a 'pincer' grip beyond their margins) semimembranosus can be felt, although less distinctly.

Evidence suggests that semimembranosus, semitendinosus and biceps femoris, though crossing hip *and* knee joints, may produce movement at *one* joint without resistance to antagonists at the other (Markee et al 1955). Each, however, usually contracts as a whole and consequent movement at the hip or knee is determined by fixation by other muscles at one articulation or the other.

Applied Anatomy. Contracture of the flexor tendons is a complication of genual disease, causing flexion and partial posterior dislocation of the tibia, with slight lateral rotation probably due to the biceps femoris. When flexor tendons require surgical manipulation the common peroneal nerve's relation to the medial border of the biceps tendon must be remembered. Relative lengths of flexors vary; sometimes they are so short that they limit flexion at the hips when the knees are extended. Stooping is then largely effected by flexion of the vertebral column or by squatting.

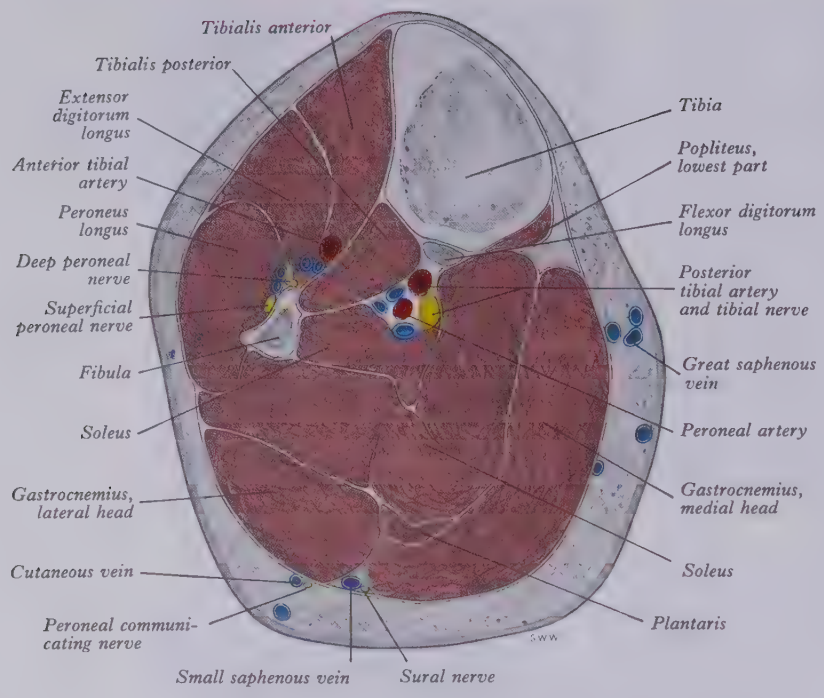
5.95B Transverse section through the right thigh, about 4 cm superior to the adductor tubercle of the femur: proximal (superior) aspect.

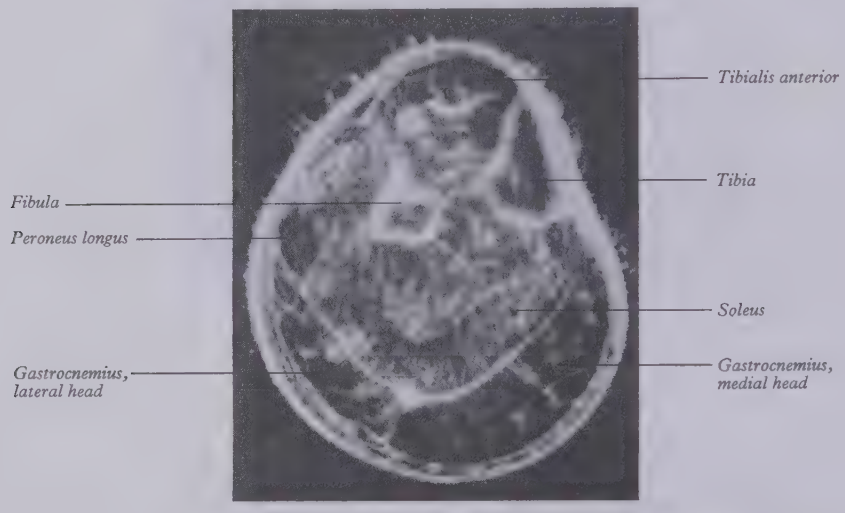
3. Muscles of the Leg

These comprise anterior extensors and posterior flexors, and the lateral peronei, derived from extensors.



(a) Anterior Crural Muscles

This group includes (5.97): a common digital extensor, an extensor of hallux and two dorsiflexors of the foot, tibialis anterior and peroneus tertius.

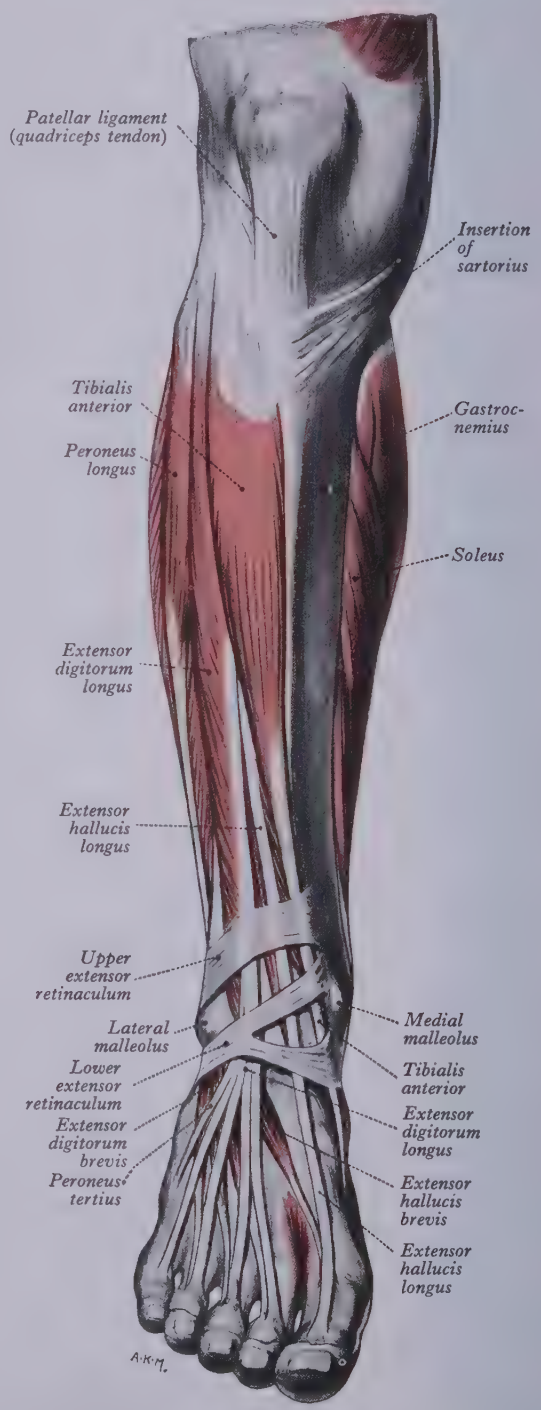


Fascia cruris, the leg's deep fascia, is continuous with the fascia lata and attached proximally to the patella, ligamentum patellae, tibial tubercle and condyles and the fibular head. Posteriorly it becomes the popliteal fascia, strengthened here by transverse fibres and perforated by the small saphenous vein. It receives lateral expansions from the tendon of biceps and multiple medial expansions from tendons of sartorius, gracilis, semitendinosus and semimembranosus. It blends with the periosteum on subcutaneous surfaces of the tibia and fibular head and its malleolus; it is continuous distally with the extensor and flexor retinacula (p. 651). Thick and dense in the proximal and anterior regions, its deep surface is a partial attachment of tibialis anterior and the extensor digitorum longus; it is thinner over gastrocnemius and soleus. Laterally it is continuous with the *anterior* and *posterior crural intermuscular septa*, attached respectively to the anterior and posterior fibular borders. Over flexors and extensors the fascia has several slender extensions enclosing muscles: a *deep transverse fascia of the leg* (5.99) passes between the superficial and deep muscles in the calf (posterior compartment). All such named sheets are united together and to bone as a connective tissue 'skeleton'.

Tibialis anterior (5.96A,B,97) arises from the tibial lateral condyle and proximal half or two-thirds of the tibial shaft's lateral surface, adjoining the anterior surface of the interosseous membrane, fascia cruris, and intermuscular septum between the muscle and extensor digitorum longus. It descends vertically to a tendon on its anterior surface in the distal third of the leg; this traverses the medial compartments in the superior and inferior extensor retinacula, inclines medially and is attached to the medial and inferior surfaces of the medial cuneiform and adjacent part of the first metatarsal base. The muscle overlaps the anterior tibial vessels and the deep peroneal nerve proximally in the leg. Further attachments to the talus, the first metatarsal head and the proximal phalangeal base of hallux have been recorded.

Action: dorsiflexor at the talocrural joint and invertor of the foot, most active when both are combined, as in walking. (It is probably operative in the pedal pronation/supination cycle, see p. 657). It elevates the first metatarsal base and medial cuneiform and rotates their dorsal aspects laterally. Lateral to the anterior

5.96A Transverse section through the right leg, about 10 cm distal to the knee joint: distal aspect.



5.96B Transverse ultrasonic scan of the right leg of an adult man, at a level similar to that of the section illustrated in 5.96A: distal aspect. (Supplied by H-D Rott and Siemens, Erlangen; photography by Sarah Smith.)

border of the tibia its tendon is visible descending to the foot's medial side. In standing the muscle is usually quiescent, the line of body weight passing anterior to the talocrural joints. It can act from below to assist in balancing the body by flexing the leg forwards at the talocrural joint. It is said to be active in any activity which raises the medial longitudinal arch. Electromyography (under somewhat artificial conditions) suggests that activity in this and other 'arch-supporting' muscles is minimal in standing, but confirms that tibialis anterior contracts powerfully to increase the arch in take-off, 'toeing' in walking, etc.

Extensor hallucis longus (5.97,99), between and partly deep to tibialis anterior and extensor digitorum longus, is attached to the middle half of the medial fibular surface, medial to the extensor digitorum longus and also to the adjacent interosseous membrane. Anterior tibial vessels and the deep peroneal nerve separate it from tibialis anterior. Its fibres descend into a tendon forming its anterior border and passing deep to the superior and through the inferior extensor retinacula, crosses medial to the anterior tibial vessels near the talocrural joint and is attached to the dorsal aspect of the distal phalangeal base in the hallux. At the metatarsophalangeal articulation a slip from each side of the tendon covers the joint's dorsal aspect; an expansion from its medial side to the proximal phalangeal base is also usually present. The muscle is sometimes united with extensor digitorum longus and it may send a slip to the second toe. The tendon is identifiable lateral to that of tibialis anterior.

Actions: extension of the hallux, dorsiflexion of the foot. With the hallux actively extended, little force is required to overcome extension of the *distal* phalanx but much is needed to overcome extension of the *proximal* phalanx.

Extensor digitorum longus (5.96A,B,97,99), a pennate muscle, arises from all aspects of the walls of an osteo-aponeurotic tunnel. It is attached to the lateral tibial condyle, the proximal

5.97 Muscles on the extensor aspect of the right leg (from Quain's *Anatomy*, 11th edn).

three-quarters of the medial fibular surface and the adjacent anterior surface of the crural interosseous membrane, deep surface of fascia cruris, anterior crural intermuscular septum and the septum between it and tibialis anterior. Proximally the anterior tibial vessels and deep peroneal nerve are between the muscle and tibialis anterior, and distally extensor hallucis longus also intervenes. The muscle's tendon passes behind the superior extensor retinaculum and within a loop of the inferior retinaculum (p. 651) with peroneus tertius (5.103). It divides into four slips on the foot's dorsum, attached in a manner that in many respects, in miniature, resembles those of extensor digitorum in the hand (p. 623). Dorsal to the metatarsophalangeal joints the tendons to the second to fourth toes are joined laterally by a tendon of extensor digitorum brevis. The *dorsal digital expansion* thus formed, like that in the fingers, receives contributions from lumbrical and interosseous muscles (pp. 655–66). Narrowing near its proximal interphalangeal joint, the expansion divides into three slips, an intermediate one attached to the base of the middle phalanx, and two collateral slips which reunite dorsal to the middle phalanx and are attached to the base of the distal phalanx. Tendons to the second and fifth toes are sometimes double. Accessory slips may be attached to the metatarsals, including the hallux.

Actions. The muscle extends the toes and dorsiflexes the foot with tibialis anterior and extensor hallucis longus; and with the latter it tautens the plantar aponeurosis (pp. 652, 657).

Peroneus tertius (5.97,104), part of extensor digitorum longus, as if it were its fifth tendon, is attached proximally to the distal third or more of the medial fibular surface, adjoining the interosseous membrane and anterior crural intermuscular septum. Its tendon passes behind the superior and in a loop of the inferior extensor retinaculum with extensor digitorum longus (5.103). It is attached to the dorsomedial surface of the fifth metatarsal base, a thin expansion usually extending along the medial border of its shaft. It is sometimes missing (in 4.4% of dissections, according to Werneck (1957) in a most extensive study of this very variable muscle).

Actions: dorsiflexion of the foot, as part of extensor digitorum longus, and perhaps eversion.

Nerve supply. All anterior crural muscles are supplied by the deep peroneal nerve. Tibialis anterior is innervated by L.4 and 5, the others by L.5 and S.1.

(b) Lateral Crural Muscles

The lateral crural muscles are peroneus longus and brevis, evertors of the foot (5.96–101).

Peroneus longus (5.96,100,101), the more superficial, is attached to the head and adjoining proximal two-thirds of the lateral surface of the fibula, to fascia cruris, anterior and posterior crural intermuscular septa and occasionally by a few fibres to the lateral tibial condyle. Between attachments to the fibular head and shaft is a gap for the common peroneal nerve. The muscle belly ends in a long tendon, descending *behind* the lateral malleolus in a groove shared with the tendon of peroneus brevis, behind which it lies, both covered by the superior peroneal retinaculum in a common synovial sheath (5.104). The tendon runs obliquely forwards lateral to calcaneus, below the peroneal trochlea and tendon of peroneus brevis and beneath the inferior peroneal retinaculum (p. 651); crossing the lateral aspect of the cuboid, it then curves and enters a plantar groove on the cuboid which is closed by the long plantar ligament (4.90). It crosses the sole obliquely to be attached by two slips to the lateral sides of the first metatarsal base and the adjacent medial cuneiform; a third slip may reach the second metatarsal base. The tendon changes direction: (*a*) distal to lateral malleolus, (*b*) on the cuboid bone, and is thickened at both sites with, at the second, a sesamoid fibrocartilage (sometimes ossified) usually developed in it. A second synovial sheath invests the tendon in the sole.

Tendinous slips to the bases of the third to fifth metatarsal bone may occur, or to adductor hallucis. Fusion of peroneus longus and brevis is a rare variation.

Nerve supply: superficial peroneal nerve, L.5, S.1 and 2.

Actions. Doubtless peroneus longus can evert and plantar-flex the foot, and perhaps act on the leg from the distal attachment. Its oblique course across the sole also favours support of longitudinal and transverse arches. How do these powers contribute to actual movements? With the foot off the ground, overall pedal eversion is obvious. How far this helps to maintain plantigrade contact is less certain; electromyographic evidence indicates little or no activity in standing. But peroneus longus and brevis are strongly active in maintaining a concave foot in take-off and tip-toeing. In lateral swaying peronei contract on that side; but their involvement in the postural activity between the foot and leg remains uncertain. (Pedal movements during maintenance of plantigrade contact, with the leg and trunk in different postures on uneven surfaces and during walking, running, jumping, thrusting etc, involves talocrural activity while inversion and eversion are modified and compounded with pronative or supinative actions, see pp. 656–659.)

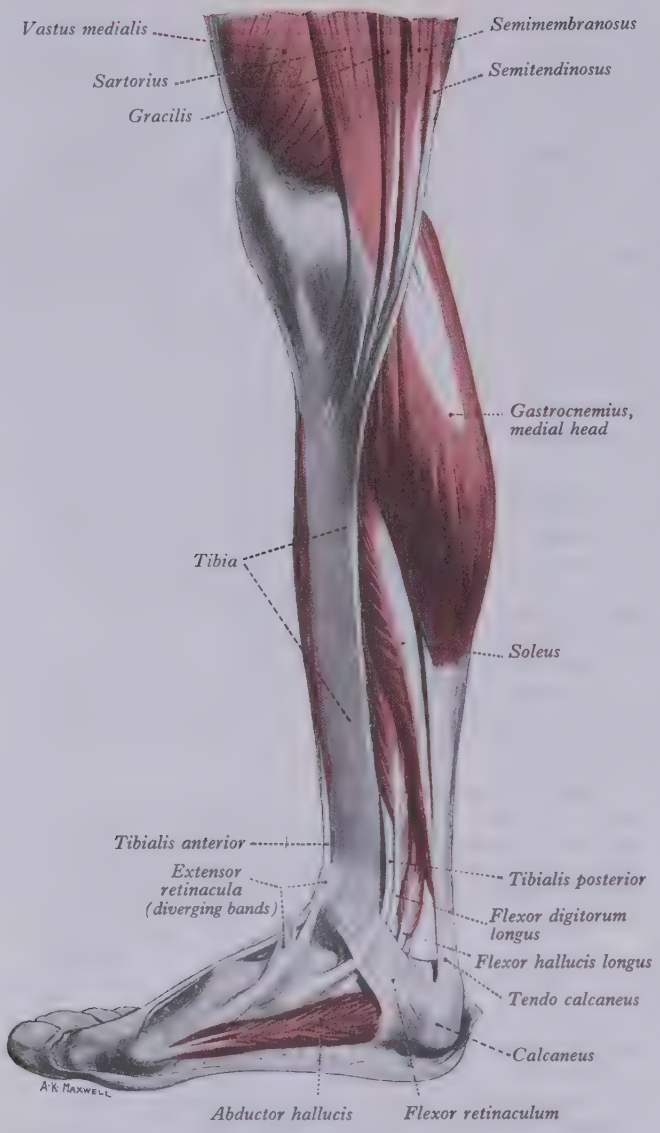
Peroneus brevis (5.100,101) is attached to the distal two-thirds of the lateral fibular surface, anterior to peroneus longus, and to the anterior and posterior crural intermuscular septa. It descends vertically to a tendon passing behind the lateral malleolus anterior to that of peroneus longus, both deep to the superior peroneal retinaculum in one synovial sheath (p.651). It passes lateral to the calcaneus, above the peroneal trochlea and the tendon of peroneus longus, to be attached to a lateral tubercle on the fifth metatarsal base.

Lateral to the calcaneus the tendons of peronei longus and brevis occupy *separate* osseo-aponeurotic canals between calcaneus and the inferior peroneal retinaculum, each in a separate prolongation of their proximally common synovial sheath (5.104).

Nerve supply: superficial peroneal nerve, L.5, S.1 and 2.

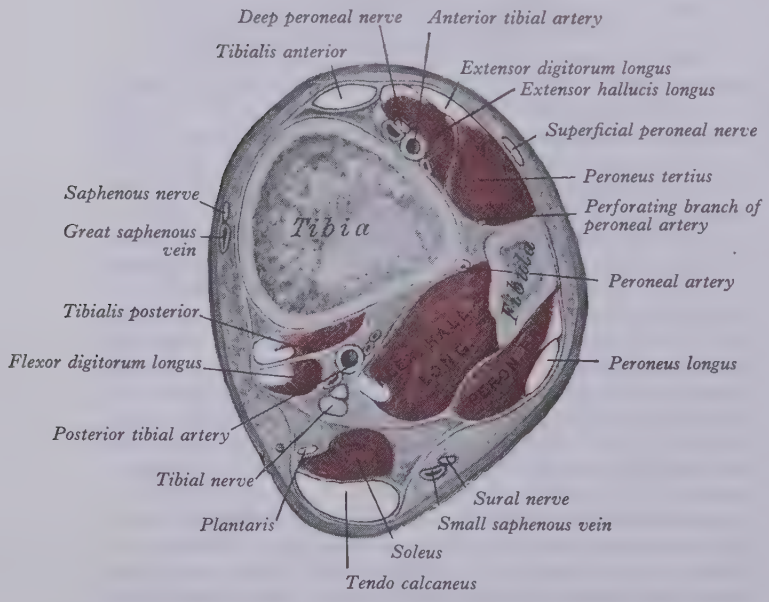
Action. Peroneus brevis may limit inversion, relieving the ligaments tightened by this movement (the lateral part of interosseous talocalcanean, lateral talocalcanean and calcaneofibular). It aids eversion and may help to steady the leg on the foot (cf. peroneus longus, above).

(c) Posterior Crural Muscles



The muscles in the calf form superficial and deep groups, separated by the *deep transverse fascia* (pp. 645, 649). Superficial is a powerful muscular mass forming most of the calf, flexing the knee and plantar-flexing the foot. Its size is a characteristic feature of human musculature, directly related to upright stance and the mode of progression.

SUPERFICIAL GROUP OF MUSCLES



This group (5.100) comprises gastrocnemius and plantaris, acting on the knee and ankle, the soleus only on the latter.

Gastrocnemius (5.96,98,100), most superficial of the muscles, forms the 'belly' of the calf and is attached by two heads connected to the femoral condyles by strong, flat tendons. The medial and larger head descends from a depression on the upper and posterior part of the medial condyle behind the adductor tubercle and a slightly raised area on the femoral popliteal surface proximal to the condyle. The lateral head is attached to a recognizable area on the lateral surface of the lateral condyle and the adjoining supracondylar line. Both are also attached to subjacent areas of the articular capsule. Each spreads into a tendinous expansion and from their anterior surfaces muscular fibres descend, those of the medial head further distally. The two muscular masses remain separate to their attachment to a broad aponeurosis on the muscle's anterior surface. This gradually narrows and thickens, uniting with the tendon of soleus to form the *tendo calcaneus* (p. 648). The lateral head or whole muscle may be absent; more frequent is a third head from the femoral popliteal surface.

Relations. Fascia cruris separates the muscle's *superficial surface* from the small saphenous vein and the peroneal communicating and sural nerves; the common peroneal nerve crosses the lateral head, partly deep to biceps femoris. The *deep surface* is posterior to the oblique popliteal ligament, popliteus, soleus, plantaris, popliteal vessels and tibial nerve. A bursa, sometimes

5.98 The muscles of the right leg: medial aspect.

5.99 Transverse section through the right leg, about 6 cm superior to the tip of the medial malleolus: proximal (superior) aspect.

connected to the knee joint, is anterior to its medial tendinous head; the lateral tendon sometimes contains a sesamoid fibrocartilage or bone where it plays over the lateral femoral condyle, and occasionally the medial head has one.

Nerve supply: tibial nerve, S.1 and 2.

Soleus (5.96,98), a broad, flat muscle placed anterior to gastrocnemius, is attached to the posterior aspect of the head and proximal quarter of the shaft of the fibula, the tibia's soleal line and the middle third of its medial border, and to a fibrous arch between the tibia and fibula over the popliteal vessels and tibial nerve. This attachment is a wide aponeurosis; most soleal muscular fibres pass obliquely from the posterior surface of the aponeurosis to the main tendon, which is on the muscle's *posterior* surface; other fibres also start from its *anterior* (deep) aponeurotic surface, being short and bipennate and these reach a narrow, central deep *intramuscular* tendon merging distally with the main one (5.96). The latter, gradually compacted and narrowed, joins the tendon of gastrocnemius to form the *tendo calcaneus*.

Relations. *Superficial* are gastrocnemius and plantaris; *deep* are flexor digitorum longus, flexor hallucis longus, tibialis posterior and the posterior tibial vessels and tibial nerve, all separated from soleus by the deep transverse fascia.

Nerve supply: two branches from the tibial nerve, S.1 and 2. Intramuscular distributions in gastrocnemius, soleus and plantaris have been detailed by Schumacher et al (1973).

Gastrocnemius and soleus form a tripartite mass sharing the tendo calcaneus, and hence sometimes termed *triceps surae*.

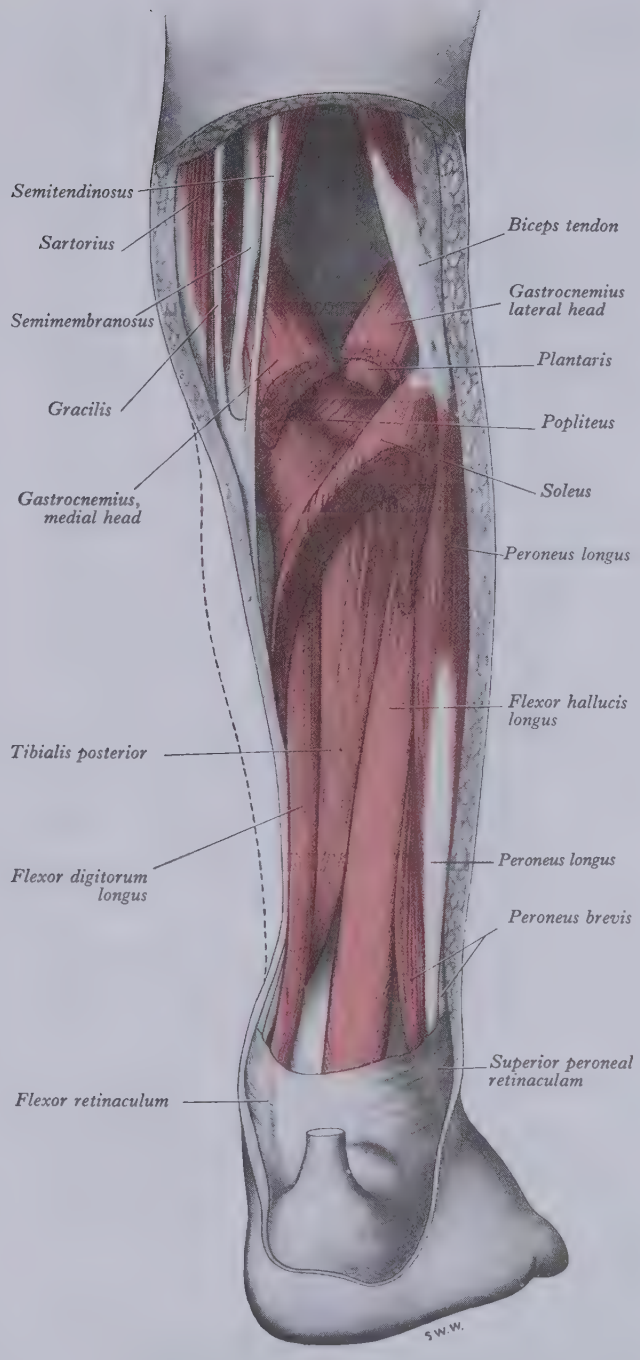
The tendo calcaneus (5.100), the largest and strongest human tendon, is about 15 cm long, beginning near mid-level in the leg, but its anterior surface receives muscle fibres from the soleus almost to its distal end. It gradually becomes rounder to about 4 cm proximal to the calcaneus, expanding then to be attached to the posterior calcaneal surface at its mid-level, a bursa separating it from the bone's proximal area. Tendon fibres spiral through 90° in descending, when the medial fibres become most posterior (White 1943). This permits some elongation and elastic recoil and hence storing of energy, which can be released at an appropriate phase of locomotion. Alexander & Vernon (1975) have studied elastic recoil (in kangaroos), and Alexander has made a mathematical analysis of the contribution of elasticity in tendo calcaneus to bipedal gait.

Actions. Muscles of the calf are major plantar flexors and gastrocnemius also flexes the knee; they possess great power, being usually large.

Gastrocnemius propels in walking, running and leaping. Soleus is said to steady the leg on the foot in standing; this postural function is emphasized but such a rigid distinction between the muscles is probably an over-simplification. In standing, the centre of gravity is on a vertical passing anterior to the talocrural joints (in this erect position they are loose-packed) and a strong force is required behind the joint to maintain posture. Electromyography demonstrates that in symmetrical standing the soleus exhibits continuous activity, whereas the gastrocnemeus is active only intermittently (Joseph et al 1955, Joseph 1960). Phasic activity of the triceps surae in walking has not been satisfactorily analysed into the relative roles of soleus and gastrocnemius.

Plantaris (5.100) is attached proximally on the distal part of the lateral supracondylar line and to the oblique popliteal ligament. Its small fusiform belly, from 7–10 cm long, ends in a long slender tendon, which crosses obliquely between gastrocnemius and soleus to descend along the medial border of tendo calcaneus and gradually fuses with it. The muscle is sometimes double. Occasionally, its tendon merges with flexor retinaculum (p. 645) or the crural fascia. Daseler & Anson (1943) found it absent in 160 out of 1545 legs.

Nerve supply: tibial nerve, S.1 and 2.



Actions. Plantaris is the rudiment of a large muscle, its tendon attached distally to the plantar aponeurosis in some mammals. It presumably acts with gastrocnemeus but details are lacking.

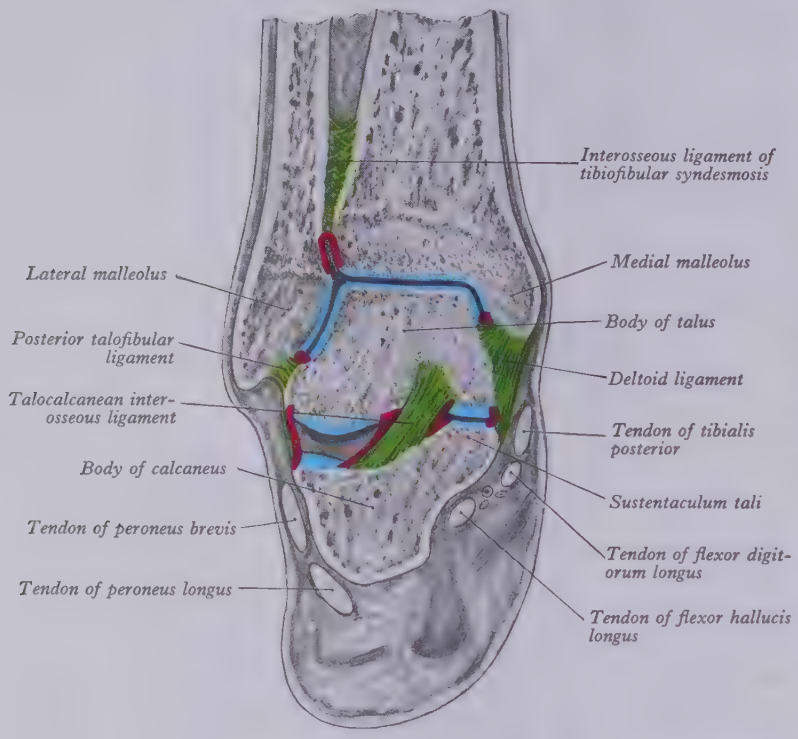
THE DEEP CRURAL GROUP

The deep crural flexors (5.98,101) include one, popliteus, acting solely on the knee joint; the others, flexor hallucis longus, flexor

5.100 Muscles of the right calf: superficial layer (from Quain's *Anatomy*, 11th edn).

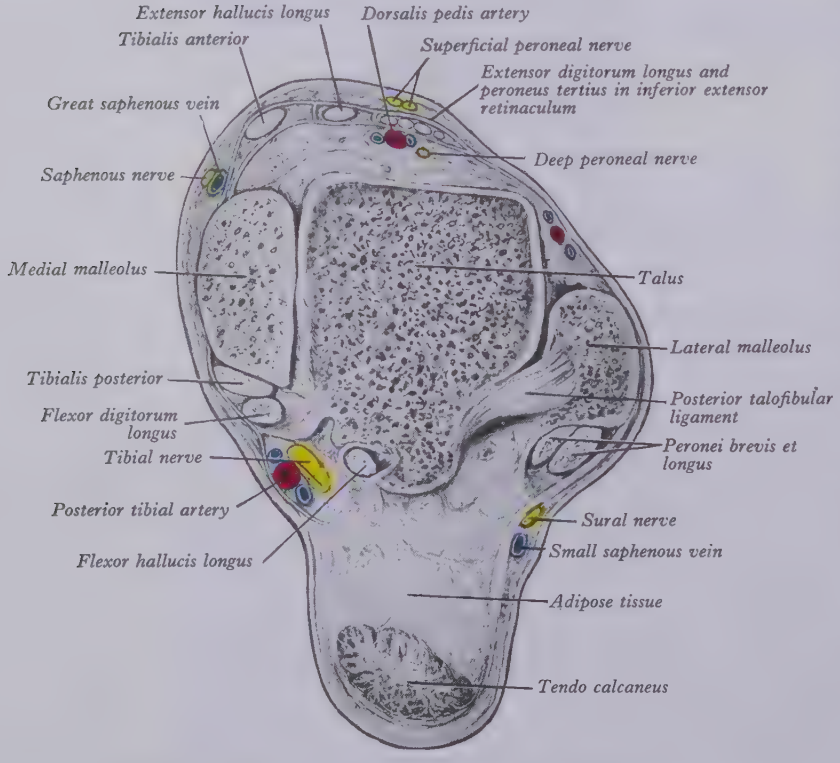
5.101 The right posterior crural muscles, deep group, in a child aged eight years.

digitorum longus and tibialis posterior, act on the talocrural and multiple other pedal joints.



Deep transverse fascia, a fibrous stratum between the superficial and deep posterior cural muscles, extends transversely between the medial tibial and posterior fibular borders. Proximally thick and dense, it is attached to the tibial soleal ridge and to the fibula inferomedial to the soleus. Between the bones it is continuous with fascia covering the popliteus and connected to the tendon of semi-membranosus. It is thin at intermediate levels but again is thick distally where it covers the tendons behind the malleoli and is continuous with the flexor and superior peroneal retinacula (p. 651).

Popliteus (5.101), flat and triangular, forms the lower part of the 'floor' of the popliteal fossa. Its lateral, larger part is attached by a strong tendon, about 2.5 cm long, to a depression at the anterior end of a groove on the lateral aspect of the lateral femoral condyle; its medial fibres are attached to the arcuate popliteal ligament (p. 528) where it blends with the fibrous capsule adjacent to the lateral meniscus, to the periphery of which some fibres are also attached. The muscle is attached distally to the medial two-thirds of a triangular area proximal to the soleal line on the posterior tibial surface and to a tendinous expansion covering it. An additional part may start from a sesamoid bone in the lateral head of gastrocnemius.



Relations. The popliteal tendon is intracapsular and overlapped by the fibular collateral ligament and tendon of biceps femoris (4.76). Invested on its deep aspect by synovial membrane, it grooves posteriorly the border of the lateral meniscus and adjoining tibia, emerging inferior to the posterior band of the arcuate ligament (4.72). In the popliteal fossa it is covered by a strong layer of fascia mostly derived as an expansion of the tendon of semimembranosus.

Nerve supply: tibial nerve, L.4 and 5 and S.1.

Actions. Popliteus rotates the tibia medially or, with tibia fixed, rotates the femur laterally. It is usually said to 'unlock' the joint when flexion starts from full extension (p. 531); electromyography supports this view. Its connection with the arcuate popliteal ligaments, fibrous capsule and lateral meniscus suggests that it may retract the latter's posterior cornu during lateral rotation of the femur and flexion of the knee to obviate its crushing between the femur and tibia (Last 1950). The muscle is markedly active in crouching, perhaps to aid the posterior cruciate ligament in limiting forward translation of the femur.

5.102 Coronal section through the left talocrural, talocalcanean and subtalar joints. Ligaments are shown in green, articular cartilage in blue and synovial membrane in red.

5.103 Horizontal section through the inferior part of the talocrural joint.

Flexor hallucis longus (5.99,101) is attached to the distal two-thirds of the posterior fibular surface, the adjacent interosseous membrane and the posterior crural intermuscular septum and also the intervening fascia covering tibialis posterior, which it overlaps. Its fibres descend obliquely to a tendon along almost all its posterior aspect. This tendon grooves the posterior aspect of the tibia's distal end, then successively the posterior talar surface and the *inferior* surface of sustentaculum tali (5.102,103). Grooves on the talus and calcaneus are converted by fibrous bands into a canal, lined by a synovial sheath. Distal to this, in the sole, it crosses the flexor digitorum longus obliquely, curving *superior* to it; at this crossing the long digital flexor receives a fibrous slip from flexor hallucis longus, whose tendon then continues and crosses the lateral part of flexor hallucis brevis to lie between the sesamoid bones below the first metatarsal head. It runs along the plantar aspect of the hallux in an osseo-aponeurotic tunnel to the plantar aspect of the distal phalangeal base. The tendon is retained over the flexor hallucis brevis by diverging stems of the distal band of the medial intermuscular septum (p. 545). The connecting slip to flexor digitorum longus varies in size, usually continuing into the tendons for the second and third toes, sometimes only the second, occasionally the tendons of the second to fourth toes.

Relations. *Superficial* are soleus and tendo calcaneus, separated by the deep transverse fascia; *deep* are the fibula, tibialis posterior, peroneal vessels, the distal part of the interosseous membrane and talocrural joint; *lateral* are the peronei; *medial* are the tibialis posterior, posterior tibial vessels and tibial nerve.

Nerve supply: tibial nerve, S.2 and 3.

Flexor digitorum longus (5.101), medial to the flexor hallucis longus, thin and pointed proximally, is attached to the posterior surface of the tibia medial to tibialis posterior from just distal to the soleal line to within 7 or 8 cm of the tibia's distal end, and also to the fascia covering tibialis posterior. Its fibres end in a tendon along almost its whole posterior surface, which gradually crosses tibialis posterior and passes behind the medial malleolus in a groove shared with tibialis posterior, but separated from it by a fibrous septum, each tendon in a separate synovial compartment. The tendon then curves anterolaterally, in contact with the *medial side* of the sustentaculum tali (5.102) and under the flexor retinaculum to enter the sole (5.109), where it crosses *superficial* to the tendon of flexor hallucis longus, receiving a slip from it, and crosses the sole to form the whole long flexor tendon of the fifth toe and contributing to those for the second to fourth toes. It may also send a slip to the tendon of flexor hallucis longus. The long flexor tendons of the second to fourth digits receive accessions from the flexor accessorius and variably from the flexor hallucis longus through the slip mentioned. Long flexor tendons of the lateral four toes are attached to the plantar surfaces of their distal phalangeal bases, each traversing a divarication in a corresponding tendon of the flexor digitorum brevis at the level of the proximal phalangeal base (cf. the arrangement in the hand, pp. 618–620).

The lateral head of the flexor accessorius may be attached to the lateral border of the tendon of flexor digitorum longus (p. 654).

Relations. In the leg the muscle's *superficial surface* is related to the deep transverse fascia, separating it from the soleus and distally the posterior tibial vessels and tibial nerve; its *deep surface* is related to the tibia and tibialis posterior. In the foot it is covered by abductor hallucis and flexor digitorum brevis and, as noted, crosses inferior to the flexor hallucis longus.

Nerve supply: tibial nerve, S.2 and 3.

Actions. *With the foot off the ground* both long flexors flex the phalanges, acting primarily on the distal phalanges; they are also plantar flexors. *With the foot on the ground and under the load* they act with the pedal intrinsic muscles and (in the case of flexor digitorum longus especially) with the lumbricals and interossei (p. 655) to maintain the pads of the toes in firm contact with the ground, enlarging the weight-bearing areas and helping to stabilize the metatarsal heads, the fulcrum on which the body is

propelled. Both long digital flexors are minimally active in standing, apparently contributing little to the longitudinal arch mechanism. During take-off and tip-toe movements, their activity is marked.

Tibialis posterior (5.96,101) is attached between flexor hallucis longus and flexor digitorum longus, but overlapped by both; it is the most deeply placed flexor. Two pointed heads, separated by an angular interval traversed by anterior tibial vessels, form its proximal end. The medial part of the muscle is attached to the interosseous membrane, except its most distal part, and to a lateral area on the posterior tibial surface between the soleal line and the junction of the shaft's middle and distal thirds. The lateral part comes from a medial strip of the posterior fibular surface in its proximal two-thirds. The muscle is also attached to the deep transverse fascia and adjacent intermuscular septa. In the leg's distal quarter its tendon passes deep to that of the flexor digitorum longus, sharing a groove behind the medial malleolus, but both are enclosed in separate synovial sheaths. It passes deep to the flexor retinaculum (p. 651) but superficial to the deltoid ligament (5.102), to enter the foot; at first inferior to the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage, it then divides. Its superficial, larger division, the direct continuation, is attached to the navicular's tuberosity, from which fibres continue to the inferior surface of the medial cuneiform. A tendinous band also passes laterally and proximally to the tip and distal margin of sustentaculum tali. The deeper, lateral division becomes the posterior tendon of the medial limb of flexor hallucis brevis, continuing between this and the navicular and medial cuneiform bones to end on the intermediate cuneiform and bases of the second to fourth metatarsals. The metatarsal slips are variable, that to the fourth being strongest. Slips to the cuboid and lateral cuneiform are described (Lewis 1964).

Relations. *Superficial* are the soleus, separated by the deep transverse fascia, flexor digitorium longus, flexor hallucis longus, posterior tibial vessels, tibial nerve and peroneal vessels; *deep* are the interosseous membrane, tibia, fibula and talocrural joint.

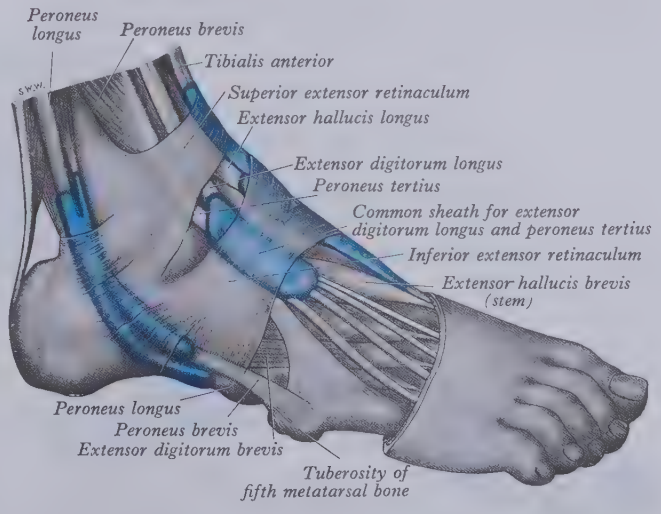
Nerve supply: tibial nerve, L.4 and 5.

Actions. Tibialis posterior is the main invertor and assists powerful plantar flexion. (It also modifies pronative and supinative activities, p. 656 et seq.) Through attachments to the cuneiform bones and metatarsal bases it may contribute to elevation of the longitudinal arch, but it is quiescent in standing, though phasically active in walking; during this, acting with the intrinsic musculature and peronei, it probably controls pronation and the distribution of weight through the metatarsal heads. It is said that with the body supported on one leg, tibialis posterior, acting from its distal end, assists balance by resisting a tendency to lateral swaying. But any act of balancing demands the cooperation of many muscles, including groups acting on the hip joints and vertebral column.

Talocrural Fasciae and Retinacula

As the tendons of muscles approach or cross the talocrural joint to the foot, they are bound down by localized retinacula of the deep fascia, comparable in form and function with those at or near the carpus (pp. 625–626). They comprise the superior and inferior extensor, flexor, and superior and inferior peroneal retinacula.

The superior extensor retinaculum (5.97,104) binds down the tendons of tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius, immediately proximal to the anterior aspect of the talocrural joint; the anterior tibial vessels and deep peroneal nerve also pass under it. Attached laterally to the distal anterior border of the fibula and medially to that of the tibia, it is proximally continuous with the deep crural fascia; connective tissue also connects its distal border to the inferior extensor retinaculum. Only tibialis anterior has a synovial tendon sheath here (5.104).



The inferior extensor retinaculum (5.97,104) is a Y-shaped band anterior to the talocrural joint; its stem (the lateral end) is attached to the upper (superior) surface of calcaneus, anterior to sulcus calcanei. It loops medially round the tendons of peroneus tertius and extensor digitorum longus (5.103); from the loop's deep aspect a band passes laterally behind the interosseous talocalcanean and cervical ligaments to be attached to sulcus calcanei (Stamm 1931). From the loop's medial end two diverging bands continue. The *proximal* has two layers, a deep one *under* the tendons of extensor hallucis longus and tibialis anterior, but *superficial* to the anterior tibial vessels and deep peroneal nerve, reaching the tibial malleolus; a superficial layer crosses the tendon of extensor hallucis longus and then adheres to the deep layer, sometimes continuing superficial to the tendon of tibialis anterior to the tibia. The *distal band* extends inferomedially as far as the plantar aponeurosis; it is superficial to the tendons of extensor hallucis longus and tibialis anterior, arteria dorsalis pedis and terminal branches of the deep peroneal nerve.

The flexor retinaculum (5.98) is attached anteriorly to the tip of the medial malleolus and is continuous distally with the deep dorsal fascia of the foot; it continues posteriorly to the medial calcaneal process and plantar aponeurosis. Its proximal border is not clearly demarcated from the adjoining deep fascia, the distal border is continuous with the plantar aponeurosis; fibres of abductor hallucis are attached to it. The retinaculum converts grooves on the tibia and calcaneus into canals for tendons and bridges the posterior tibial vessels and tibial nerve as they enter the sole. Disposed in an oblique curve, medial to lateral, are: the tibialis posterior, tendon flexor digitorum longus, posterior tibial vessels, tibial nerve and flexor hallucis longus (5.103).

Peroneal retinacula hold down the tendons of peroneus longus and brevis as they curve lateral to the ankle. The *superior peroneal retinaculum* (5.101) extends from the back of the lateral malleolus to the deep transverse crural fascia and lateral calcaneal surface. The *inferior peroneal retinaculum*, continuous anteriorly with the inferior extensor retinaculum, is attached posteriorly to the lateral calcaneal surface; some fibres fuse with the periosteum on the peroneal trochlea between the tendons of peroneus longus and brevis.

Synovial sheaths in the talocrural region. Tendons crossing the talocrural joint are all deflected from a straight course, held down by the retinacula and hence enclosed in synovial sheaths.

Anteriorly a sheath for tibialis anterior extends from the proximal margin of the superior extensor retinaculum to an interval between the diverging limbs of the inferior (5.105); a sheath for extensor digitorum longus and peroneus tertius and one for extensor hallucis longus start proximal to the malleolar level, the former a little higher. The sheath for extensor hallucis reaches the first metatarsal base, that for extensor digitorum, the fifth metatarsal base. *Medial* to the ankle (5.105) a sheath for tibialis posterior extends from about 4 cm proximal to the malleolus almost to the tendon's attachment to the navicular tuberosity. A sheath for flexor hallucis longus reaches only malleolar level, that for flexor

5.104 The synovial sheath of the tendons at the right ankle: lateral aspect. Note the superior and inferior peroneal retinacula (not labelled).

digitorum longus starting slightly more proximal; the former continues to the first metatarsal base, the latter to the navicular. *Lateral* to the ankle (5.104) a sheath, proximally single but distally double, encloses the peroneus longus and brevis, extending from about 4 cm proximal to the lateral malleolar tip for about the same distance beyond it.

4. Muscles of the Foot

The muscles *intrinsic* or confined to the foot follow a primitive pattern of dorsal extensors and plantar flexors, topographically and functionally associated with the *extrinsic* muscles already considered. Intrinsic extensor musculature is limited but, as in the hand, certain intrinsic flexors are also concerned with extensor activity.

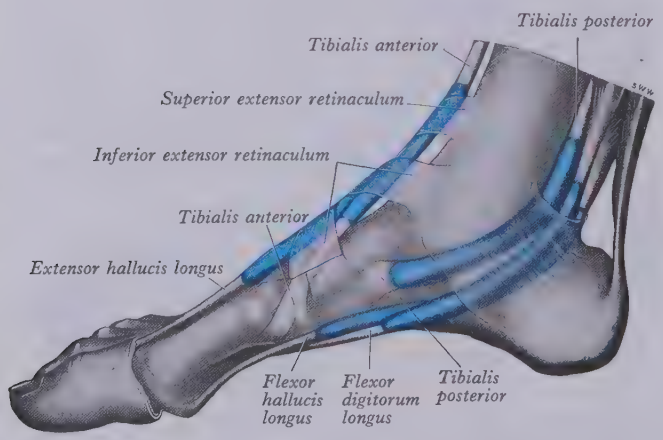
(a) The Dorsal Muscle of the Foot

Deep fascia on the foot's dorsum (*fascia dorsalis pedis*) is thin and continuous proximally with the inferior extensor retinaculum, blending marginally with the plantar aponeurosis; it covers the dorsal tendons.

The **extensor digitorum brevis** (5.97,104), a thin muscle, is attached to the anterior superolateral surface of the calcaneus, anterosuperior to the shallow lateral groove for peroneus brevis, to the interosseous talocalcaneal ligament and the stem of the inferior extensor retinaculum. It slants distomedially across the dorsum to end in four tendons. Its medial part is a variably distinct slip ending in a tendon which crosses the dorsalis pedis artery superficially to reach the dorsal aspect of the proximal phalangeal base of the hallux, hence the term *extensor hallucis brevis*. The other three tendons join the lateral sides of the tendons of extensor digitorum longus for the second to fourth toes. It is subject to much variation by accessory slips (from the talus and navicular), extra tendons, e.g. to the fifth digit, and suppression of tendons. It may be connected to the adjacent dorsal interossei.

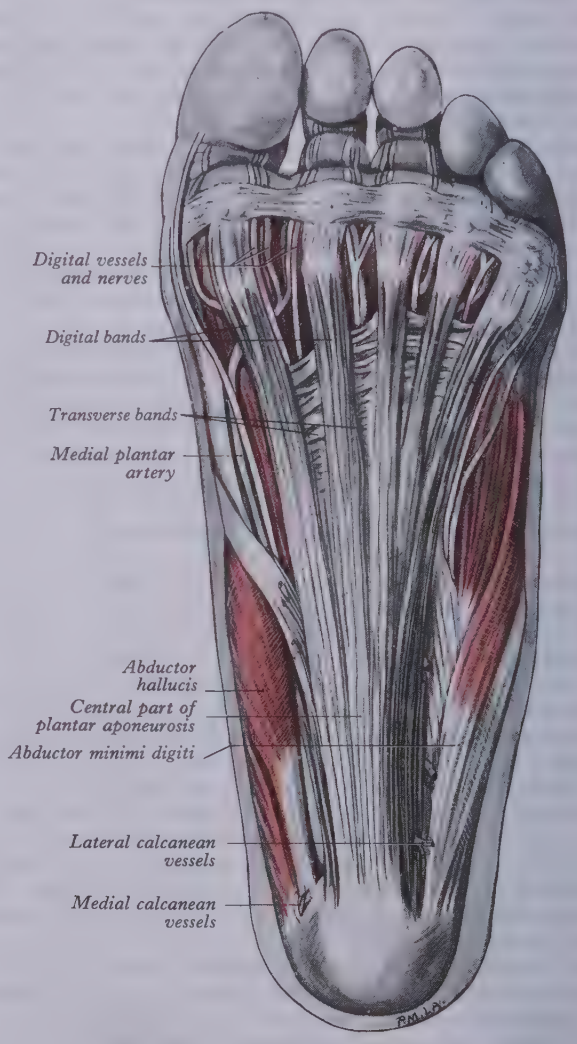
Nerve supply: the lateral terminal branch of deep peroneal nerve, S. 1 and 2.

Actions: assists in extension of phalanges in the middle three toes via the tendons of extensor digitorum longus; in the hallux it acts only on the proximal phalanx.



(b) Plantar Fasciae and Muscles

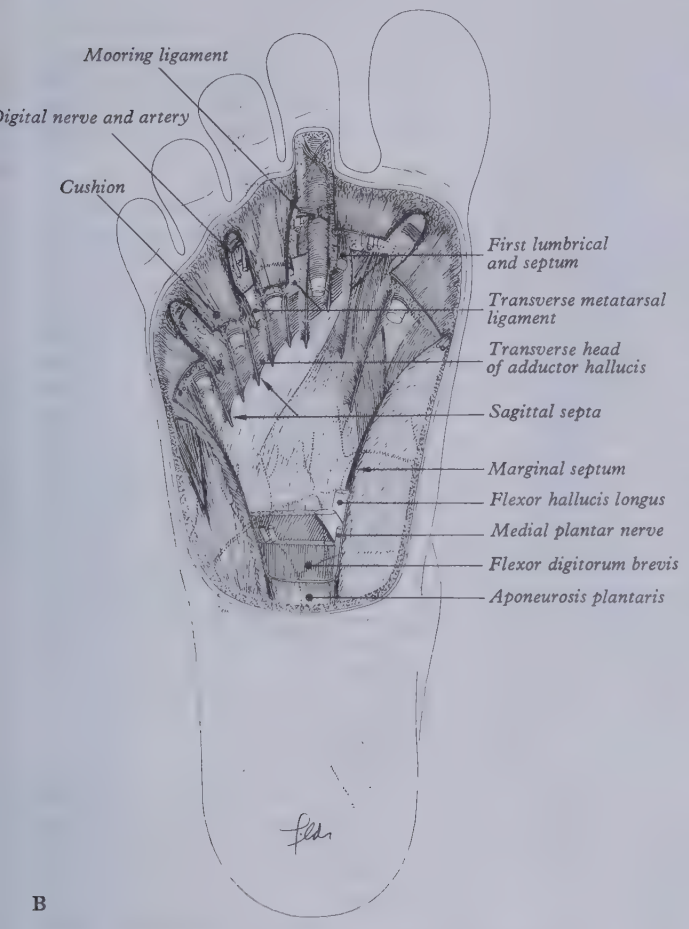
Plantar fasciae, deep and superficial are arranged much as in the hand (5.106A–D), with small differences due to the absence of digital opposition and grip. Fasciae are arranged: to limit the tangential mobility of the skin, to provide 'skin joints', linear flexure lines (p. 80) at which soft tissue angulation is permitted, to 'hold down' muscles and tendons in the sole and digits and to facilitate their excursions along the most functionally advantageous routes within the constraints of overall skeleto-arthrodial geometry, to reduce compression of plantar and digital arteries and nerves and perhaps to aid venous return. Plantar skin is subject to shearing and impact stresses in locomotion, particularly over the posterior calcaneal tubercles, metatarsal heads and pulps of terminal digital segments. As in the hand, pads of adipose tissue occur in these regions, diffusely pervaded by fine but collectively strong strands, tethering skin and limiting the displacement of fat, thus augmenting a resilient cushioning effect. Direction of the fibrous strands, which extend from the deep fascia through subcutaneous tissues to the dermis, is adapted to the prevailing stresses, as demonstrated in the sub-metatarsal region ('*ball of the foot*') by Bojsen-Møller & Flagstad (1976) (5.106D).



Parts of the deep fascia inferior to the plantar structures are collectively the *plantar aponeurosis* (vide infra); but only the central part is entirely aponeurotic and some authorities reserve the name for this. Medial and lateral parts are proximally aponeurotic for attachment of muscles (vide infra).

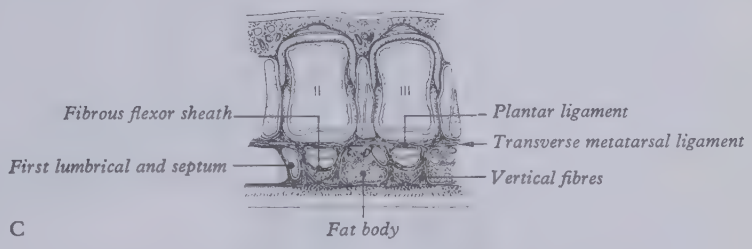
The plantar aponeurosis (5.106A) is of densely compacted collagen fibres, chiefly longitudinal but also transverse, divided into medial and lateral parts overlying the intrinsic muscles of hallux and minimus and a larger densest central part over the long and short digital flexors.

The central part is strongest and thickest. Posteriorly narrow, where it is attached to the medial process of the calcaneal tuberosity proximal to the flexor digitorum brevis, it is broader and thinner as it diverges towards the metatarsal heads, proximal to which it divides into five bands, one for each toe. These are united by the transverse and oblique fibres where they diverge (5.106A)



5.105 The synovial sheaths of the tendons at the right ankle: medial aspect.

5.106A The plantar aponeurosis of the left foot.



below the metatarsal shafts. Proximal, ventral and a little distal to the metatarsal heads and their joints a superficial stratum of each band is connected to the dermis by *skin ligaments* (*retinacula cutis*), which reach the skin proximal to, and in the floors of, furrows separating the toes from the sole (5.106D). Proximally the retinacula are condensed to form a sagittal septum but distally diverge into numerous bundles and lamellae; these intersect at right angles bundles of the plantar interdigital ligament (superficial transverse metacarpal ligament, vide infra). A deep stratum of each digital band divides into *two septa* flanking the digital flexor tendons and separating them from the lumbrical muscles and digital vessels and nerves. These septa diverge and fuse with interosseous fascia, deep transverse metatarsal ligaments, plantar ligaments of the metatarsophalangeal joints and the periosteum and fibrous flexor sheaths at each proximal phalangeal base. In webs between the metatarsal heads and bases of the proximal phalanges pads of fat are developed, cushioning the digital nerves and vessels from the tendinous structures and extraneous plantar pressures. These four *fat pads* are tied by *vertical strands* from the digital fibrous flexor sheaths to the superficial stratum of the plantar aponeurosis and thus to the skin. Distal to the metatarsal heads a *plantar interdigital ligament* (superficial transverse metatarsal ligament) blends progressively with the *deep* aspect of the superficial stratum as it enters the toes (5.106C,D). The central plantar aponeurosis is thus an intermediary between the *pedal skin* and the *osteoligamentous* skeleton, joints and tendon sheaths through numerous *cutaneous retinacula* and *deep septa* extending to the metatarsals and phalanges. It is also continuous with its medial and lateral parts, at which junctions *medial* and *lateral intermuscular septa* extend in oblique vertical planes between medial, intermediate and lateral groups of plantar muscles to reach the bone (vide infra). Thinner *horizontal intermuscular septa* pass between muscle layers from these vertical septa.

The *lateral part* covering the abductor digiti minimi is thin distally, thicker proximally where it is a strong band, sometimes containing muscle fibres, between the calcanean tuberosity's

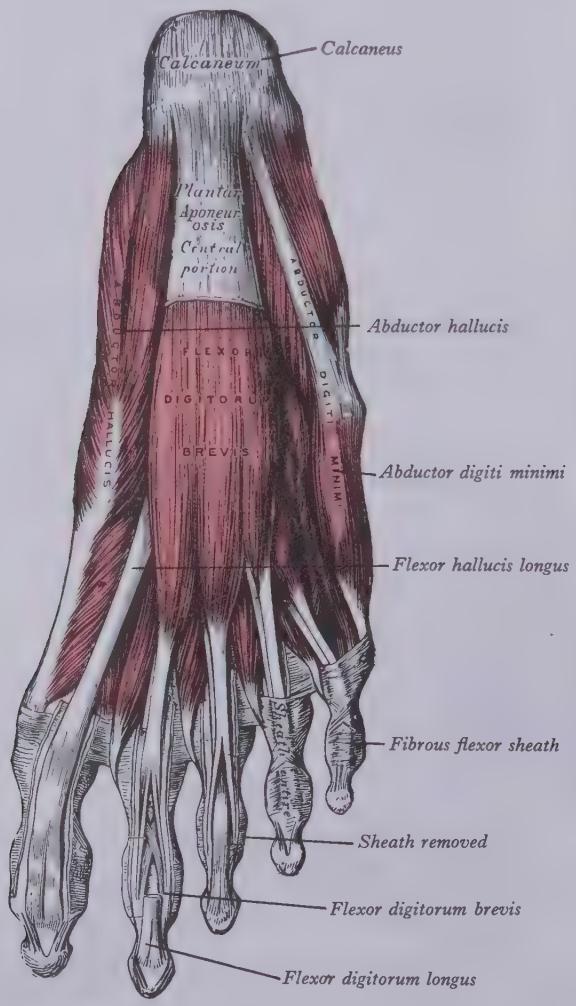
C

5.106C Transverse section through the heads of the second and third metatarsal bones showing the course of the collagen fibre bundles in the submetatarsal cushions and around the joints. Fat covers the fibrous flexor sheath inside the cushion; the digital nerves and vessels are lodged between the cushions.

D

5.106D Sagittal section through the second interosseous cleft showing the internal architecture of the three major areas of the ball of the foot. The sagittal septum is attached to the proximal phalanx through the transverse metatarsal ligament and the plantar ligament of the joint. The vertical fibres and the lamellae of the plantar interdigital ligament are attached to the proximal phalanx through the fibrous flexor sheath (from Bojsen-Møller & Flagstad 1976, by courtesy of the authors and the Cambridge University Press).

lateral process and the fifth metatarsal base; it is continuous medially with the central aponeurosis, laterally with the dorsal pedal fascia.



The *medial part* is thin, covers the abductor hallucis and is continuous proximally with the flexor retinaculum, medially (then curving dorsolaterally) with the fascia dorsalis pedis, laterally with the central aponeurosis.

The *lateral intermuscular septum* is proximally incomplete; but distally its deep attachments are to the fibrous sheath of peroneus longus and the fifth metatarsal bone. The *medial intermuscular septum*, also discontinuous, divides into bands, proximal, intermediate and distal, each with lateral and medial divisions, as it approaches its deep attachments. The *proximal band*, attached laterally to the cuboid, blends medially with the tendon of tibialis posterior; the *middle band* extends from both cuboid and long plantar ligaments to the medial cuneiform bone and the *distal band* divides to enclose the tendon of flexor hallucis longus and is also attached to the fascia over flexor hallucis brevis.

The plantar muscles form medial, lateral and intermediate groups, as in the hand, the medial and lateral comprising the intrinsic muscles of the hallux and minimus, the intermediate group including lumbricals, interossei and short digital flexors; but it is customary to describe them in four layers, as encountered in dissection. These 'layers' can be overemphasized; functionally the former grouping is more useful. Actions of all are discussed together on p. 656.

FIRST LAYER

This superficial layer (5.107) includes abductores hallucis, digiti minimi and the flexor digitorum brevis. All extend from the calcanean tuberosity to the toes, being in this case a functional group assisting in the maintenance of a concave sole.

5.107 The superficial plantar muscles of the right foot.

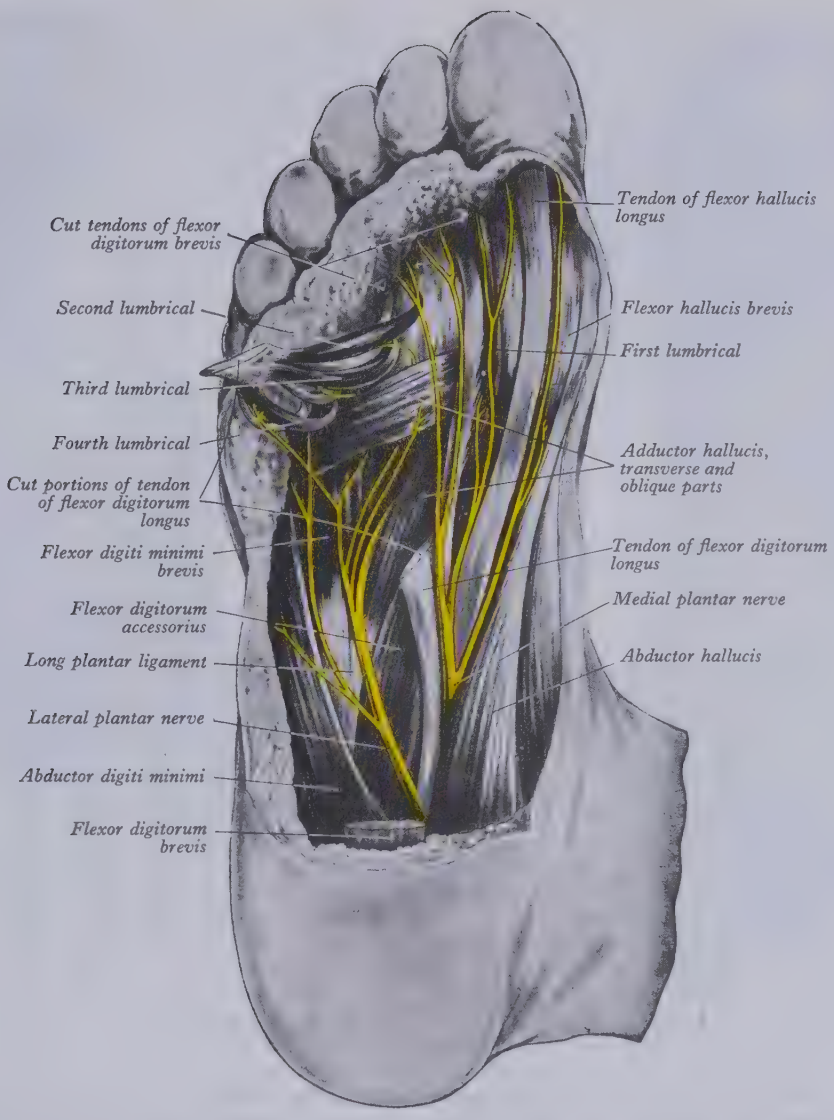
Abductor hallucis (5.107), lying along the foot's medial border, covers the origins of plantar vessels and nerves; it is attached proximally mainly to the flexor retinaculum but also to the medial process of the calcanean tuberosity, plantar aponeurosis and septum between the muscle and flexor digitorum brevis. Muscle fibres end in a tendon attached distally with the medial tendon of flexor hallucis brevis to the medial side of the proximal phalangeal base in the hallux; some fibres are attached proximally to its medial sesamoid; the muscle may derive some fibres from the dermis along the medial pedal border. It flexes and abducts the hallux.

Nerve supply: medial plantar nerve, S.2 and **3**.

Flexor digitorum brevis (5.107) is immediately superior (deep) to the central part of the plantar aponeurosis and separated from the lateral plantar vessels and nerves by a thin fascia. It is attached by a narrow tendon to the medial process of the calcanean tuberosity, and to the central plantar aponeurosis and adjacent intermuscular septa. It divides into tendons for the four lateral toes; at their proximal phalangeal bases, each divides into slips around a tendon of flexor digitorum longus; the two slips, their borders spirally reversed, then reunite, partially decussate, forming a groove (i.e. completing a tunnel) for the long flexor tendon. The short tendon divides again to attach to both sides of the intermediate phalangeal shaft. These details are identical to those in the hand but, of course, in miniature. The tendon for the fifth toe is often absent, sometimes replaced by a muscular slip from the *long* flexor tendon or flexor accessorius. Variations have been surveyed by Nathan & Gloobe (1974), comparing previous findings with observations on 100 feet, 63% of which showed variations, the slip to the fifth toe being most variable (63%), those to the fourth and fifth less so (10%), that to the second almost invariable. Variability from total absence to a supernumerary slip was noted, on occasion, in each toe.

Nerve supply: medial plantar nerve, S.2 and **3**.

Abductor digiti minimi (5.107), near the lateral border, its medial margin being related to the lateral plantar vessels and nerve, is attached to *both* processes of the calcanean tuberosity, the plantar surface between them, the plantar aponeurosis and the septum between the muscle and flexor digitorum brevis. Its tendon glides in a smooth groove plantar over the base of the fifth metatarsal and is attached laterally, with the flexor digiti minimi brevis, to the proximal phalangeal base of the minimus. Some *muscular* fibres from the lateral calcanean process usually reach the tuberosity of the fifth metatarsal (**3**.203), sometimes forming a separate *abductor ossis metatarsi digiti quinti*. An accessory slip from the fifth metatarsal base also occurs.



Nerve supply: lateral plantar nerve, S.2 and **3**.

Fibrous sheaths of flexor tendons (5.107). The terminations of the long and short flexor tendons are in osseo-aponeurotic canals, as in the fingers, formed by the plantar aspects of phalanges and *digital fibrous sheaths* over the tendons and attached to the phalangeal margins. In traditional accounts proximal and intermediate phalanges are often described as having across their shafts bands that are strong, their fibres transverse (*annular part*); but opposite joints they are thinner and the fibres decussate (*cruciform part*). (However, in recent researches on the fibrous flexor sheaths of *the fingers* Jones & Amis 1987 modified and amplified this account and added hitherto unrecognized features. Their ongoing investigations will necessitate a reappraisal of pedal arrangements. See comments on p. 618.) Each osseo-aponeurotic canal has a synovial lining reflected around its tendon; *vincula tendinum* are said to be arranged as in the fingers (p. 621); here again, the same reservations apply.

SECOND LAYER

This group comprises the flexor digitorum accessorius and four lumbrical muscles (5.108,109). Intimately associated with the intrinsic muscles of the second layer are the preterminal tendons of flexor hallucis longus and flexor digitorum longus.

Flexor digitorum accessorius (5.109) has two heads separated by the long plantar ligament. The medial, muscular and

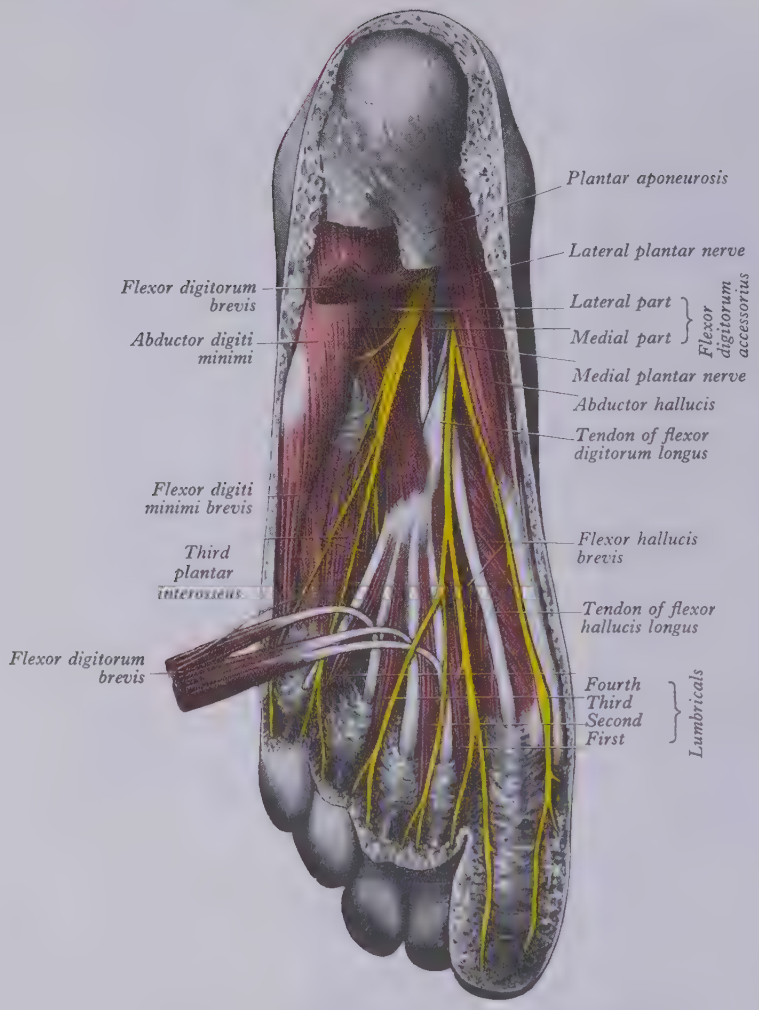
5.108 The plantar muscles and their nerve supply. Most of the flexor digitorum brevis has been removed. The flexor digitorum longus has been divided partially and its distal end has been turned forwards together with the second, third and fourth lumbricals.

larger, is attached to the medial concave surface of the calcaneus below the groove for flexor hallucis longus; the lateral, flat and tendinous, is attached to the calcaneus distal to the lateral process of its tuberosity and to the long plantar ligament. The medial head may end distally in a fibrous lamina, deep to the tendon of flexor digitorum longus, dividing into slips joining the long flexor tendons to the second, third and sometimes fourth digits; but almost as often it joins the lateral border of the long flexor tendon. The lateral head either joins this fibrous *lamina* on its superficial or lateral aspect or may fuse with the lateral border of the long flexor *tendon* (Lewis 1962), perhaps partially 'correcting' its diagonal vector. The muscle is sometimes absent and varies in the digits supplied; the slip to the fourth toe is often absent; a slip to the fifth sometimes occurs.

Nerve supply: lateral plantar nerve, S.2 and 3.

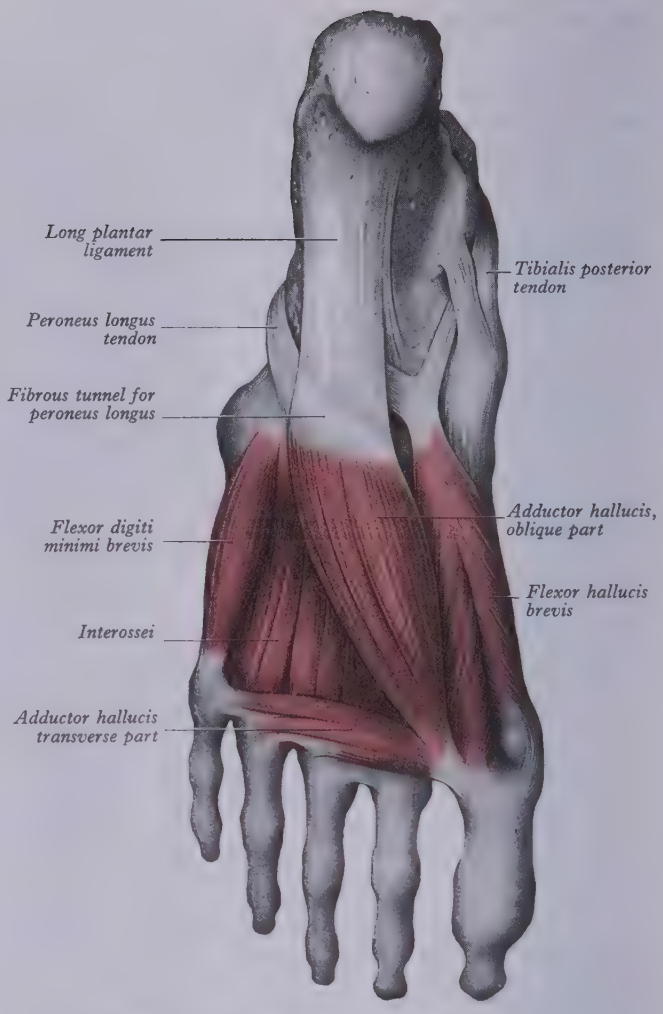
Lumbrical muscles (5.109) are four small muscles accessory to the tendons of flexor digitorum longus, numbered from the medial side. They arise along adjacent sides of the tendons from their angles of separation, except the first which is from the medial side only of the first tendon. The muscles end in tendons which pass distally on the medial sides of the four lesser toes to the dorsal digital expansions on their proximal phalanges.

Nerve supply. The first lumbrical is supplied by the medial plantar nerve, the rest by the deep branch of the lateral plantar nerve, S.2 and 3.



THIRD LAYER

This comprises the short intrinsic muscles of the hallux and minimus: flexor hallucis brevis, adductor hallucis and flexor digiti minimi brevis (5.108,110), the deepest in the sole, except for the interossei which are superior to them.



Flexor hallucis brevis (5.110) has a bifurcate tendon, its lateral limb attached medially on the plantar surface of the cuboid proximal to the groove for peroneus longus and to the adjacent part of the lateral cuneiform; the medial limb has a deep attachment continuous with the lateral part of the tendon of tibialis posterior and a more superficial attachment to the middle band of the medial intermuscular septum (Lewis 1964). Its belly divides into medial and lateral parts whose twin tendons reach and attach to the sides of the base of the proximal hallucial phalanx, a sesamoid bone usually embedded near each attachment; the medial part is blended with abductor hallucis, the lateral with adductor hallucis as they reach their attachments. Accessory proximal slips from the calcaneus or long plantar ligament may occur; a tendinous distal slip may reach the second toe's proximal phalanx.

Nerve supply: medial plantar nerve, S.2 and 3.

Adductor hallucis (5.110) has oblique and transverse parts. The *oblique head* springs from the second to fourth metatarsal *bases* and the fibrous sheath of the tendon of peroneus longus, the

5.109 The plantar muscles of the left foot: first and second layers.

5.110 The plantar muscles of the left foot: third layer.

transverse head from the plantar metatarsophalangeal ligaments of the third to fifth toes (sometimes only the third and fourth) and from the deep transverse metatarsal ligaments between them. The oblique head has medial and lateral parts: the medial blending with the lateral part of flexor hallucis brevis and attached to the lateral hallucial sesamoid bone; the lateral part joins the transverse head and is also attached to the lateral sesamoid bone and directly to the base of the first hallucial phalanx. According to Cralley et al (1976) the transverse part is sometimes absent (3 out of 50 feet dissected); they could not identify a phalangeal attachment for the transverse part; fibres failing to reach the lateral sesamoid were attached with the oblique part. Part of the muscle may be attached to the first metatarsal, as an *opponens hallucis*; a slip may also reach the proximal phalanx of the second toe.

Nerve supply: deep branch of lateral plantar nerve, S.2 and **3**.

Flexor digiti minimi brevis (5.110), proximally attached to the medial plantar surface of the fifth metatarsal base and sheath of peroneus longus, has a distal tendon attached laterally on the proximal phalangeal base of the minimus. Some deeper fibres may end on the lateral and distal half of the plantar surface of the fifth metatarsal bone as a distinct *opponens digiti minimi*.

Nerve supply: superficial branch of lateral plantar nerve, S.2 and **3**.

FOURTH LAYER

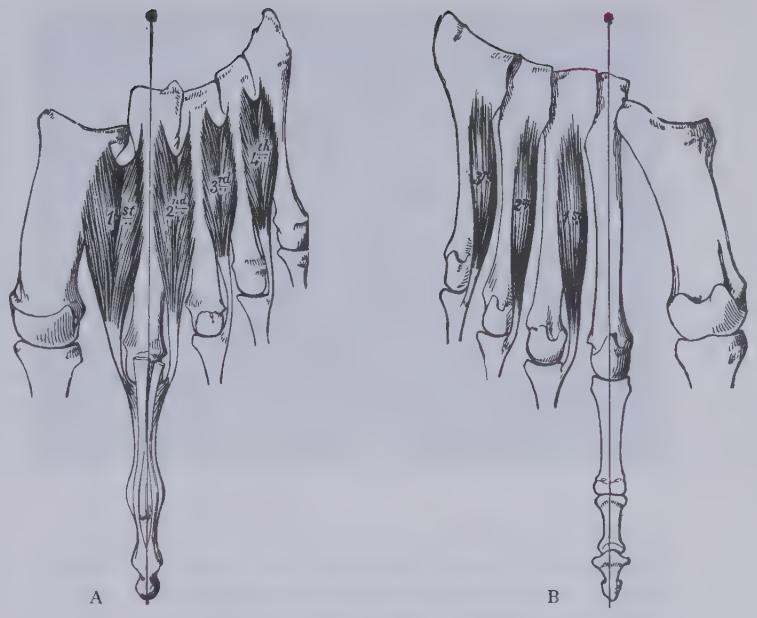
This comprises plantar and dorsal **interossei**, resembling those in the hand but arranged relative to an axis through the *second* digit, not the third as in the hand, this having the least mobile metatarsal bone.

Dorsal interossei (5.111A), between the metatarsal bones, are four bipennate muscles, each with two heads from the sides of adjacent metatarsal bones; their tendons are attached to the proximal phalangeal bases and dorsal digital expansions, the first on the medial side of the second toe, the others on the lateral sides of the second to fourth toes. In angular gaps between the proximal heads of each of the lateral three a perforating artery passes dorsally through the same space that in the first muscle transmits the arteria dorsalis pedis to the sole.

Plantar interossei (5.111B) are *inferior* to their metatarsal bones, each of the three being connected to one metatarsal. They pass from the bases and medial sides of the third to fifth, passing to the medial sides of the proximal phalangeal bases of the same toes and to their dorsal digital expansions.

Nerve supply. The dorsal and plantar interossei are supplied by the deep branch of the lateral plantar nerve (S.2 and **3**), except in the fourth interosseous space, where the supply is its superficial branch. The first dorsal interosseous often has an extra ramus from the medial branch of the deep peroneal nerve from the pedal dorsum, and the second a ramus from its lateral branch.

ACTIONS OF INTRINSIC MUSCLES IN THE FOOT



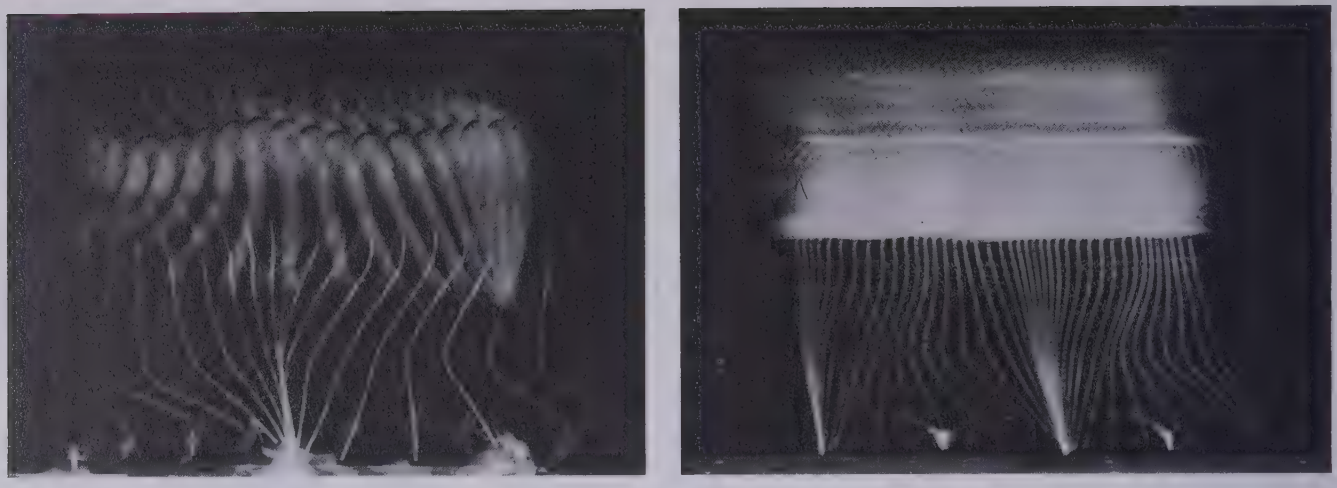
As elsewhere the actions of pedal muscles, or at least their potentialities, can be deduced from the geometry of their fascicular architecture and attachments, as the names applied to some indicate. But purely structural deductions must take into consideration the modifying effects of contact with the ground; they are unlikely to provide more than suggestions of the actual roles of individual muscles in particular activities. Direct observation, by eye or touch, is difficult; even with electromyography only crude data are available, from very few experiments. Despite some attractive speculation (p. 657), much uncertainty persists, as attested by the volume of controversial literature on pedal function.

There are two major conditions in which intrinsic musculature may aid or modify the effects of muscles operating from the leg: these are standing still and maintaining progression. In standing, with feet flat on the ground they are platforms for the distribution of weight, the body's centre of gravity being maintained above them by adjustment of tension and length in the leg and trunk muscles. It might be supposed that the largely longitudinal muscles in the sole would then be sustaining its arches against the flattening effect of body weight; this has long been a canon of anatomical teaching, despite increasing doubts amongst clinical and experimental observers. All evidence from such sources, though limited, indicates that ligamentous ties, including the plantar aponeurosis, are largely sufficient. Similarly, intrinsic muscles, especially abductors and short flexors, have long been believed to exert a 'tonic' effect, steadying the toe pads on the ground. Electromyographic evidence, admittedly scant, contradicts this; simple observation shows that the toes can easily be extended out of contact with little adverse effect upon pedal efficiency in standing. Suzuki (1972), in a study of normal and flat-footed individuals, found the intrinsic muscles relatively inactive in the normal when standing, but active in the flat-footed, as were the long arch-supporting muscles such as peroneus longus.

When the heel is lifted in beginning a stride, in walking or running, all weight and muscular thrust is transferred to the forefoot region of the metatarsal heads and toe pads. This changes the foot from platform to lever, intensifying the forces acting on the forefoot, especially in running and jumping. So much argument has been extended on the nature and behaviour of 'arches' in the foot and on the agents, muscular and ligamentous, which can or do act as 'tie-beams' across them, that the foot's basic role as a lever has been obscured. It appears ill-suited to act as such, being a series of links, though its arched form has good mechanical precedents. As the heel lifts, the sole's concavity is accentuated; electromyographic evidence available shows the intrinsic muscles to be strongly active. This might slacken the plantar aponeurosis, but dorsiflexion of the toes must tighten it. The foot is also inverted and supinated and close-packing of the intertarsal joints is reached as the foot takes the full effects of leverage, losing its pliancy (Inman 1969). The toes are thus held extended at metatarsophalangeal and distal interphalangeal joints and flexed at proximal interphalangeal joints, including that in the hallux. This probably results from contraction of the long and short digital flexors, by drawing terminal phalanges towards the sole and passively buckling the toes into the position just described. Buckling is perhaps controlled by the lumbrical and interosseous muscles, by opposing extension at the metatarsophalangeal and flexion at the proximal interphalangeal joints. Flexor hallucis brevis could prevent excessive extension at the hallucial metatarsophalangeal joint. Abductors of the hallux and minimus act as flexors, with probably little abductor effect, though their geometry varies. Analyses such as this are speculative; in view of the difficulties of electromyography in active feet, present uncertainties may long persist (p. 659). Various imbalances in the actions of toe muscles are held to explain dysfunctions and deformities, such as contracted toes. Actual observation is rare; an evaluation of the weights of lumbrical muscles has shown no correlation with toe contractures (Challey et al 1975).

STANDING, WALKING AND RUNNING

Though birds are in a sense bipeds, as are some reptiles and eutherian mammals, only the human primate has evolved a completely habitual upright posture. Some animals, particularly other primates, may adopt it for considerable periods, but none has reached the degree of specialization as has human adaptation to continuous upright standing and locomotion. Human erect posture is often described as if attained at the cost of such painfully difficult evolution that it is still a precarious habit, prone to all manner of defects and pathology, perhaps due to the influence of medically orientated thinking. A full upright posture existed in most, if not all extinct hominids, foreshadowed in other primates for an even greater period of time. The disadvantages of the quadrupedal habit do not appear to have attracted similar veterinary attention!



5.111 The interossei of the left foot. A. Dorsal interossei viewed from the dorsal aspect. B. Plantar interossei viewed from the plantar aspect. The axis to which the movements of abduction and adduction are referred is as indicated.

In *posture* the human primate is singular, if not unique, in having straightened the trunk and lower limbs enough to bring the centre of gravity above the joints on which weight impinges; even the head is largely balanced upon the cervical spinal column. A vertical from the centre of gravity (about a centimetre posterior to the sacral promontory) is anterior to the ankle joints. Strong plantar flexion, particularly by the soleus, is hence needed to prevent forward sway or actual falling. But in most individuals standing in a symmetrical manner, the same vertical is so related to the hips and knees that gravity tends to *increase* their extension, partly opposed by ligamentous structures (associated with a nearly close-packed position of the joints, p. 483), rather than by muscle activity. Such a posture, often maintained for long periods, thus requires minimal muscular activity (Akerblom 1948, Joseph 1960), except for brief bursts in appropriate muscle groups when the body sways from it. The standing position is often changed, intermittently relieving stress on ligaments by transferring it to the muscles (Smith 1950), a common habit being to hyper-extend one knee and slightly flex the other; one leg and then the other takes the major stress of body weight, the slightly flexed leg acting temporarily as a prop. Evans (1977) has emphasized the use of the iliotibial tract in achieving and sustaining the 'locked' hyper-extended (close-packed) posture of the weight-bearing leg in asymmetrical standing. The line of gravity is related to spinal curvatures in such a way that they are largely exaggerated by gravity, but controllable by small muscular tensions. However, over details controversy persists. Swaying of the trunk above the pelvis entails not only responsive activity in the leg muscles but also in those of the trunk, such as psoas major, when the body sways back.

Energy-sparing by using gravity to hyperextend (or sometimes flex) joints is applied in some birds, such as the upright penguin, and passerine birds which perch in trees. It is regarded as unique in man among mammals, but many quadrupeds also habitually stand for even more prolonged periods, apparently without great effort (and much less complaint than the human biped).

In *locomotion*, whether walking, running, jumping or climbing, the economical pattern of standing at once ceases. All the muscles of the trunk, arms and legs may be involved, as prime movers, fixators or stabilizers. Arms are swung as balancers and as weighted pendulums to increase the impetus, especially in running and jumping; their use in climbing is obvious.

In studies of locomotion (vide infra) attention has been largely on an analysis of walking movements and the temporal sequences

A B

5.112 Chronocyclograms of two individuals walking relatively fast. In A the support phase, with one foot on the ground, occurs at midpoint of the recording, which occupies one full cycle. In B two such support phases are apparent and the recording occupies somewhat less than two cycles. The bright lines are successive images of a stripe attached to the trousered leg proximal to the camera. Note the concentration of lines at the support phase and also the varying angulation at hip, knee and ankle. (Photographs supplied by D W Grieve, Department of Anatomy, Royal Free Hospital Medical School, London.)

of contraction and relaxation in the muscles involved. As the first step is taken from standing, the trunk leans forwards with the feet slightly inverted and the longitudinal arches accentuated (p. 543). One heel is lifted, transferring the weight progressively along the lateral border of the opposite foot to the metatarsal heads and toes. This is *stance phase*, passing into *swing phase* as soon as the foot leaves the ground, which it then again meets in reverse order, heel first and then a repetition of the roll forwards on to the toes. From one heel's impact to the next is termed a *walking cycle*, which alternates in the legs.

The **stance phase** has been variously analysed (Barnett 1956, Gray & Basmajian 1968, Elftmann 1966); it is essentially a continuous process of weight transference from the heel to the toes, especially the hallux. These pedal movements should not be viewed in isolation; the whole body moves laterally above the leg that is in stance phase, the body's centre of gravity shifting variably (on average about 5 cm). Simultaneously the ipsilateral arm begins to swing forwards with the contralateral leg; the pelvis, at first rotated 'forwards' on the stance side (i.e. relative lateral rotation of the stance femur, its hip being in advance), now advances on the opposite side with an accompanying forward swing of the opposite leg. The foot is fixed on the ground, and hence, as the knee extends and the ankle dorsiflexes, the tibia *rotates medially*, taking the talus with it, and the femur undergoes obligatory conjunct medial rotation at the knee (p. 530) and hence also at the hip joint, medial femoral rotation being accentuated by the pelvic rotation in the opposite direction, as mentioned above. This sequence of congruent medial rotations, combined with dorsiflexion and transient supination of the subtalar skeleton (p. 542), brings all articulations in the leg and foot near to their close-packed positions. The resulting momentary rigidity coincides with maximal thrust by the powerful plantar flexors. Thereafter, as the heel rises again, the foot passes into plantar flexion and pronation, thrust now being transmitted through a loosely packed pliant lever to the head of the first metatarsal and dorsiflexing the hallux, which finally leaves the ground to end the stance phase. (The above should be compared with the analysis of movements of the pedal skeleton, pp. 542–544.)

In the **swing phase** the toes leave the ground as the opposite heel meets it, to transfer support; the leg, relieved of weight bearing, swings forwards with flexion at the hip and knee, dorsiflexion of the foot and lateral rotation of all elements which had undergone congruent medial rotation during their previous stance phase. The swing is pendular, by the hip flexors. As the limit of stride is reached, momentum is overcome by the hip extensors to bring the heel to the ground, to start another cycle.

These events are more rapid than can be described, but this analysis is supported by cinematographic records, from which, of course, it is partly derived. The role of many muscles involved has been investigated at every stage, but details should be sought in original studies (e.g. Alexander 1983,1984).Speed in walking can be increased by augmenting work by the muscles involved and acceleration of their actions. In running, the movements are similar but the heels do not touch the ground, thrust being entirely by the forefoot. Moreover, the body is carried forwards by its momentum *entirely unsupported* between take-off from one foot and descent on the other. A similar unsupported phase characterizes hopping. In jumping, take-off may be from one foot or two, simultaneously or in quick succession; landing is similar.

In all progression, the forces involved are gravitational, inertial and muscular, the latter varying from minimal exertion, sustainable over long periods, to maximal effort for briefer periods; but reliable estimates of the relative expenditures of energy are few.

MECHANICAL ANALYSIS OF LOCOMOTION

The mathematical analysis of the mechanics and energetics of locomotion, studied in many animals including invertebrates, has advanced rapidly. (For introductory literature consult Alexander & Goldspink 1977.) Locomotion in many vertebrates has been analysed, particularly in mammalian quadrupeds. Basic data are usually cinephotographic and force platform recordings (Alexander et al 1977), but X-ray cinephotography and electromyography (Wentink 1976) have also been used. Bipedal locomotion has been studied in amphibia, marsupials and primates including mankind. A most interesting result is confirmation of the storage of recoil energy in muscles *and* tendons (Alexander & Bennet-Clark 1977, Alexander 1984a). Cinematic analysis of human walking and running has already contributed to phasic analysis, as noted above, but mathematical studies go further in accounting for the forces concerned. For example, it is possible to predict a limiting optional velocity for walking, beyond which it becomes more economical, in terms of muscle energetics and oxygen consumption, to introduce a 'floating' phase with a change to running. Elastic recoil in human tendons has been studied by combined light and X-ray cinephotography, but reliable data are lacking. A mathematical interpretation of locomotor mechanics has also renewed interest in bodily proportions, especially those in limbs, which are necessary data for such analyses (McMahon 1977). Not only the dimensions of limb bones relative to body size and weight, but also the strength and proportions of osseous segments and muscle masses have become basic data in comparative mechanical studies of gait (Alexander 1984b). The arrangement of fibres in muscles has acquired renewed significance in quantitative analysis (e.g. Alexander & Vernon 1975). Coordination of such data into even general concepts of quadrupedal or bipedal

locomotion is inevitably complex; but progress has been rapid and highly interesting; valuable results are to be expected. For a discussion of the optimal techniques in bipedal walking consult Alexander & Jayes (1978).

The foregoing largely concerns analyses of electromyographic and cinematographic recordings in which data are interpreted qualitatively rather than quantitatively. Some workers (e.g. Grieve & Cavanagh 1974) have made efforts to quantify electromyograms with improved accuracy by computerized techniques, coupled with accurate measurement of cinematic records obtained simultaneously in two or three cardinal planes. Since a temporal parameter is involved, and measurable from recordings, detailed analysis of angular displacements between the segments of limbs in walking (and speeds of movement in each segment) can be undertaken. The data obtained can be integrated by appropriate programmes and may also be graphically illustrated. Such integrated graphs of cycles of movements, in space and time, are '*chronocyclograms*'. So-called 'heel-strike' and 'toe-off' points in a cycle are commonly chosen as datum points. Chronocyclography (5.112) has already demonstrated changes in pattern with alternation of speed in walking; comparisons between events in 'normal' records with those in patients afflicted with locomotor disturbances can be made. These developments have facilitated and refined the description of abnormal gaits; it was hoped that they would have applied value but in their original form the techniques are lengthy and tedious. It has been further improved by Grieve and co-workers (1979) by a computer evaluation of cycles of angular change in thigh and foreleg segments, the angles being recorded by impingement of a rotating beam of plane-polarized light upon sensors attached to the limb segments. Since the signals produced by this polarized light goniometer are passed to a suitably programmed computer, a graphic recording is *immediately* available of the subject's angulation cycle in stepping or walking. This renders the technique clinically applicable. A stroboscopic method of recording has also been used; the records shown in 5.112A,B illustrate the cycle in walking.

GRAY'S ANATOMY

ANGIOLOGY

6

Introduction

All cells live within the body in a fluid environment upon the stability of which, in terms of physico-chemical characteristics, each cell is dependent for its normal functioning. This fluid environment, whilst being maintained at a steady state within certain limits, also allows for the diffusion of metabolites between cells and between the external and internal environments. In small animals with a relatively simple type of organization, unaided diffusion is rapid enough for nutrients, gases and waste materials to pass to and from the individual cells to satisfy their metabolic demands. In more complex animals diffusion is assisted by the muscular movements of the body and in larger and yet more complex forms, particularly those with a coelom which interrupts the continuity of the tissues, a system of cell-lined tubes separates the body fluids into blood, confined within the tubes and able to circulate by muscular propulsion, and tissue fluid lying in the extracellular spaces outside the tubes. The coelom forms a third compartment which also possesses the function of a circulatory system in some groups of invertebrates. In the vertebrates a fourth division is added in the form of the medullary cavity of the central nervous system which contains the cerebrospinal fluid (p. 1090). A fifth compartment is provided by a system of further vessels which are cell-lined lymphatics, returning some of the tissue fluid to the blood circulation.

In animals with a true blood vascular system (p. 682) a high level of circulatory efficiency is possible. The system of cell-lined tubes also allows for the segregation within the circulation of some elements such as respiratory pigments able to store and carry oxygen and often carried within special cells, as in vertebrates; also present are various types of defensive cell, many migrating into the tissues when required, so achieving rapid access to all parts of the body, and other large molecules such as polysaccharides and proteins, which may gain only limited entry to the tissues. With the development of a pumped circulation the hazard of leakage from damaged vessels is increased; various cellular and chemical *haemostatic* mechanisms ensure that such blood loss is limited.

In mammals most tissues are served by an extensive blood supply circulating by way of the heart through arteries, arterioles, capillaries, venules and veins (p. 684). The capillaries form the main site of exchange by diffusion between blood and tissues. Most cells lie within a few tens of microns of a capillary, active tissues receiving a richer and more intimate supply than less active ones. Some tissues, however, are not penetrated directly by capillaries and diffusion gradients may be several hundreds of microns in length; such tissues are cartilage, some epithelia and the connective tissue of the cornea and dentine.

HAEMAL AND LYMPHOID TISSUE

Before consideration of the detailed organization of the vascular channels, the biology of the circulating cellular components of the blood and lymphatic systems and their development in the bone marrow and lymphoid tissue will be outlined. Collectively, these various cells constitute the **haemolymphoid system**, a complex array of cells and tissues which are closely interdependent in their origins and functions in the body. The **haemal** component, arising in the bone marrow, provides: *red cells* (*erythrocytes*) which carry oxygen and to a lesser extent carbon dioxide between the lungs and general tissues; a wide variety of defensive cells, *leucocytes*, including the *neutrophil*, *eosinophil* and *basophil granulocytes*, and *monocytes* (*macrophages*), engaged in a plethora of defensive activities, and *platelets* which assist in haemostasis. Of these cells, only two, erythrocytes and platelets, are generally confined to the blood vascular system once they have entered it from haemopoitic tissue. All leucocytes possess the ability to leave the circulation and enter the extravascular tissues, the numbers of cells so doing being greatly increased in local infections and other disease conditions. The **lymphoid** component includes cells which are formed both in the bone marrow and in many sites outside it: the thymus, lymph nodes, spleen and lymphoid tissue associated with the alimentary tract and bronchi (lymphoid nodules). These produce different varieties of *lymphocytes*, which in the blood are included among the leucocytes and like the others of this class are able to migrate into extravascular sites although, unlike haemal cells, lymphocytes may also be found within the channels of the lymphatic system. Lymphocytes are concerned with various types of defence and indeed are the main source of the body's ability to resist infections. Included in lymphoid tissue are various types of phagocytic cell which, with the monocytes in the blood and some other phagocytic cells in other tissues (e.g. macrophages), are often considered as a distinctive component of the body, the *mononuclear phagocyte system* (p. 668).

Tissue Fluid and Lymph

The walls of the vascular system are lined by endothelial cells (p. 683) which allow the free diffusion of water, ions, gases in solution and small organic molecules. Large molecules are mostly retained within the blood, although some leakage does occur. Water and dissolved substances pass into the extravascular space which lies between the tissue cells, being termed *tissue fluid*. Because of the relatively high pressure at the arteriolar ends of the capillaries tissue fluid is constantly being formed; some of this passes back into the venous end of the capillary and the post-capillary venules, which are at relatively low pressure, but the remainder passes into the neighbouring lymphatic vessels as *lymph*. The lymphatic vessels eventually return the lymph to the blood circulation via the thoracic duct or the right lymphatic duct; en route to these ducts, the lymph is filtered by its passage through successive lymph nodes (p. 822) and whilst in them it picks up a population of lymphocytes and macrophages. Blind-ending lymphatics in the villi of the small intestine contain lymph which picks up great quantities of lipid (chyle) absorbed across the intestinal mucous membrane during alimentation. This is added to the lymph (and eventually to the blood) as minute lipid droplets (*chylomicrons*) each about 0.2–1.0 μm in diameter, which may be seen using light microscopy with dark field illumination. The lymphoid tissue also adds proteins in the form of antibodies (*immunoglobulins*) to the lymph and hence to the bloodstream.

Characteristics of Blood

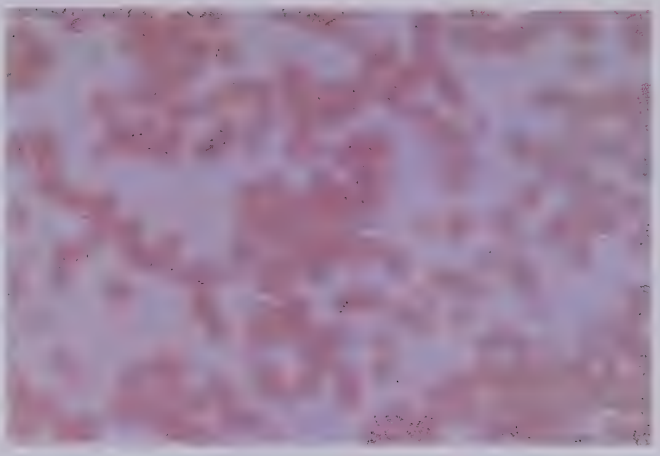
Blood is an opaque turbid fluid with a viscosity somewhat greater than that of water (mean relative viscosity 4.75 at 18°C), and a specific gravity of about 1.06 at 15°C. When oxygenated, as in the systemic arteries, it is bright scarlet and when deoxygenated, as in systemic veins, it is dark red to purple.

Blood is a heterogeneous fluid consisting of a clear liquid, *plasma*, and formed elements, *corpuscles*; because of this admixture it behaves hydrodynamically in a complex fashion and belongs to that class of fluids termed non-Newtonian. This characteristic has important consequences in the physical study of blood flow in vessels (haemorrheology).

Plasma

This is a clear, slightly yellow fluid which contains many substances in solution or suspension; the *crystalloids* give a mean freezing-point depression of about 0.54°C. Plasma is rich in sodium and chloride ions and also contains potassium, calcium, magnesium, phosphate, bicarbonate and many other ions, glucose, amino acids, etc. The *colloids* include the high molecular weight plasma proteins, composed chiefly of those associated with clotting, particularly prothrombin, the immunoglobulins and

complement proteins involved in immunological defence (p. 672) and glycoproteins, polypeptides and steroids concerned with hormonal activites. Since most of the metabolic activities of the body are reflected in the composition of the plasma, routine chemical analysis of this fluid has become of great diagnostic importance and a considerable body of information on its chemistry is available.



The formation of clots by the precipitation of the protein fibrin from the plasma is initiated partly by the release of specific materials from damaged cells and blood platelets (p. 668) in the presence of calcium ions. If blood or plasma samples are allowed to stand, clot formation occurs to leave a clear yellowish fluid, the *serum*. Removal of the available calcium ions by means of citrate, various organic calcium chelators (EDTA, EGTA) and oxalate prevents clot formation in vitro; heparin is also widely used as an anti-clotting agent, its action interfering with another part of the complex series of chemical interactions leading to fibrin clot-formation.

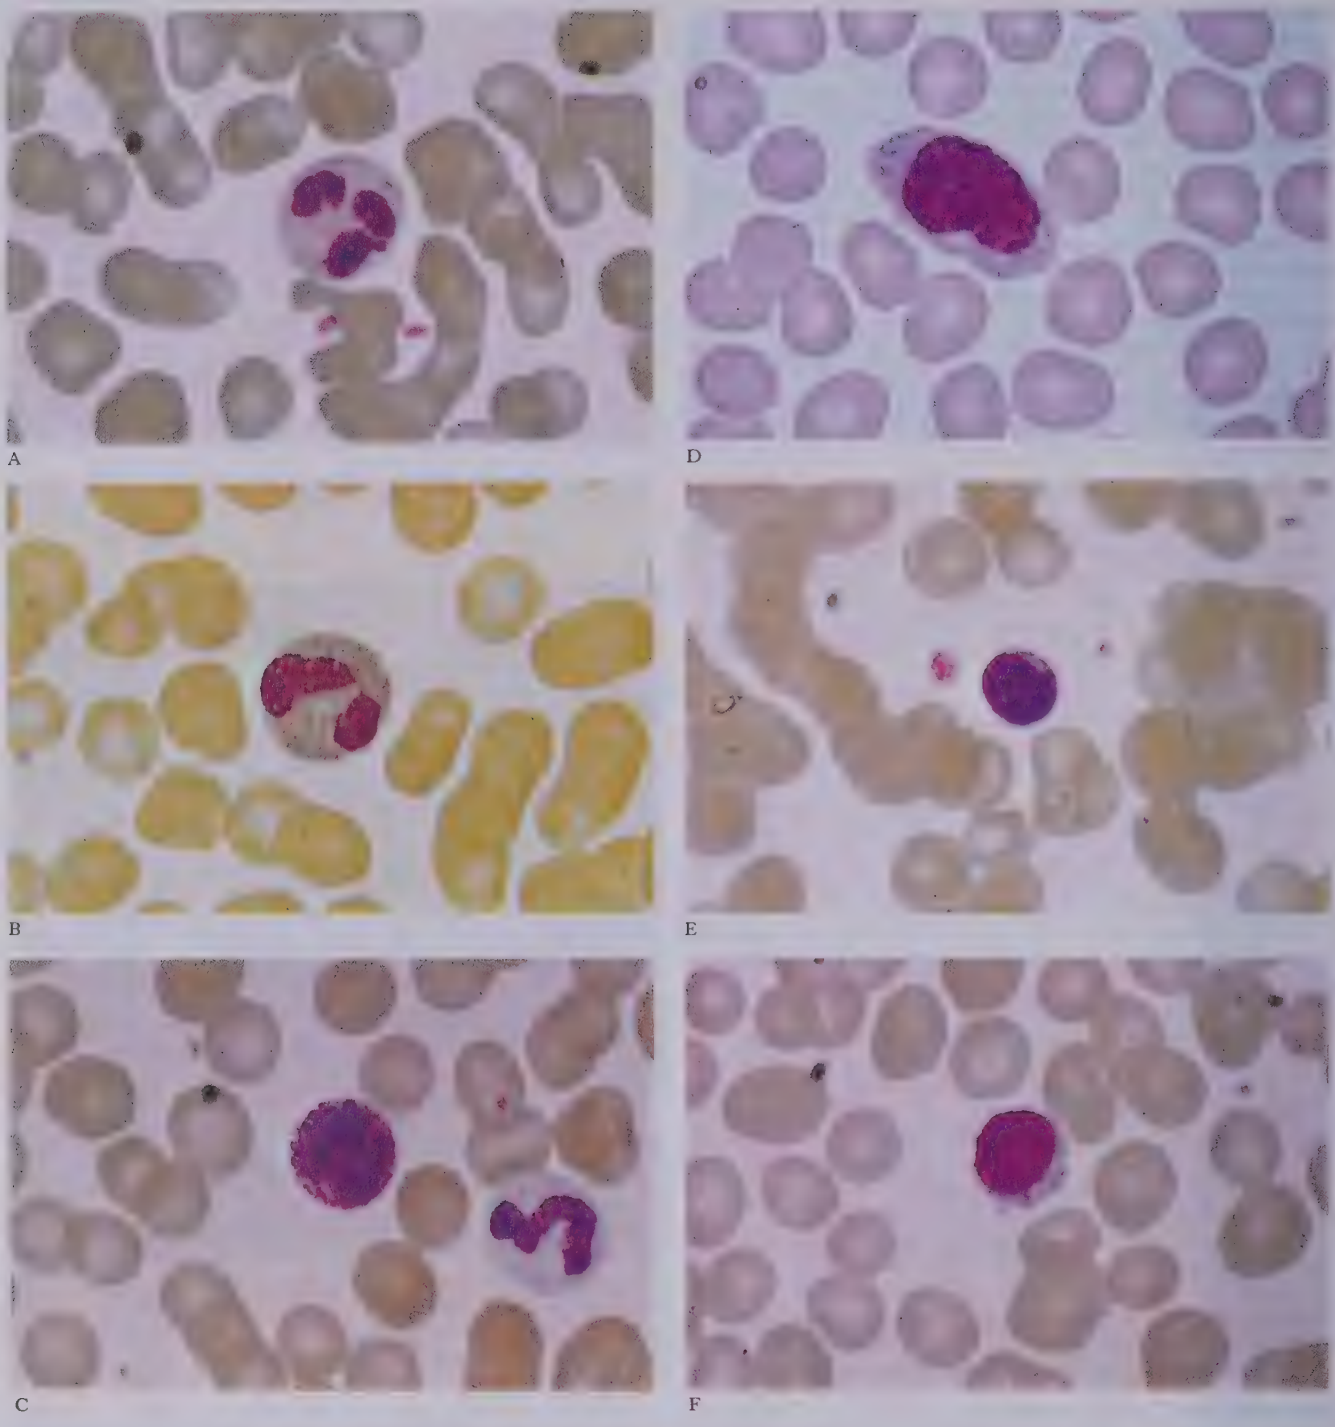
Blood as a Tissue

Blood has many affinities with connective tissue, as, e.g. in the mesenchymal origin of its cells, the free exchange of leucocytes with the connective tissues and the relatively low cell:matrix ratio. Many of the plasma substances and some of the cells, however, arise from a variety of sources (e.g. many of the proteins associated with clotting are formed in the liver) and so blood is really a composite tissue pool.

The Formed Elements of Blood

Blood contains three groups of formed elements: red and white blood corpuscles and platelets (see Wintrobe 1981, for a detailed description of these cells). Some structural aspects of these elements are visible in fresh blood, but many others are seen only in fixed and stained specimens. The examination of blood cells is of considerable clinical importance since their numbers, proportions of different cell types and structure are valuable indicators of pathological changes in the body. Amongst other techniques, the Romanowsky methods of staining are particularly valuable and are widely used in clinical laboratories. These methods involve staining in aqueous solutions with methylene blue-eosin mixtures which colour both acidic dye binding and basic dye binding structures. The Giemsa and Leishman stains belong to this group. (It should be noted that throughout this section, the figures given for cell dimensions and numbers are approximate ranges only. The data provided by different authorities vary somewhat; further, the dimensions of some cells when measured in the fresh state are substantially smaller than when measured in a dried smear; with erythrocytes the converse applies. In particular the upper limit for the diameter range of the small lymphocyte given here (10 μm) is rather higher than that chosen by some workers, who hold that cells over 8 μm in diameter should not be so classified. The differences stem from methodological and site variations and the somewhat arbitrary nature of the chosen dividing line.)

6.1 Fresh preparation of living erythrocytes showing rouleaux formation and red pigmentation. Magnification × 500.



6.2 A scanning electron micrograph of erythrocytes, showing biconcave discoidal and other shapes; the filaments are fibrin resulting from clotting of the plasma after extravasation of blood. Photographed by Michael Crowder, Guy's Hospital, London. Magnification × 1500.

Red Blood Corpuscles

The red blood corpuscles (*erythrocytes* or *red blood cells*) (**6.1–3**) form the greater proportion of the blood cells (99% of the total number), with a count of 4.1–6.0 × 10^6/μl in adult males and 3.9–5.5 × 10^6/μl in adult females. Each cell is a biconcave disc with a diameter of 6.3–7.9 μm (mean 7.1 μm) and a rim thickness of 1.9 μm; in wet preparations the mean diameter is 8.6 μm. Erythrocytes lack nuclei and are pale red by transmitted light with paler centres because of their biconcavity. They show a tendency to adhere to one another by their rims to form loose piles of cells (*rouleaux*), a character probably determined by the properties of their cell coat. In normal blood a few assume a shrunken star-like, *crenated* form (**6.1**), a shape which can be reproduced by placing normal biconcave erythrocytes in a hypertonic solution, which results in osmotic shrinkage. Such cells are called *echinocytes* (Bessis 1973). In hypotonic solutions erythrocytes take up water and become spherical and may eventually lyse to release their haemoglobin (*haemolysis*); they are then termed *red cell ghosts* (erythrocytic umbrae).

Erythrocytes are bounded by a plasma membrane and consist internally of a single protein, haemoglobin, apart from a few remnants from their initial development. The plasma membrane of erythrocytes has received much attention because of the ease with which it can be obtained for analysis in quantity (Bretscher & Raff 1975). It is about 60% lipid and glycolipid and 40% protein and glycoprotein. More than 15 classes of protein are present, including two major types. Firstly, the glycoproteins *glycophorins A* and *B* (each with an *Mr* of about 50 000) span the membrane, and its negatively charged carbohydrate chains project from the outer surface of the cell, conferring most of the fixed charge on the cell exterior by virtue of its sialic acid groups. Secondly, comes the 'Band 2' protein which may bear some antigenic groups; 'Band 3' protein is also a transmembrane macromolecule, composed of four subunits which fit together and leaving a central hole through which ions can pass, thus constituting the important chloride channels in the erythrocyte membrane; these protein assemblies are visible as intramembranous particles in freeze-fractured erythrocyte membranes (p. 1.12); the ABO antigens (p. 681) are

6.3 Blood cell types stained in smeared preparations by the Giemsa method. Erythrocytes are shown in all figures which also demonstrate other cell types: A. neutrophil leucocyte and platelets; B. eosinophil leucocyte; C. basophil leucocyte with prominent densely staining cytoplasmic granules and neutrophil leucocyte; D. monocyte; E. small lymphocyte; F. medium-sized lymphocyte. Material provided by J P Black, Department of Haematology, Guy's Hospital.

all glycolipids (Race & Sanger 1975). Other proteins include several enzyme systems, some concerned with ionic regulation, others with the addition of lipid to the cell membrane from serum lipid. (This is necessary because the cell does not possess its own synthetic apparatus.)

The shape of the eythrocyte is largely determined by the protein *spectrin* (a name which reflects its biochemical preparation from red cell 'ghosts') which is attached to integral membrane proteins (Band III) on the inner surface of the cell membrane via short lengths of actin filaments and other proteins (e.g. 'Band 4.2' protein, and *ankyrin*), forming a stabilizing network. This considerably stiffens the membrane, an effect which is aided by the large amount of cholesterol in the membrane itself. Red cells can thus regain their shape and dimensions after passing through the lumina of the finest ramules of the blood-vascular system; microscopic examination has shown that erythrocytes often pass through capillaries flattened face-first, buckling somewhat to a shield-like shape (Brånemark 1972) rather than rolling up, as might be expected.

Haemoglobin is a globular protein with a molecular weight of 67 000, consisting of *globulin* molecules bound to *haem*, an iron-containing *porphyrin* group (Perutz et al 1960). Each molecule is made up of four subunits, each in turn consisting of a coiled polypeptide chain with a cleft holding a single *haem* group. In normal blood, four types of polypeptide chain can occur, namely: α, β, γ and δ. Each haemoglobin molecule contains two α-chains

and two others, so that several combinations and hence a number of different types of haemoglobin molecule are possible. Haemoglobin A (HbA), which is the major adult class, contains 2 α- and 2 β-chains. Haemoglobin A_2 (HbA2), a minor component in adults, is composed of 2 α- and 2 δ-chains. Haemoglobin F (HbF), found in fetal and early postnatal life, consists of 2 α- and 2 γ-chains. In the pathological condition *thalassaemia* only one type of chain is synthesized, so that a molecule may contain 4 α-chains (β-thalassaemia) or, more commonly, 4 β-chains (α-thalassaemia) —Haemoglobin H (Wintrobe 1981).

Each polypeptide chain is determined by a separate gene; a number of variant haemoglobins are known in which only one or a few amino acid residues are abnormal, reflecting slight alterations in the corresponding genes. In the Haemoglobin S of sickle-cell disease a single alteration in the β-chains (valine substituted for glutamine) causes a major alteration in the behaviour of the red cell and its oxygen-carrying capacity which, however, may confer some protection against malarial infection, where the disease is endemic. Other common variants include Haemoglobins C and D. The oxygen-binding power of haemoglobin is provided by the iron atoms of the haem groups, and these are always maintained in the ferrous (Fe^{++}) state by the presence of glutathione.

In addition to haemoglobin, erythrocytes possess a number of enzyme systems, notably those concerned with glycolysis and ionic transport, which together maintain low sodium levels within the cell against diffusion gradients, and thus create the appropriate conditions of *p*H and ionic strength for the normal functioning of haemoglobin. As intimated above, glutathione metabolism is also active. Although, of course, in the absence of a nucleus and ribosomes, no protein synthesis takes place in mature erythrocytes, lipid in the plasma membrane can, however, be replaced to some extent from circulating serum lipids, by the activity of membrane enzyme systems.

The iron-containing compound *ferritin* is also often present in newly formed erythrocytes, as are also persisting remnants of the apparatus of protein synthesis (ribosomes and other RNAs) from the stage of differentiation of the cell in the bone marrow. After Romanowsky staining, the residual RNA of young erythrocytes causes a slight bluish tinge; with the supravital stain brilliant cresyl blue it forms a reticulum, giving the name *reticulocyte* to this type of cell. Later in maturation such evidences of basophilia disappear. Other inclusions may be present in red cells, particularly in pathological conditions; amongst these are nuclear remnants (*Howell–Jolly bodies*) and altered haemoglobin (*Heinz–Ehrlich bodies*).

Life Span and Destruction

Erythrocytes which have been labelled radioactively or antigenically and then injected into the circulation, have been shown to last between 100 and 120 days before being destroyed (Berlin et al 1959). As erythrocytes age they become increasingly fragile and their surface charge changes as their content of negatively charged membrane glycoproteins is progressively reduced (Marikovsky & Daron 1969). Perhaps as a result of the changes in charge they are eventually ingested by the macrophages of the spleen and liver sinusoids without previous lysis, and are then hydrolysed. Here, the haemoglobin is broken into its globulin and porphyrin moieties; the globulin is then further degraded into its constituent amino acids which pass to the general amino-acid pool of the body. The iron is removed from the porphyrin and can be used either directly in the synthesis of new haemoglobin in the bone marrow, or stored in the liver as ferritin or haemosiderin; the remaining haem portion is converted in the liver to bilirubin and is then excreted in the bile.

Red cells are produced by the bone marrow (p. 675) and are destroyed at the rate of about 5×10^{11} cells a day.

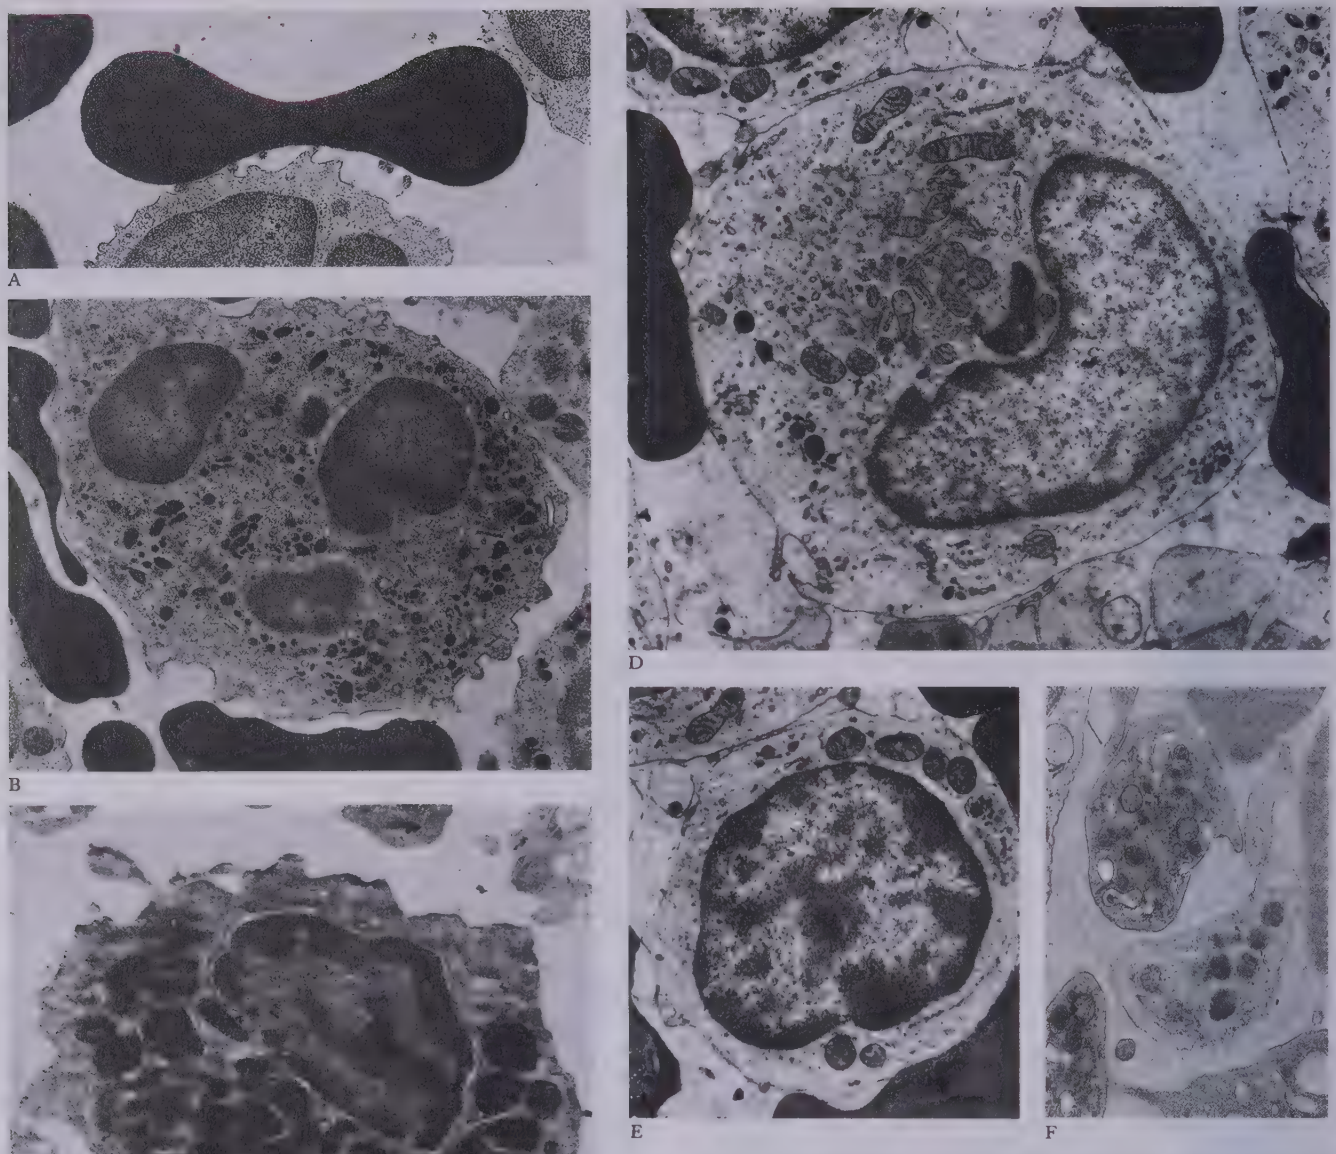
Fetal erythrocytes up to the fourth month of gestation differ markedly from those of adults, in that they are larger (10 μm), are nucleated and contain a somewhat different type of haemoglobin (Hb-F). From this time they are progressively replaced by the adult type of cell.

The Leucocytes

Leucocytes (*white blood corpuscles* or *cells*) belong to at least five different categories, distinguishable by their size, nuclear shape and cytoplasmic inclusions (**6**.3,4,8). For practical convenience, these types of cell are often divided into two main groups, namely those with prominent stainable cytoplasmic granules, the granulocytes, and those without, the agranulocytes. However, in terms of their biology, this distinction is now known to be quite arbitrary.

The granulocytes or *granular leucocytes* all possess irregular or multilobed nuclei and are often termed **polymorphonuclear leucocytes** for this reason. This group is comprised of three types of cell, the granules of which give different staining reactions with the Romanowsky dyes: they are *acidophil* (or *eosinophil*) leucocytes with granules which bind acidic dyes such as eosin, *basophil* leucocytes the granules of which bind basic dyes (methylene blue) strongly and *neutrophil* leucocytes whose granules stain weakly with both elements by a different type of reaction (see Wintrobe 1981, Zucker-Franklin et al 1981).

NEUTROPHIL LEUCOCYTES



Neutrophil polymorphonuclear leucocytes (*neutrophils, neutrophiles, heterophile leucocytes* or '*polymorphs*') form the largest proportion of the leucocytes (60–70% in adults, with a count of 3000–6000/μl). In dried smears, where the cells have flattened, they have a circular profile with a diameter of 10–15 μm. In the living state the cells may be spherical whilst passively circulating, but can flatten and become actively motile on contact with a suitable surface.

Within the cytoplasm the numerous granules give a variety of colour shades ranging from violet to pink when stained with Romanowsky stains such as Wright's and May-Grünwald-Giemsa, which are commonly employed in haematology. Under the electron microscope, too, the *granules* are heterogeneous in size, shape and content, but all are membrane-bound bodies containing hydrolytic and other enzymes. Two major categories can be distinguished according to their developmental origin and contents (Bainton et al 1971). Firstly, *non-specific* or *primary granules* which are formed early in neutrophil genesis (p. 680); these are relatively large (0.5 μm) spheroidal lysosomes containing myeloperoxidase, acid phosphatase and several other enzymes. With light microscopy they stain strongly with neutral red and azure dyes and are thus said to be azurophilic. Secondly, *specific* or *secondary granules*, formed a little later, assume a wide range of shapes including spheres, ellipsoids and rods. These contain several substances with strong bactericidal actions, including alkaline phosphatase, aminopeptidase, lactoferrin and also collagenase, all of which are lacking in the primary granules. The secondary granules, however, lack peroxidase and acid phosphatase. Some enzymes such as lysozyme are present in both. The presence of these granules correlates well with the phagocytic activity of neutrophils.

In *mature neutrophil* granulocytes the nucleus is characteristically multilobate with up to six segments joined by narrow nuclear strands (the *segmented* stage). Less mature cells have fewer lobes, the earliest to be released under normal conditions being *juveniles (band* or *stab cells)* in which the nucleus is an unsegmented crescentic band. In certain clinical conditions, even earlier stages in neutrophil formation with indented or rounded nuclei (*metamyelocytes* or *myelocytes*, p. 680) may be released from the bone marrow. In mature cells the edges of the nuclear lobes are often irregular; in females about 3% (range 1–17%) of the nuclei of neutrophils show a conspicuous 'drumstick' formation which represents the sex chromatin of the inactive X chromosome (*Barr body*) (see also p. 48).

Mitochondria, a Golgi complex, a sparse endoplasmic reticulum and glycogen are present in the cytoplasm. A conspicuous array of microtubules is often seen between the 'arms' of the nucleus, and it is interesting that locomotion of neutrophils is in the direction in which the free arms point.

Neutrophils form an important element in the defence systems of the body; they can engulf microbes and particles in the

See text for further details.

circulation and, after migrating between the endothelial cells lining capillaries or venules, can perform local phagocytosis in the extravascular tissues, wherever it is needed. The engulfing of foreign objects is followed by digestion through fusion of the phagocytic vacuole, first with the *specific* granules, the pH being reduced to 4.0 by active transport of protons, then with the *non-specific* (azurophilic, primary) granules, which finish the process of bacterial killing and digestion. The chemical reactions occurring in these events have been intensively studied and prove to be quite complex. They involve the oxidation and addition of halide (chloride and iodide) radicals to the engulfed materials by means of enzymic action (myeloperoxidase, etc.) which have the effects of denaturing their proteins and other macromolecules. Lysozyme and lactoferrin are also highly toxic to bacteria. These processes require atmospheric oxygen for successful completion, so that neutrophils active in defence have a high oxygen demand. Phagocytosis, or the release of granules, may be enhanced by the presence of antibodies attached to the surfaces of neutrophils which can bind specifically to target antigens, e.g. in a type of bacterium to which the body has previously been exposed. Opsonizing antibodies (*opsonins*, p. 672) coating the antigenic target may also promote phagocytosis. The antibodies in both cases are secreted by lymphocytes (p. 672), and the neutrophil granulocyte is just one in a series of defensive cells which form an interrelated system for the elimination of foreign materials from the tissues (**6.6**).

After phagocytosis, the neutrophil's cytoplasmic granules gradually become used up, so that a marked reduction in their number (degranulation) occurs. Granules may also be discharged from the surface of the cell when it is suitably stimulated, to damage or kill neighbouring organisms or cells.

The numbers of circulating neutrophils vary considerably, often rising during episodes of acute bacterial infection. They may circulate freely in the blood (the *circulatory pool*), or they may adhere to the walls of post-capillary venules and other vessels (the *marginal pool*) to re-enter the circulation when suitably recruited, e.g. during brief exercise or by exposure to noradrenalin. However, neutrophils are short-lived (half-life 7.5 hours); they may either be destroyed in the bloodstream, or pass through the endothelial walls to the extravascular tissues, engaging in defence;

alternatively, after entering various secretory ducts such as the bronchi, salivary gland ducts and the urinary tract, they are lost to the body.

EOSINOPHIL LEUCOCYTES

These cells (*acidophil leucocytes*) are similar in size, shape and motile capacity to neutrophils but are present only in small numbers in normal blood (100–400/μl). The granules of the cytoplasm are uniformly large (0.5 μm) and give the living cell a slightly yellowish colour; with Romanowsky stains they are uniformly orange to red. The nucleus has two prominent lobes connected by a thin strand. Ultrastructurally (Zucker-Franklin 1980, 1985), the cytoplasm is seen to be packed with specific granules (**6.4**) which are spherical or slightly ellipsoidal. Each of these bodies is bounded by a membrane and contains an amorphous material (the *matrix* or *externum*) in which is embedded a prominent crystal (the *crystalline core* or *internum*); in man the crystalline core shows a square lattice structure with a 4 nm repeat pattern. The matrix contains several lysosomal enzymes including acid phosphatase, ribonuclease, phospholipase and a myeloperoxidase unique to eosinophils. The crystalline core is composed of the characteristic *major basic protein*, with an *M*r of 9200; this protein contains a high ratio of arginine residues and gives the granules their strong eosinophilic staining properties. Apart from these granules, the cytoplasmic organelles are similar to those of neutrophil granulocytes.

Like other leucocytes, eosinophil granulocytes are able to pass into the extravascular tissues from the circulation when suitably stimulated. In small numbers they are typical constituents of the dermis and the connective tissue components of the bronchial tree, alimentary tract, uterus and vagina and thymic medulla. The total life span of these cells is a few days, of which about 30 hours is spent in the circulation and the remainder in the extravascular tissues.

The functions of eosinophils are not yet fully understood. Their ratio to other leucocytes rises greatly (an *eosinophilia*) in certain allergic disorders, and also in worm infestations, and their is now much evidence that they play an important part in the immune system, phagocytosing and inactivating antigen–antibody complexes and also various inflammatory substances, e.g. histamine and leukotrienes I and II; so they may be important in limiting the effects of these substances on the surrounding tissues. It has also been shown in vitro that they can attach themselves to and kill parasitic schistosome larvae which invade the circulation.

BASOPHIL LEUCOCYTES

Like other granulocytes, these are 10–15 μm in diameter (**6.3**), but form only 0.5–2% of the total leucocyte population of normal blood, with a count of 25–200/μl. Their distinguishing feature is the presence of large, conspicuous basophilic granules, varying in number from 10–100 per cell. The nucleus is somewhat irregular but not usually lobated, unlike those of the other granulocytes. Ultrastructurally, the basophilic granules are membrane-bound vesicles with densely stained contents showing a variety of crystalline, lamellar and granular inclusions. Heparin, histamine and several other inflammatory agents are contained in these granules, which closely resemble those of mast cells (p. 60). These substances are apparently associated with polysaccarides, since the granules are also positive to carbohydrate stains, e.g. periodic acid-Schiff (PAS) and Azure A, with which they are *metachromatic*, i.e. they stain a different colour from that of the dye. Their life span in the circulation is long (9–18 months in mice).

Although they resemble mast cells (Selye 1965) and, like these, are formed in the bone marrow, there is much evidence that basophils represent a different, albeit closely related cell line peculiar to the circulation, as shown by their reactions with monoclonal antibodies and differences in cell development (see also p. 681). Their functions in the circulatory system are at present rather obscure.

MONOCYTES

These are the largest of the agranular leucocytes (15–20 μm in diameter in smears) but they form only a small proportion of the leucocytes (2–8% with a count of 100–700/μl of blood). The nucleus, which is euchromatic, is relatively large and has a characteristic indentation on one side. The cytoplasm forms a wide rim around the nucleus, near the indentation of which lies a prominent Golgi complex and vesicles stainable with neutral red. Ultrastructurally (Cawley & Hayhoe 1973, Zucker Franklin et al 1981) many lysosomes are seen to be present, together with some peripheral rough endoplasmic reticulum. Mitochondria are quite abundant, reflecting the highly motile nature of the cell. Monocytes are actively phagocytic.

All of these characteristics are similar to those of macrophages. There is strong evidence that monocytes are mainly or all macrophages in the process of passing from the bone marrow, where they are formed, to the peripheral tissues via the bloodstream, these cells passing into extravascular sites through the walls of capillaries and venules. This topic is discussed further on p. 668–669.

LYMPHOCYTES

These cells (**6.3,4**) are the second most numerous type of leucocyte, forming 20–30% of their total number, i.e. 1500–2700/μl of blood. Like other leucocytes, they are also found in extravascular tissue, but they are remarkable in being formed in large numbers outside the bone marrow as well as within it. They therefore constitute a widely distributed *lymphoid* system (see p. 670 for a fuller description).

Until relatively recently, lymphocytes were regarded as cells of little functional importance, perhaps representing degenerative stages of some other type of blood cell. The work of Miller, Yoffey, Gowans and others in the 1950s showed that these cells play a vital part in the body's defences and since that time they have come to be a focal point of modern immunology (see e.g. Roitt 1984).

In the blood, the term 'lymphocyte' refers to agranular leucocytes 5–15 μm in diameter. This size range represents a heterogeneous collection of various lymphocyte types in different states of maturity and activity, as well as a small percentage of cells ('null cells') which are not apparently true lymphocytes at all but either related cells (e.g. natural killer cells) or some other quite different form, such as circulating haemopoietic stem cells. The various types and conditions of cells can now be at least partially separated by means of immunocytochemical techniques, involving the use of monoclonal antibodies (see p. 675) raised against different components of their cytoplasm. Where these detect specific macromolecules exposed at the surface of lymphocytes, living cells can also be separated into different classes by various techniques.

Small lymphocytes, which form the majority of lymphocytes in circulating blood, each contain a rounded densely staining nucleus, surrounded by a very narrow rim of cytoplasm. The nucleus contains dense, coarse bands of chromatin (a leptochromatic nucleus: *leptos* = a thread), and one or more small nucleoli. The cytoplasm stains slightly blue with Romanowsky dyes. Under the electron microscope (**6.4**), few organelles can be seen in the cytoplasm, apart from a small number of mitochondria, single ribosomes (monosomes), sparse profiles of endoplasmic reticulum and occasional lysosomes; these features indicate a low metabolic rate and such lymphocytes are said to be in the 'resting' phase. However, these cells are freely motile when they settle on to solid surfaces, and can pass between endothelial cells to exit from or enter the vascular system. They may make extensive migrations within the various tissues, including epithelia, even passing into the body's secretions such as saliva. *Larger lymphocytes* in the circulation are a mixture of very immature cells (lymphoblasts) capable of cell division to produce small lymphocytes, and maturing or mature cells which have become functionally active after stimulation of the immune system, e.g. by the presence of antigens. Both lymphoblasts and maturing cells are actively engaged in synthesizing proteins, and thus contain a

nucleus which is at least in part euchromatic, and a basophilic cytoplasm with numerous polyribosome clusters. The ultrastructure of these cells varies according to their class and will be described where appropriate (vide infra).

The life span of lymphocytes ranges from a few days to many years and so we can distinguish between *short-lived* and *long-lived* lymphocytes, the latter being of great significance in the mechanisms of *immunological memory* (see p. 674).

As already stated, lymphocytes can be divided into several functional and maturational classes, but two major groups exist in the circulation, designated **B-** and **T-lymphocytes** (or **B** and **T cells**), according to the histories of their cell lineages. These will be considered in detail in another place (p. 671). In normal blood, about 85% of the lymphocytes are T cells.

PLATELETS

Blood platelets, also known as *thrombocytes* (**6**.3,4), are relatively small (2–4 μm across) irregular or oval discs present in large numbers (250 000–500 000/μl) in blood. In fresh blood samples they readily adhere to each other and to all available surfaces, unless the blood is treated with citrate or other substances which reduce the availability of calcium ions. In Romanowsky-stained preparations, platelets show an outer clear zone (*hyalomere*) and an inner basophilic (or azurophilic) granular region (*granulomere*). Ultrastructurally (Cawley & Hayhoe 1973, Zucker Franklin et al 1981) each platelet is seen to be anucleate, unlike similar cells in submammalian vertebrates (for which the term *thrombocytes* is perhaps best reserved). Each platelet is surrounded by a plasma membrane bearing a thick glycoprotein-rich coat, responsible for the adhesive properties of platelets. Beneath the surface is a band of about 10 microtubules which runs around the perimeter of the cell and probably determines its shape. Associated with these are actin filaments, myosin and other proteins related to cell contraction. Within the cytoplasm are also mitochondria, glycogen, a few profiles of agranular endoplasmic reticulum, including some narrow tubular channels and tubular invaginations of the plasma membrane and various membrane-bounded vesicles. These vesicles include three major types, designated alpha, delta and lambda.

Alpha-granules are the most prominent, with diameters of up to 500 nm; they contain platelet-derived growth factor (PGDF), fibrinogen and other substances. In the smaller (300 nm) *delta*-granules are 5-hydroxytryptamine (serotonin), taken up and concentrated from the blood plasma, calcium ions, ADP, ATP and pyrophosphate. In the smaller (250 nm) lambda set, granules contain several lysosomal enzymes (Bentfield & Bainton 1975).

Platelets are important in haemostasis (the limiting of bleeding after injury to vessels) and a number of more general, systemic functions which at present are rather poorly understood. When a blood vessel is damaged, platelets first aggregate at the site of injury, assisting to staunch the wound with a *platelet plug*. Adhesion between platelets (agglutination) and to other tissues is a function of the thick platelet coat and is promoted strongly by the release of ADP and calcium ions from the platelets as a response to vessel injury. Then, substances released from the alpha-granules, together with factors released from the damaged tissues, initiate a complex sequence of chemical reactions in the blood plasma, leading to the precipitation of insoluble *fibrin* filaments, generating a three dimensional meshwork, the *fibrin clot*, to which more platelets adhere, inserting extensions of their surfaces (filopodia) deep into the spaces between the filaments, to which they adhere strongly. Next, the platelets contract (*clot retraction*) by actin–myosin interactions within their cytoplasm (p. 50), concentrating the fibrin clot and pulling the adhering walls of the blood vessel together, limiting further any leakage of blood. Eventually, on repair of the vessel wall, *clot removal* occurs as a result of complicated enzymic activities, including those of *plasmin* formed by plasminogen activators in the plasma, and probably assisted by lysosomal enzymes derived from the small (lambda) granules of platelets.

Platelets may also be involved in various other biological activities, e.g. they have receptors for class IgE antibody molecules which enable them to adhere to and damage antibody-coated targets by means of their lysosomal secretions. Platelet-derived growth factor is also a potent trophic substance in laboratory cell cultures and may also exert a similar effect elsewhere, e.g. in regenerating tissues after damage (see Longenecker 1985).

Cells of the Mononuclear Phagocyte and Lymphoid Systems

It has already been stated in the description of blood cells that certain leucocytes (monocytes and lymphocytes) have special, interdependent roles in the body's defences against infection and constitute two major systems of cells dispersed throughout the body, present both within and external to the vascular channels.

THE MONONUCLEAR PHAGOCYTE SYSTEM

This term, given by Aschoff in 1924, denotes a diffuse system of phagocytic cells present throughout the body, engaged in a wide range of activities concerned with defence and various 'housekeeping' functions in the tissues where they reside. It is in part equivalent to the *reticulo-endothelial system*, but for various reasons has superceded it in modern literature on this subject (see e.g. Roitt 1984).

Although all cells of the mononuclear phagocyte system are indeed capable of phagocytosis, this is only a part of their overall role in the body, for they also perform many other actions vital to the effectiveness of the immune system and the biology of many tissues of the body. A feature which all mononuclear phagocytes have in common is that their surfaces bear a unique group of Major Histocompatibility Complex molecules (class II MHC antigens, see p. 672) which enable them to interact cooperatively with lymphocytes (vide infra).

As an historical accident, the cells of this sytem were originally given different names according to their location: in connective tissue they include *macrophages* (histiocytes or clasmatocytes); in the liver, *littoral cells of the sinusoids* (*von Kupffer cells*); in the central nervous system, *microglial* cells; and in the meninges, *meningocytes*. They are termed *pleural, peritoneal, alveolar* and *splenic macrophages* in their respective sites and in the synovial joints the *types A* and *B synovial cells* (p. 475). In the blood they are *monocytes*. Cells with similar properties but having a highly branched form (*dendritic* and *interdigitating cells*) are also present in various regions (lymph nodes, lymph nodules, spleen, thymus, epidermis, see e.g. Hoefsmit 1982).

In subserous tissue of the pleura and peritoneum, macrophages often aggregate as *milky spots*, near small lymphatic trunks. In the spleen they also occur in clusters (*ellipsoids*) around the exits of small (penicillar) arterioles (p. 829). Macrophages may fuse to form large syncytia (*foreign body giant cells*) contacting large particles which are too big to be phagocytosed, or when stimulated by the presence of infectious organisms, e.g. tubercle bacilli (*epithelioid cells*). In some situations they appear to be relatively sedentary (*fixed macrophages*), whereas in others they can migrate freely within tissues, or can traverse endothelial linings of blood vessels and lymphatic vessels.

Origins of cell lineages. There is now much evidence that all cells of this system arise from stem cells in the bone marrow related to the production of the monocyte–neutrophil granulocyte line (the CFU-G/M stem cell, see p. 681); indeed it appears that monocytes represent blood-borne cells of these types circulating en route to their final tissue destinations, migrating into them through the endothelial walls of capillaries and venules. Once arrived they may undergo further limited cell division and may also move on to other sites, e.g. lymph nodes (p. 822). Their final form and activities are closely related to the nature of the tissues where they reside but its not yet known whether mononuclear phagocytes undergo this tissue-specific differentiation because of their environment or if it is predetermined in the bone marrow, the cells migrating selectively to their appropriate tissue. Osteoclasts and chondroclasts may also be in some distant way related to these cells, since they have several structural and functional similarities and also arise from stem cells in the bone marrow; however, for various reasons it appears unlikely that they originate directly from the monocyte lineage (see p. 295).

Functions of Mononuclear Phagocytes

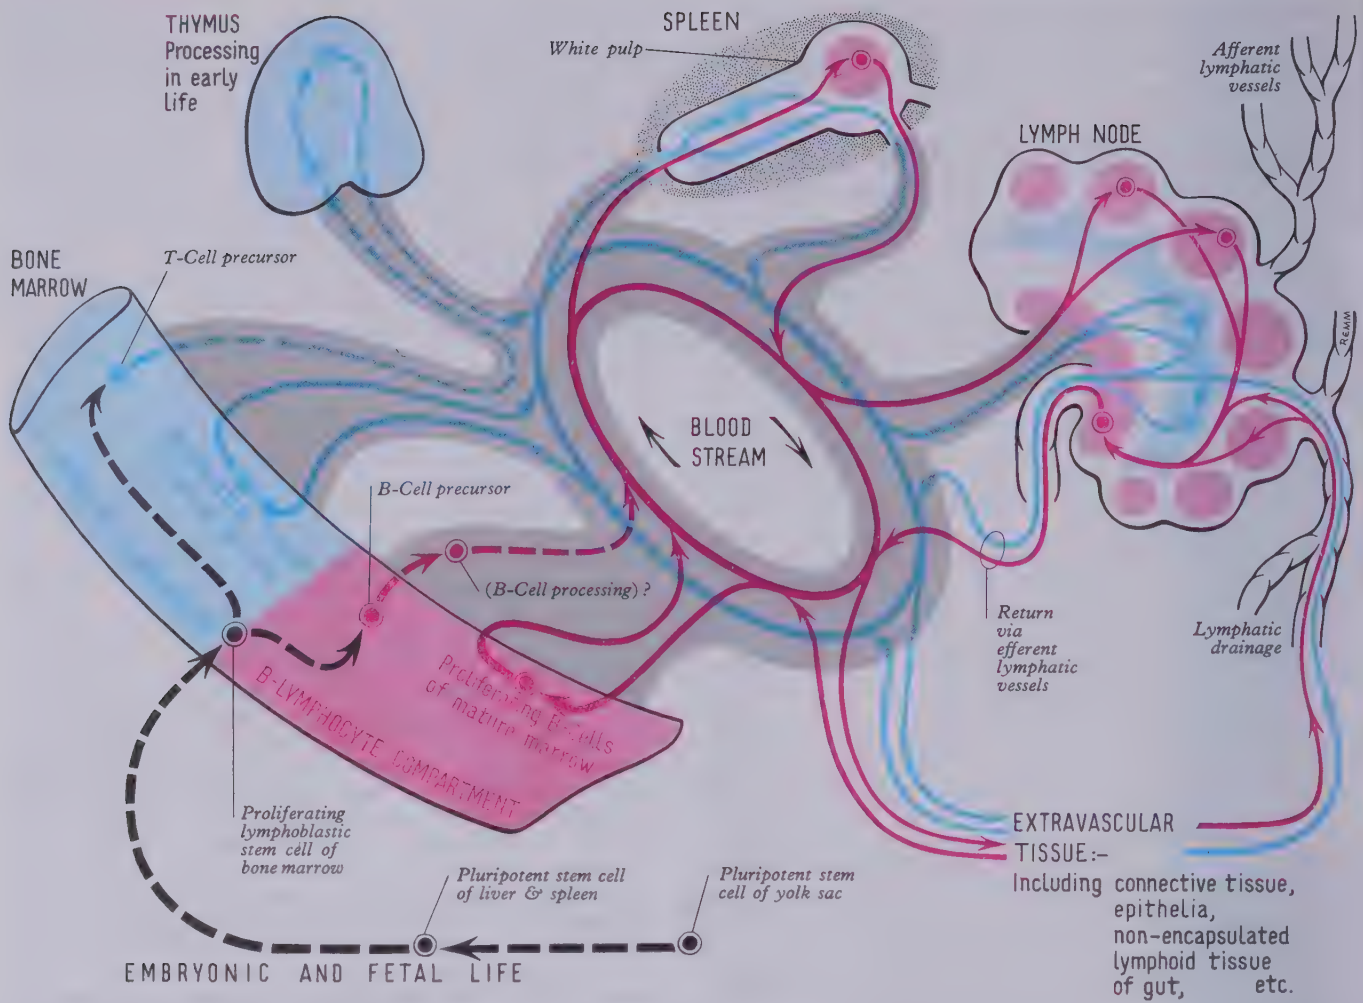
Phagocytosis of particulate material and organisms is carried out by macrophages and similar cells in many locations. In general connective tissue they can dispatch invading micro-organisms and remove debris engendered by tissue damage, or in growth and remodelling in undamaged tissue. In the lung, alveolar macrophages constantly patrol the surfaces of alveoli into which they migrate via intercellular junctions of the epithelial cells; they engulf inhaled particles including bacteria and debris and enter the sputum (hence 'dust cells' and, in cardiac disease, 'heart failure cells' full of extravasated erythrocytes). Similar activities occur in the pleural and peritoneal cavities. In lymph nodes they line the walls of sinusoids ('littoral macrophages') and remove particulate matter from the passing lymph as it percolates through these narrow passages.

In the spleen and liver, macrophages carry out similar particle removal but are also involved in the detection and destruction of aged or damaged erythrocytes, whose haemoglobin they begin to degrade preliminary to recycling iron and amino acids (see p. 665).

The part which mononuclear phagocytes play in immune responses is complex and incompletely known. As mentioned elsewhere (p. 673), they bear class II MHC antigens at their surface, which enable them to stimulate different classes of T-lymphocyte through close-range interactions: macrophages phagocytose alien antigens and partially digest them in their lysosomes, passing some of the antigenic remnants to the cell surface where they are bound by MHC molecules. This complex of alien antigen and MHC molecule is then presented to a T-lymphocyte, which, if it possesses the appropriate receptor on its surface, is stimulated in various ways, depending on the type of T cell involved (p. 672). In turn, macrophages are also affected by activated T- and B-lymphocytes: lymphokines (including macrophage-activating factors, Interleukin II, etc) secreted by certain T cells can determine their migration and degree of phagocytic activity (p. 672) and under such influences the macrophages themselves can synthesize and secrete various other bioactive substances, e.g. Interleukin I which stimulates the proliferation and maturation of other lymphocytes, so greatly amplifying the reaction of the immune system to foreign antigens. When activated by Interleukin II and other lymphokines, macrophages synthesize and release many other bioactive molecules, including Tumor Necrosis Factor (TNF) which is able to kill neoplastic cells and appears to be a mechanism for the removal of small tumours which may appear in the body from time to time throughout life; it is interesting that TNF also depresses the anabolic activities of many cells in the body and this may be a major factor in caccexia (wasting) which typically accompanies more advanced cancers. Other macrophage products include plasminogen activator, promoting clot removal (p. 668), and various lysosomal enzymes, several complement and clotting factors and lysozyme (an antibacterial protein). In pathogenesis, such substances may be 'erroneously' released to damage healthy tissues, e.g. in rheumatoid arthritis and various other inflammatory conditions.

Macrophages also have receptors on their surfaces for the Fc ends of antibodies and for the C3 component of complement, and so can bind readily to and avidly phagocytose antibody-coated (opsonized) microbes and other 'alien' material. Such close antibody-mediated binding may also initiate the release of lysosomal enzymes on to the surfaces of the cellular targets to which the macrophages are bound (an example of *antibody-dependent cell-mediated cytotoxicity*, ADCC, also shown by various other cells including neutrophils), particularly if these are too large to be phagocytosed (e.g. nematode worm parasites such as *Wuchereria bancrofti*). These reactions are much enhanced when macrophages are stimulated by lymphokines.

Macrophages and related cells also produce several growth and differentiation factors with actions on other tissues. They release factors which stimulate haemopoiesis, including erythropoietin, and have complex metabolic actions through their production of prostaglandins, thromboxanes and other bioactive substances, including the stimulation of bone resorption by osteoclasts.



In summary, these various activities appear to be related to three quite distinct roles: the first associated with defence, the second with repair and regeneration of damaged tissues and the third with the ongoing maintenance of normal proliferation and differentiation of healthy tissues throughout the body. The full extent of macrophage-mediated effects has yet to be determined and some of them are quite unexpected, e.g. high levels of Interleukin I induce sleep, as found in some severe systemic infections. It seems that macrophages may be intricately connected with a vast array of cellular activities in a network of great complexity.

Classes of mononuclear phagocytes. In broad outline, we can group the different mononuclear phagocytes into two major classes: one highly phagocytic, and the other less so but with other important activities. The *highly phagocytic cells* include all the mononuclear phagocytes named above, apart from the dendritic cells. Their phagocytic function is chiefly to remove from the tissues and circulating fluids any particulate material such as microbes of various kinds, tissue and cellular debris and moribund or dead cells (e.g. aged or damaged erythrocytes by splenic and hepatic macrophages, vide supra). Such phagocytic cells contain numerous lysosomes and can be readily labelled with particulate dyes (e.g. colloidal carbon, trypan blue) and electron-dense tracers (horse-radish peroxidase, colloidal gold, etc,) which they readily take into their cytoplasm. The second major group, the *dendritic mononuclear phagocytes*, although capable of moderate uptake of particulate material, consists of cells which are specialized to initiate immune reactions in lymphocytes mainly within lymphoid tissue masses. These cells include the *follicular dendritic cells* and *interdigitating cells* of lymph nodes and lymphoid nodules, similar cells of the spleen and thymus and the epidermal dendritic (Langerhans) cells of the skin. The microglial cells of the central nervous system may possibly be included in this class, although there is evidence for very active phagocytosis under some conditions (see p. 895).

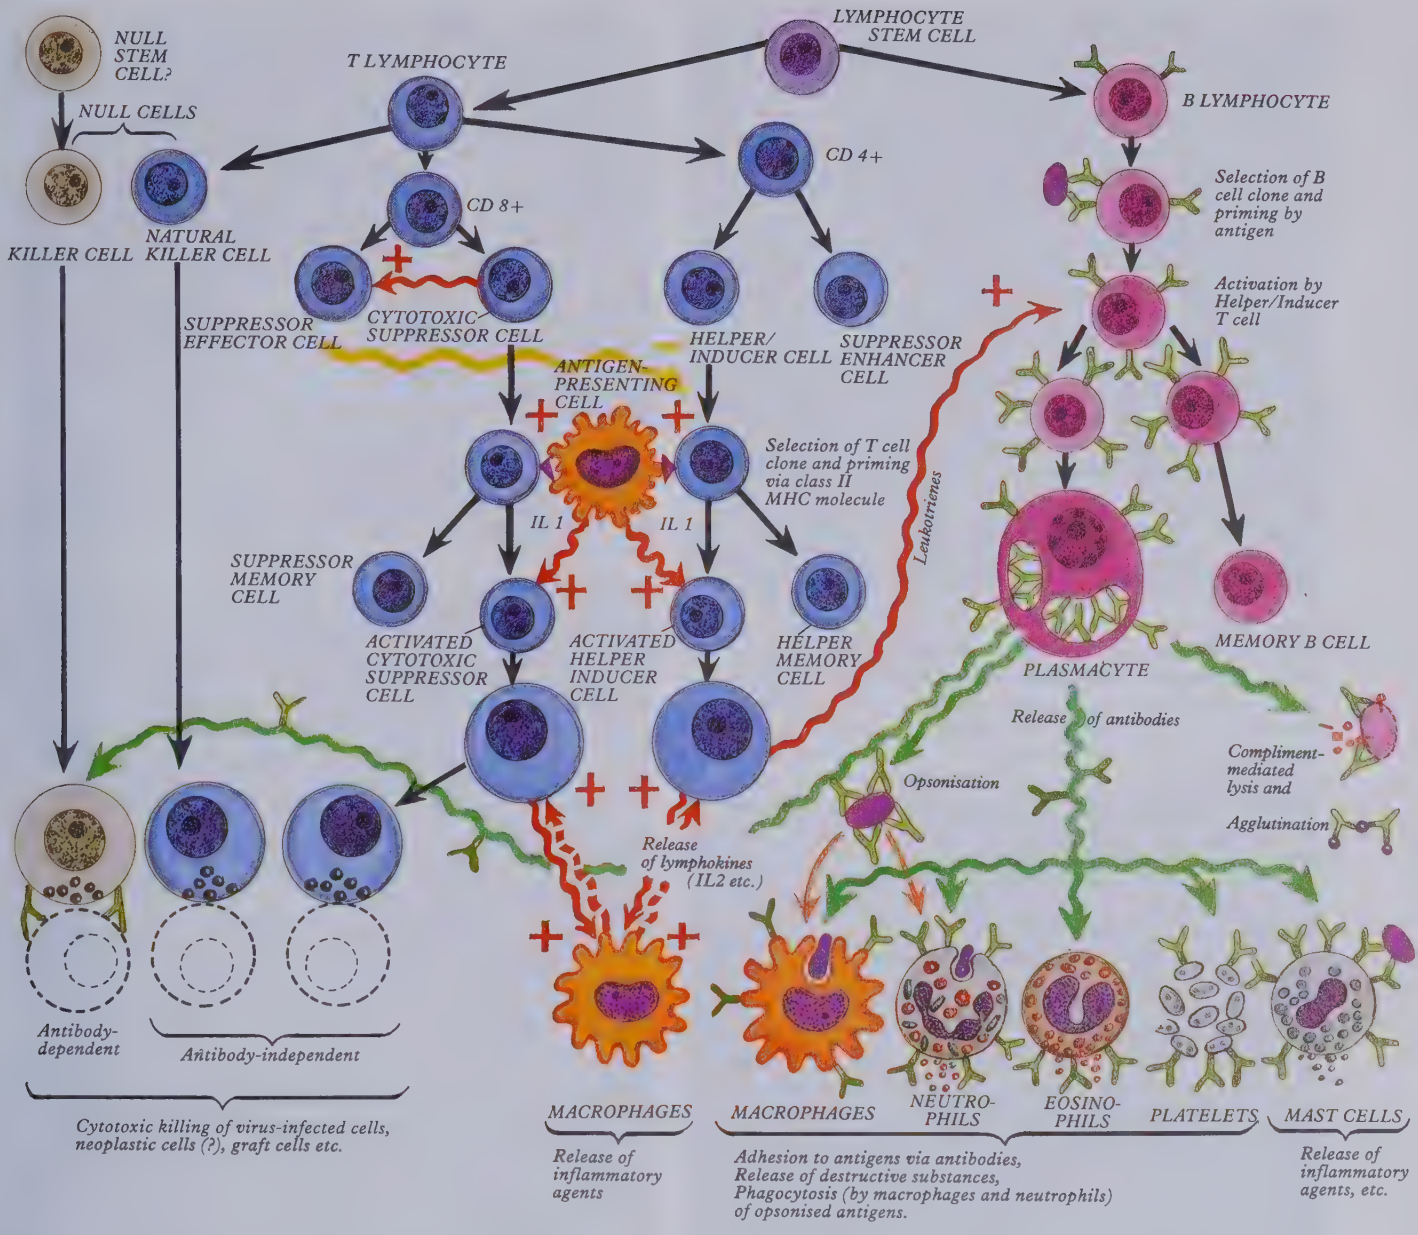
The main action of dendritic cells appears to be to phagocytose alien antigens and present them in association with class II MHC molecules at their surfaces to the neighbouring lymphocytes. The relative contributions of the dendritic and other mononuclear phagocytes to the general activation of lymphocytes in response to an antigen has yet to be determined. Within the dendritic cell populations, at least two varieties occur, one of which (the epidermal or Langerhans cells and some thymic and non-follicular dendritic cells of lymph nodes) has characteristic 'Birbeck' granules (see p. 77) while the other dendritic cells lack these. It has been suggested that those with the characteristic granules are all epidermal dendritic cells; those present in lymph nodes and the thymus are cells which have migrated in from their peripheral positions, carrying with them antigens which they have picked up in the skin, to trigger appropriate responses in T- and B-lymphocytes. Such stimulated lymphocytes may then either pass to the skin and carry out defensive actions there or populate regional lymph nodes to deal with any infectious agents which might pass into them from the lymphatic drainage of the area.

Because of their branched form and locations, the various, dendritic cells lie in intimate contact with numerous cells in their vicinity and, in view of the known trophic functions of macrophages, it is possible that dendritic cells help to regulate the cells they lie close to. The epidermal dendritic cells may help to control epidermal proliferation (p. 77), those of the bone marrow may assist to control haemopoiesis, etc.

Mononuclear phagocytes vary in structure depending on their location in the body. All are large cells (15–25 μm across) which are moderately basophilic and contain some granular and agranular endoplasmic reticulum, an active Golgi complex, mitochondria, etc. and a large, euchromatic nucleus, signifying an active metabolism and continuing synthesis of lysosomal enzymes, unlike neutrophil granulocytes which virtually cease synthetic activity shortly after leaving the bone marrow. All cells have irregular surfaces with many filopodia and contain varying numbers of endocytic vesicles and lysosomes. Some macrophages are highly motile, whereas others tend to remain attached and sedentary (e.g. the littoral cells of hepatic and lymphoid sinusoids). For further descriptions of these cells, see other sections (pp. 673, 824, 830, 837).

6.5 Diagram depicting the current views of the origins and circulation of the two major classes of lymphocyte from the bone marrow to the peripheral lymphoid tissues. B-lymphocytes are shown in red, T-lymphocytes in blue.

The reticulo-endothelial system. The concept of an interrelated system of mononuclear phagocytes has in recent years supplanted that of the *reticulo-endothelial system*, which at its inception was envisaged as a diffuse network of various phagocytic cells, mainly endothelial, lying in or in close proximity to the walls of certain blood vessels and lymphatics. It was found that these cells took up many particulate dyes and other substances infused into blood and lymph and thus seemed well fitted for the removal and destruction of particulate materials from these fluids. However, more detailed study showed that, in general, true endothelial cells are only mildly phagocytic, as indeed are many other tissue cells; the highly phagocytic cells are not endothelial cells at all, but types of macrophages of myeloid origin and, unlike endothelial cells, bear Class II MHC molecules at their surfaces.



THE LYMPHOID SYSTEM

Origins of Lymphocytes

Much of the knowledge of lymphocyte life history (**6.5,6**) has come from experimental situations which include the tracing of radioactively or genetically labelled cells, the latter involving transfusion of lymphocytes with chromosomal abnormalities into normal but inbred strains of laboratory animals. Other experiments are based on the sensitivity of lymphocytes to ionizing radiation, the various components of the lymphocytic system being eliminated by selective irradiation, accompanied by appropriate transfusions or transplants of lymphopoietic tissue from bone marrow, lymph nodes, thymus and so forth. Thirdly, selective surgical removal of various lymphopoietic components and the removal of lymphocytes from the lymphatic channels has been carried out. In addition to these, a whole battery of immunological techniques has been brought to bear on the problem, including immunoassay, tissue culture methods, techniques for the localization of antibodies by their reactions with antigens or antigen-antibody complexes previously labelled with fluorescent compounds or electron-dense substances (or enzymes) with subsequent examination by fluorescence and electron microscopy respectively.

The picture which has emerged is still far from clear; nevertheless tentative views can be expressed at this stage.

Lymphocytes originate in the embryo from mesenchymal cells of the yolk sac initially, and later in the liver and spleen. These primitive lymphoid *stem cells* subsequently take up residence in the bone marrow, which becomes the only site of stem cell proliferation after birth. Such stem cells divide unequally to throw off lymphoblasts which again divide a number of times and transform into small lymphocytes. Some of these pass in the blood circulation to the thymus where they migrate into the lobules and divide repeatedly (p. 834); the resulting small thymus-processed *T-lymphocytes* then re-enter the bloodstream and can return to the bone marrow or to the *peripheral lymphoid tissues* (tonsils, lymphoid tissue of the alimentary and respiratory tracts, lymph nodes, spleen), which they enter by migrating through the walls of the capillaries or post-capillary venules. Here, the cells are found in the sinusoids of the lymph nodes and in the loose superficial tissue of the lymph nodes (i.e. paracortical areas) and *periarteriolar white pulp* of the spleen, i.e. in both cases, tissue neighbouring the *germinal centres* (p. 824). They can enter the general flow of lymph, returning to the bloodstream via the thoracic and right lymphatic ducts and the brachiocephalic veins, and so

6.6 Schema of the origins and functional interactions by lymphocytes and other cells of the immune system.

eventually back to the lymphoid tissues again. This *circulation of lymphocytes* first established by Gowans, is responsible for the large number of lymphocytes found in the blood (**6.5**). When stimulated antigenically such lymphocytes enlarge and multiply, and their progeny are capable of interacting with tissue cells (vide infra).

The *B-lymphocytes* do not pass through the thymus, but move directly via the circulation to the general lymphoid tissues. where they settle down. En route they may undergo a phase of differentiation similar to that of the T-lymphocytes in the thymus, although it is not clear where this step might take place. Various sites have been suggested, including the intestinal lymphoid tissue; as yet conclusive proof is not available but it appears likely that the bone marrow is the site of B-cell differentiation. In birds, B-lymphocytes are derived from a specialized diverticulum of the cloaca, called the *bursa of Fabricius* (giving this type of lymphocyte its title—the *bursa equivalent*—or *B*-lymphocytes, although subsequently it appears that such a prefix can be even more appropriately applied to denote the bone marrow origin of the B-cell class in mammals). On antigenic stimulation they multiply to form the *germinal centres*; such lymphocytes can, while still within the lymphoid tissues or after further migration, mature into the large pyroninophilic (i.e. RNA-rich) plasma cell series, which produce antibodies in their extensive rough endoplasmic reticulum.

FUNCTIONING OF THE LYMPHOCYTIC SYSTEM (6.6)

The lymphocytes, together with the phagocytes of the mononuclear phagocyte system, are responsible for the defensive reactions of the body, the former by non-phagocytic interactions of various kinds, the latter mainly by phagocytosis. These defences are directed against foreign invasion by bacteria, viruses, fungi, protozoa, helminth worms, etc. or their metabolites (toxins) and against any unwanted or abnormal materials within the body such as alien or altered proteins and effete, neoplastic or virally transformed cells.

B-lymphocytes

These cells can, when antigenically stimulated, proliferate and their progeny transform to larger cells (*plasmocytes*) which

synthesize and secrete *circulating antibodies*; the latter chemically 'recognize' and bind specifically to foreign chemical substances (*antigens*) to inactivate them or cause their destruction. Antibodies may circulate freely in the body fluids (*soluble antibodies*) or may be secondarily attached to a variety of defensive cells (*homocytotropic antibodies*) to enhance their activities or to enable them to carry out a wider range of functions.

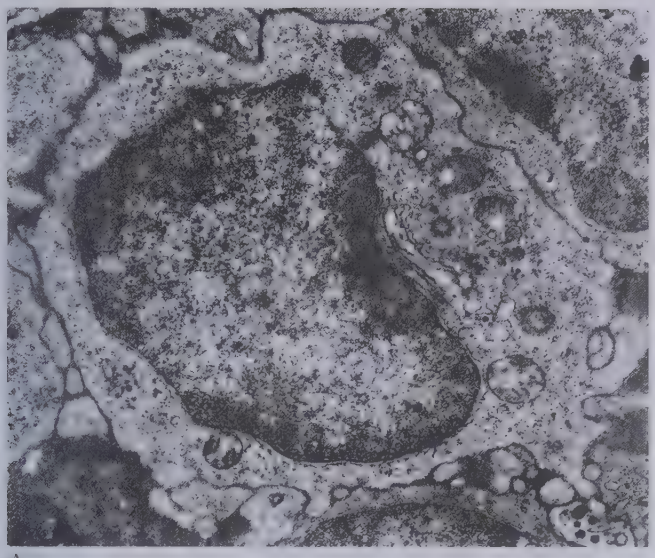
Chemically, **antibodies** (or *immunoglobulins*) are proteins with a relative molecular mass (*M*r) of 150 000–950 000. Each antibody molecule consists of four polypeptide chains, two of them long (about 15 nm, *heavy* chains) and two shorter (*light* chains) all joined together by sulphydryl links. The whole molecule is Y-shaped, two of the arms of the Y being able to swing around a central hinge. One end of the molecule (the *Fab* fraction) is highly variable in its amino-acid sequences and, since this end is responsible for specific binding to antigens, there is a vast number of possible antibody varieties, each type being able to bind a specific antigen in a manner closely analogous to enzyme-substrate binding. The other end of the molecule, the *Fc* portion, is much less variable and can attach to certain cells if they possess specific *Fc* receptors on their surfaces (or, in the case of IgM molecules, by virtue of hydrophobic *Fc* ends able to insert themselves into membranes), thus conferring antigen-binding properties upon them by virtue of the free *Fab* ends of the bound antibodies.

At present, five classes of antibodies are distinguishable in the blood plasma and elsewhere. These are: Immunoglobulin G (IgG), which forms the bulk of circulating antibodies; Immunoglobulin M (IgM), which is often formed early in the immune response and is usually present as a pentamer, the monomers joined near their *Fc* ends into a star-like aggregate; Immunoglobulin A (IgA), which is present in secretions of the body, particularly saliva and other fluids of the alimentary tract; Immunoglobulin E (IgE), which is a *homocytotropic* antibody found on the surface of mast and perhaps other cells; and finally Immunoglobulin D (IgD) of uncertain significance, although believed to be important in the ontogeny of the immune system. All classes can be soluble antibodies, and IgG and IgE can also be homocytotropic (vide infra).

The defensive functions of antibodies are numerous. They can *agglutinate* antigens by forming cross-links between them so rendering them inactive as infective agents (e.g. viruses). After binding an antigen they may also co-bind *complement*, a protein complex in plasma which punctures cell membranes, so causing the lysis of bacteria and other cells attacked by antibody. If only part of the complement protein complex is bound (e.g. C^3), they can form bridges between defensive cells such as macrophages and target cells, causing their destruction. They may also bind to antigens after attachment by their 'safe' *Fc* ends to other defensive cells which are thus armed to detect, adhere to and ingest or enzymatically damage foreign bodies; examples are macrophages and neutrophils both of which bear *Fc* receptors on their surfaces. Such cell-bound antibodies can also activate the complement complex to cause lysis of bacteria, etc. Antibodies may first coat an antigen (*opsonizing antibodies* or *opsonins*) before they attach to a macrophage, thereby stimulating its phagocytic capacity. Homocytotropic antibodies may cause the activation of cells in other ways when they bind antigens. Thus, IgE antibodies trigger the release of histamine and other vasoactive agents and stimulate the synthesis and release of others (e.g. interleukins I and II, prostaglandins, etc.) from mast cells to which they are bound, when activated by antigens; this is seen in certain types of allergy, e.g. to the proteins of pollen but, normally, it plays an important part in defence against microbial invasion.

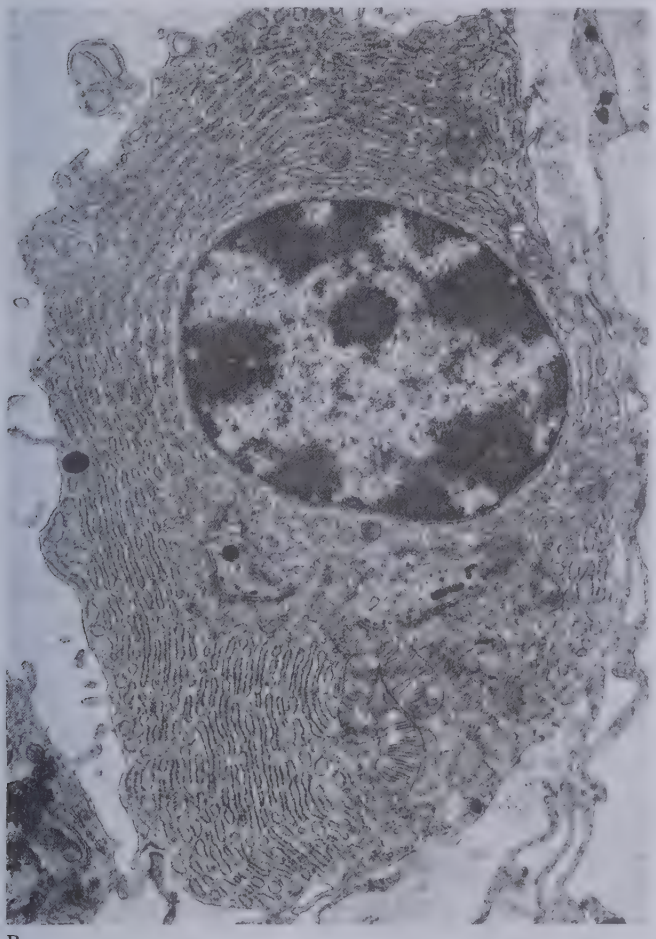
B-lymphocytes, themselves, can be activated to divide and transform into antibody-secreting plasmocytes by antigenic stimulation of cytophilic IgG bound to their surfaces and T-lymphocytes are also activated in the same manner. In all these cases it should be emphasized, that antibodies are derived from transforming B-lymphocytes (including plasmocytes) and come to be attached to other cells only after passing into the tissue fluids or blood. Some B-lymphocytes may also be very long-lived and so constitute a '*memory*' of previous reactions of the immune system (vide infra).

When circulating antibodies bind to antigens they form *immune complexes* which, if present in abnormal quantities, may cause pathological damage to the vascular system and other tissues either, as in some types of glomerulonephritis, by interfering mechanically with permeability to fluids; or alternatively, by causing local activation of the complement system to attack cell membranes, thus causing vascular disease.



In pregnancy some IgG is transferred across the placenta, conferring a measure of *passive immunity* on the fetus; but in the case of Rhesus factor incompatibility, it brings about the destruction of Rhesus-positive fetal erythrocytes. In some mammals (oxen, sheep), antibodies are transferred in the first-formed milk (colostrum) after birth. In humans, maternal milk contains secretory immunoglobulins (IgA) which help to combat bacterial and viral organisms in the alimentary tract of the baby during the first few months.

T-lymphocytes



These cells include a number of subclasses (see Marrack & Kappler 1986), all derived from stem lymphocytes originating in the bone marrow but later differentiating in the thymus (hence thymus-derived cell) and passing into various other lymphoid organs (**6**.6, 7). They carry out a wide variety of cell-mediated defensive actions which are not directly dependent on antibody activity and are therefore included under the heading of *cellular immunity*. T-lymphocyte responses can be loosely divided into *effector* and *controlling* actions. Effector responses are direct and indirect attacks against virus-infected tissue cells, fungi, some protozoal infections (e.g. trypanosomes), neoplastic cells (probably) and, unhappily for transplant surgeons, the cells of grafts from other individuals (allografts) when the tissue antigens are not sufficiently similar. Controlling functions are the induction or suppression of immune responses in other lymphocytes, namely B cells and T cells engaged in effector responses and, it appears likely, various non-lymphocytic cells such as those of the bone marrow. Effector cells can be divided into two major classes, those which are responsible for cytotoxic killing of virus-infected cells, etc. and other cells which give rise to a combination of defensive actions by non-lymphocytic cells, seen most clearly though pathologically in delayed hypersensitivity reactions.

Cytotoxic T cells cause cell death in a number of different ways, including the release of toxic lysosomal proteins ('perforins') able to lyse the cell membranes of other cells by forming large pores; such actions occur at close range, the effector cell having contacted the target cell and recognized it as being pathological. This recognition step is of great interest and generally depends on the presence at the surface of the attacked cell of an alien antigen (e.g. of viral origin) in combination with Class I Major Histocompatibility Complex molecules; the latter are expressed at the surfaces of nearly all tissue cells and, although highly variable from person to person, are invariant within the tissues of an individual (p. 682). It is thought that during the development of T-lymphocyte stem cells in the thymus, they in some way 'learn' to recognize the MHC molecules characteristic of the individual to whom they belong. The T cells have specific receptors (also variable, see p. 675) at their surfaces, matched to these MHC molecules and, if at a later time the T cell meets a tissue cell in which the Class I MHC markers are in some way altered, e.g. by binding an alien antigen, or in the case of transplants, by being a different variant, T cells mount an attack on the cell which bears these 'strange' markers. In this way, intracellular pathogens such as viruses beyond the reach of antibodies and perhaps 'transformed' neoplastic cells, can be killed; of course, the same applies to the 'alien' cells of an allograft. T-lymphocytes of this kind include some of the larger lymphocytes with cytoplasmic granules containing the cytotoxic substances (large granular lymphocytes), although natural killer cells (vide infra) may have a similar appearance (see Hieberman 1985).

Delayed type hypersensitivity-related T cells also react to the presence of antigens by synthesizing and releasing *lymphokines*, soluble proteins with an *M*r of 20 000–80 000 and having a wide variety of actions on other cells. These include chemotactic substances which attract macrophages into the area of release (macrophage chemotactic factor) and then prevent them from

migrating away (macrophage inhibitory factor); others stimulate phagocytosis and the destructive activities of macrophages (see p. 669), natural killer and other cells (macrophage activating factor or γ-interferon). Another lymphokine is interleukin II, which acts on B and other T cells to stimulate their proliferation and maturation; there are also many other actions of this complex group of secretions.

Helper T cells are vital to cell proliferation and secretion of antibodies by mature B-lymphocytes. These processes are initiated by a foreign antigen being phagocytosed and partially digested by a macrophage, some of the products passing to the macrophage surface where they are bound by a Class II MHC molecule embedded in the plasma membrane (a surface antigen found only on macrophages and a few related cells with similar functions). This combination of antigen and MHC molecule is then presented at the macrophage surface to a helper T cell which bears a (complementary) T-cell receptor. This interaction causes the activation of the T cell and such a cell is able to recognize and activate immature B cells capable of producing antibody to that particular antigen. In this rather indirect way, a clone of B cells

producing a single type of antibody matching an antigen can be stimulated to proliferate and secrete their products. A similar activation of cytoxic T cells may occur through a separate group of helper T cells, although delayed-type hypersensitivity-related T cells also have this function, as mentioned above.

If such helper cell activities are suppressed, potentially pathogenic organisms present in the body but normally kept in check by the immune system may become uncontrollable, causing overt pathology and even death. The best known example of this is the Acquired Immune Deficiency Syndrome, AIDS, where a virus (HIV 1) specifically infects and kills helper T cells; similar though less lethal immunosuppression may also be caused by other viral infections and a multitude of other factors, e.g. malnutrition.

Suppressor T cells. These appear to be a separate class of cells which, when antigenically stimulated, suppress the defensive activities of B cells and other T cells. The mechanism of their action is not well understood but may have features in common with cytotoxic effector cells. The existence of both positive and negative controls in the immune system is of great significance, since for normal effective defence against infection, this system must be finely balanced to ensure destruction of alien organisms without the body itself being damaged by the powerful agents released by the various defensive cells. Failure of this delicate control may be seen, at one extreme, in immune incompetence and, at the other, in various pathologies such as autoimmune disease and hypersensitivity reactions (e.g. allergic asthma, allergic dermatitis) etc.

Structurally T-lymphocytes present different appearances depending on their type and state of activity. When 'resting' they are typical small lymphocytes morphologically indistinguishable from small B-lymphocytes; but when stimulated they become large (up to 15 μm), moderately basophilic cells with a partially euchromatic nucleus. In the cytoplasm are numerous free ribosomes, some agranular and granular endoplasmic reticula, a golgi complex and a scattering of mitochondria (**6**.7). Cytotoxic effector T cells also contain dense lysosome-like vacuoles.

Natural killer cells constitute a pool of defensive elements which appear to have similarities to cytotoxic T cells functionally, although they lack some typical lymphocyte features (vide infra). They normally form only a small percentage of all lymphocyte-like cells and are included technically in the 'large granular lymphocyte' category. Natural killer cells, when mature, have a mildly basophilic cytoplasm and a partially euchromatic nucleus. Ultrastructurally, the cytoplasm contains ribosomes, granular endoplasmic reticulum and dense, membrane-bound vesicles 200–500 nm in diameter with crystalline cores (Heiberman 1985). These contain some hydrolases, but the major active component is a protein, cytolysin, capable of inserting holes in other cells, so causing their death. Natural killer cells are activated to attach themselves to and kill target cells of various kinds by a number of factors, including interleukin II from T cells (vide supra). They represent a relatively non-specific means of attacking virus-infected cells, protozoa and other pathogenic cells (see also Henkart & Martz 1984).

Classes of T cells. When monoclonal antibodies were developed in cell cultures against lymphocytes, it was found that different classes of T-lymphocytes could be grouped together according to the characteristic range of monoclonals that they bound. The various species of antibody-binding molecules responsible for these reactions can be divided into a few typical combinations (known as '*differentiation clusters*', CD, see Reinherz 1987). The three major T cell differentiation clusters are termed, respectively: CD3, CD4 and CD8. All 'true' T cells appear to be CD3 positive, but may also be either CD4 or CD8 positive; those which are CD4 positive (termed '$CD4^+$ lymphocytes') include helper-inducer cells important in triggering antibody production from B-lymphocytes, cytotoxic-suppressor T cells and T cells involved in delayed hypersensitivity reactions. Those bearing CD8 ('$CD8^+$ lymphocytes') as well as CD3 markers comprise suppressor and cytotoxic-suppressor T-cell lines. Natural killer cells are CD3 positive, but bear neither CD4 nor CD8 markers. This scheme of classification will no doubt give way to a more discriminating taxonomy when more is known about the functions of T cells and their developmental patterns; the two major groups can already be divided into a number of subsets by their reactions with other monoclonal antibodies.

The CD molecular complexes are believed to act co-operatively with T-cell receptors, CD3 possibly to mediate stimulus transduction, CD4 to initiate 'helper' or other related activities, CD8 for 'suppressor' functions, etc.

Although the plethora of activities carried out by lymphocytes seems highly complex, it is to be expected that the potent and wide-ranging defensive mechanisms of the body should be subject to multiple strict checks, controls and balances. As yet, relatively little is understood about the manner in which the various parts of the whole system of cellular and chemical defences are *integrated*, but it is increasingly clear they they must be viewed as a *single system* of great efficiency and elegance. When, however, such integration breaks down, the effects may be far-reaching as, e.g. in the wide variety of *auto-immune diseases*, and in neoplasia of the immune system, such as myeloma.

Immunological Memory

If after one antigenic response the body is again exposed to the same antigen, the second response is much more rapid and extensive, even after a period of years; this forms the basis of clinical immunization. This phenomenon implies the presence of some type of immunological 'memory'. This appears to be largely retained by long-lived lymphocytes which have been specifically activated by antigens via mononuclear phagocyte contact (p. 669). Such cells can be either T or B cells; when the same antigens are encountered a second time, these memory cells are able to multiply rapidly and initiate a variety of other cell activities, typical of the secondary immune response. Over-reactivity of this system may be associated with various types of hypersensitivity, e.g. anaphylactic shock and delayed-type hypersensitivity.

The Nature of the Antigenic Response

The antibody-antigen reaction is *highly specific*, each antigen requiring its own antibody for binding to occur.

In the life of an individual an enormous range of antigens must impinge on the immunological system, requiring a correspondingly large number of antibodies in B-lymphocytes and an equally large number of receptors for antigens at the surfaces of T-lymphocytes (*T-cell receptors*). How these are coded for by the limited genome of each lymphocyte is a severe intellectual problem. Two possibilities exist: firstly, that the antigen in some way interacts with the cell's DNA or RNA to dictate the type of antibody or T-cell receptor to be formed by the lymphocytes (the *instructive theory*). Alternatively, it is proposed that from a wide range of types of lymphocyte, each capable of synthesizing only one, a limited number of antibodies, only the appropriate lymphocytes are stimulated by a particular antigen to multiply and synthesize antibody (the *clonal selection theory*). The weight of evidence now conclusively favours the second of these two possibilities (p. 675).

Recent studies on the mechanisms of generating a wide enough variety of antibodies capable of recognizing any conceivable macromolecule which might be introduced into the body during infections have indicated that variability results from a number of different processes which operate during the formation and maturation of B-lymphocytes. As already stated, antibody molecules consist of four chains each (two light and two heavy chains), and each of these has an antigen-binding end (Fab) of variable structure, as well as a constant (Fc) region. The constant and variable regions are coded for by separate genes, so that, for IgG antibody, at least eight genes are needed to code for a single molecule, four of which are variable and four constant. Different combinations of only a few types of variable gene would therefore already produce a sizeable number of different antibody structures. In fact, there are large numbers of variable (*V*) genes, since within each of these genes there are many subunits which can be spliced together in different combinations, to give a vast range of

possibilities. The possible variations are again increased by somatic mutations in the genes during B-cell development, and probably by other factors such as variations in the translation of DNA into messenger RNA. It has been calculated that according to the known evidence about the system in mice, it would be simple to generate at least 10^9 different antibodies by random combinations of these different factors. Similar considerations apply to T-cell receptor molecules.

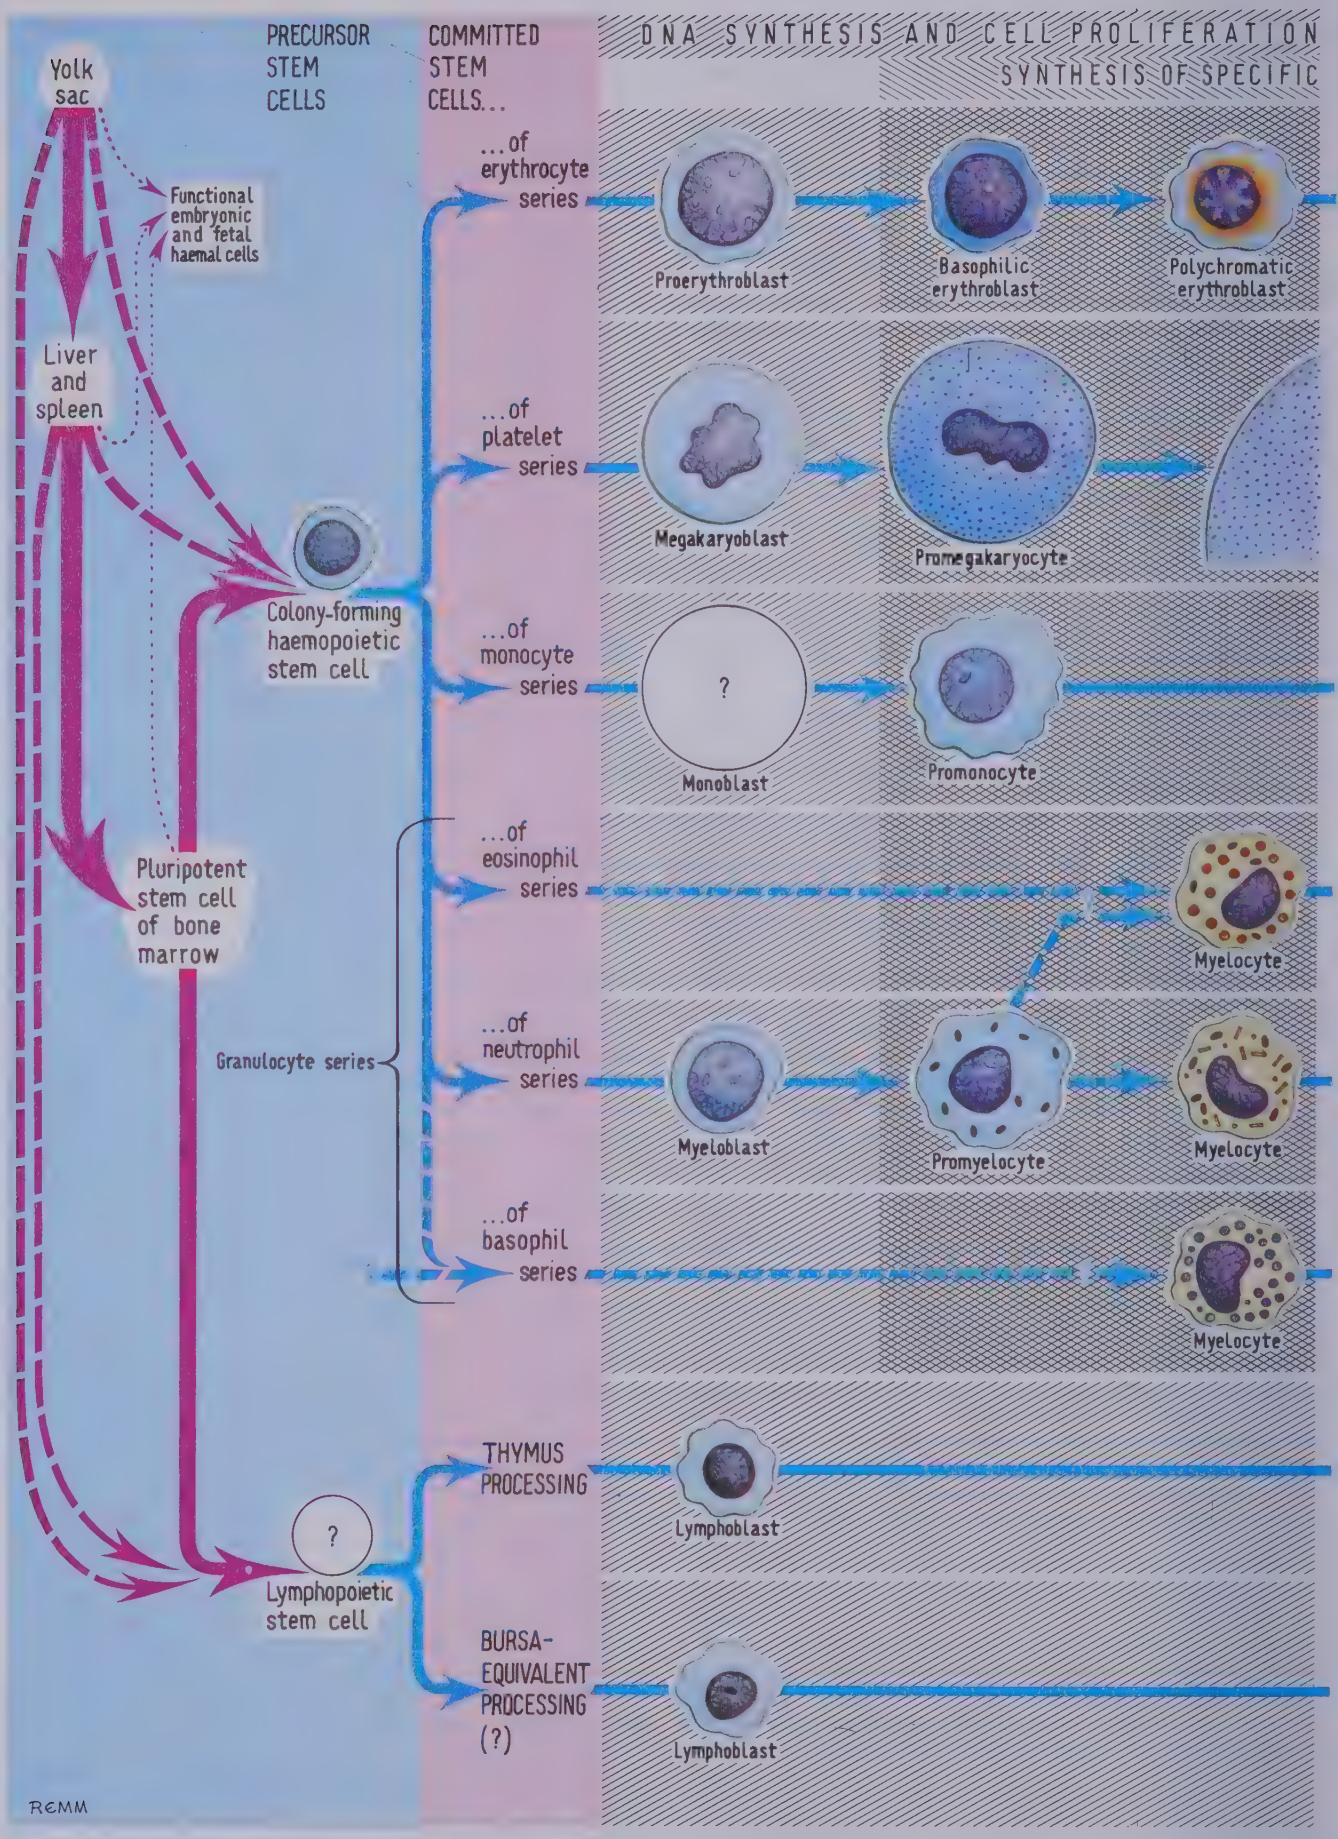
The T-cell receptor. This molecule consists of at least five polypeptides, two of which (the Ti α and β chains) are highly variable, and are each encoded by a cluster of variable genes which can be rearranged (probably in the thymus) to generate the wide variety of T-cell receptors encountered. Such receptors are said to be MHC-restricted because they will only recognize an antigen in the presence of an MHC molecule (of Class II, in the case of mononuclear phagocytes, and Class I in other cells). Other types of T-cell receptors have also been described (see Reinherz 1968), and these may play a part in developmental processes.

Clonal selection theory

When the great diversity of antibody specificities became apparent, the mechanism by which the body is able to produce the appropriate antibody to neutralize a particular antigen came under scrutiny and two alternative mechanisms were proposed. The *instructive theory* envisaged some sort of interaction between the antigen and a lymphocyte leading to a change in the antibody it produced, each cell having the capacity to carry out a series of such alterations depending in the prevalent antigen. The alternative *selective theory* proposed that the lymphocyte populations of the body include cells which already have the capacity to make almost any antibody which might be required in the life of the individual; and that an antigen causes only the cell type appropriate to it to proliferate into a series of identical cells (a *clone*) which all produce the same antibody. As an extension of this, it was postulated that clones inappropriate to defence, e.g. those able to produce antibodies against the body's own substances, are in some way suppressed, being either eliminated by induced cell death or kept quiescent.

The discipline of immunology has moved on from that time and it has been amply confirmed that the basic clonal selection hypothesis accurately describes the matching of antibody production to antigen specificity. Of the huge range of possible antibodies a B cell might synthesize, it is found in practice that only one is expressed in a particular B cell (*allelic exclusion*), and that its progeny will express the same antibody, exclusively. When suitably stimulated, such B cells proliferate and mature into plasmacytes synthesizing identical antibodies. Besides its importance in immunology, this phenomenon forms the basis for modern monoclonal antibody technology.

Although the clonal selection concept originally applied to antibody production, T cells being virtually unknown at the time, it has since become clear that the specificity of T-cell responses to antigens are controlled in the same way. As already stated, T helper and cytotoxic T cells, and perhaps other types of lymphocyte, are activated by interaction with antigen-presenting cells (macrophages, etc.), the specificity to a particular antigen being determined by the major T-cell receptor (Ti). Thus, like B cells, a great variety of T cells exists, each with a particular T-cell receptor pre-adapted to recognizing almost any antigen that might enter the body and thus able to launch an immune attack upon it (either by itself, or by helper actions on other defensive cells). When stimulated by the antigen–MHC II complex at the surface of the presenting cell, the various reactions lead to the proliferation of the clone of T cells responsive to that antigen and thus to a greatly multiplied response. Cells not bearing the T-cell receptor corresponding to that antigen are hence unresponsive. The existence of the same phenomenon in two cell types is not accidental, since most B-cell responses are indeed the result of induction by helper T cells responding to the same antigen, recognized by the T cell at the surface of the B-cell, bound to surface-expressed immunoglobulin molecules produced by that lymphocyte. Direct activation of B cells by antigen in the absence of T cells can also occur, but only by a narrow range of rather unusual antigens which can cross-link their surface immunoglobulins, e.g. pneumococcus polysaccharide; this leads to the production of IgM rather than IgG molecules and must be regarded as of limited importance to the main immune response observed in vivo.



Immunological Tolerance

Since lymphocytes react to foreign antigens and not usually to the proteins and carbohydrates of the body itself, there must be some mechanism which ensures the distinguishing of *self* from *non-self*, that is an *immunological tolerance* to self. This may break down in auto-immune diseases such as Hashimoto's syndrome—self-immune destruction of the thyroid gland—and possibly in disseminated sclerosis which causes demyelination of tracts in the central nervous system. Self-tolerance is achieved in humans during fetal development, involving the action of the thymus (p. 835). Burnet widened the theory of selective antigenic response (vide supra) to attempt an explanation for the mechanism of self-tolerance (the *clonal theory*), suggesting that those cell lines (*clones*) of lymphocytes which produce antibodies (and subsequently, it appears, specific T-cell receptors, in the case of T-lymphocytes) to the body's own tissues are suppressed in fetal life and are then no longer available to multiply at a later stage (see Burnet 1969, Edelman 1974). Self-tolerance may be extended to the antigens of a genetically identical or closely similar individual, so that grafts of tissue between monozygotic twins or inbred strains of animals may be accepted.

All tissues from within a particular species show antigenic classes similar to those seen in the erythrocytes (p. 681) and in man a number of *histocompatibility* tissue antigen groups have been recognized (p. 682). The success or failure of *isologous grafts* (i.e. grafts between genetically dissimilar members of the same species) depends largely on the degree of matching of these antigens between donor and recipient.

Haemopoiesis (6.8)

The earliest sign of blood *vessel* formation in the human embryo occurs when, during the early primitive streak stage of development, angioblastic tissue differentiates almost simultaneously in various extra-embryonic sites, namely, in the mesenchyme of the yolk sac wall and in similar tissue of the connecting stalk and chorion. The earliest formation of blood *cells* (**6**.8), however, appears to be confined to the wall of the secondary yolk sac, where they differentiate from deeply placed mesenchymal cells which lie next to the yolk sac endoderm. Whilst a mesodermal or endodermal origin for these cells is still debated, they are unquestionably mesenchymal in character and differentiate into the primitive *stem cells* of the haemopoietic line, which give rise directly to fetal blood cells. Beginning in the second month, a number of intra-embryonic sites of haemopoiesis appear and slowly replace the earlier sites. These intra-embryonic sites *succeed but overlap* each other in time, each site gradually increasing in importance and then waning. Initially, the intra-embryonic sites are broadly *intravascular*, but soon *extravascular* loci of haemopoiesis supervene. Rapidly the *liver* becomes the dominant organ of embryonic blood formation, its activities continuing until about the seventh month. Lagging somewhat behind the liver, the *spleen* is then added, its haemopoiesis continuing from the third to sixth months. From late in the third month, an additional source of blood cells emerges, namely the *bone marrow (myeloid tissue)* where *all blood cell types* are formed, and later the peripheral lymphoid tissues, where only lymphocytes are produced (lymphopoiesis). The *thymus* is an active lymphopoietic organ from this stage (whilst initially it also has some general haemopoietic functions). The myeloid and lymphoid tissues become the dominant source of supply by the seventh month and shortly after birth all other sites have regressed completely. Occasionally, clumps of tissue capable of total haemopoiesis are found outside the bone marrow (*extramedullary tissue*) in paravertebral sites; in pathological cases, where there is more demand for haemopoiesis, and especially during early childhood,

6.8 Haemopoiesis: a schema of the origins, developmental stages and fates of the different classes of haemal cells. Where details of development are uncertain, putative routes are shown in broken lines. Developmental pathways of the prenatal period are indicated (left) in red and different

stages of cellular development are hatched diagonally according to the column headings. It should be noted also that there is evidence for macrophage proliferation in the extravascular tissues, a finding not indicated in this scheme.

complete haemopoiesis may also occur in the liver, spleen and lymph nodes and infrequently also in the kidneys, adrenals, adipose tissue, general connective tissue and even in cartilage.

BONE MARROW

This is a soft pulpy tissue which is found not only in the cylindrical marrow cavities of the long bones but also in the spaces between the trabeculae of all bones and even in the larger Haversian canals. It differs in composition in different bones and at different ages and occurs in two forms, *yellow* and *red marrow*.

During fetal life and at birth there is red marrow throughout the skeleton. After about the fifth year the red marrow is gradually replaced in the long bones by yellow marrow. The replacement commences earlier and is more advanced in the more distal bones. Further, in each bone the replacement, in general, proceeds from the distal to the proximal end, though some maintain that it commences in the centre of the shaft and extends in both directions, but more rapidly in the distal. By 20–25 years of age the red marrow persists only in the vertebrae, sternum, ribs, clavicles, scapulae, pelvis, cranial bones and in the proximal ends of the femora and humeri. In old age the marrow of the cranial bones undergoes degeneration and is then termed *gelatinous marrow*.

The yellow marrow consists of a basis of connective tissue, supporting numerous blood vessels and cells, most of which are fat cells, although a small population of typical red marrow cells persists.

The Red Marrow (6.10,11)

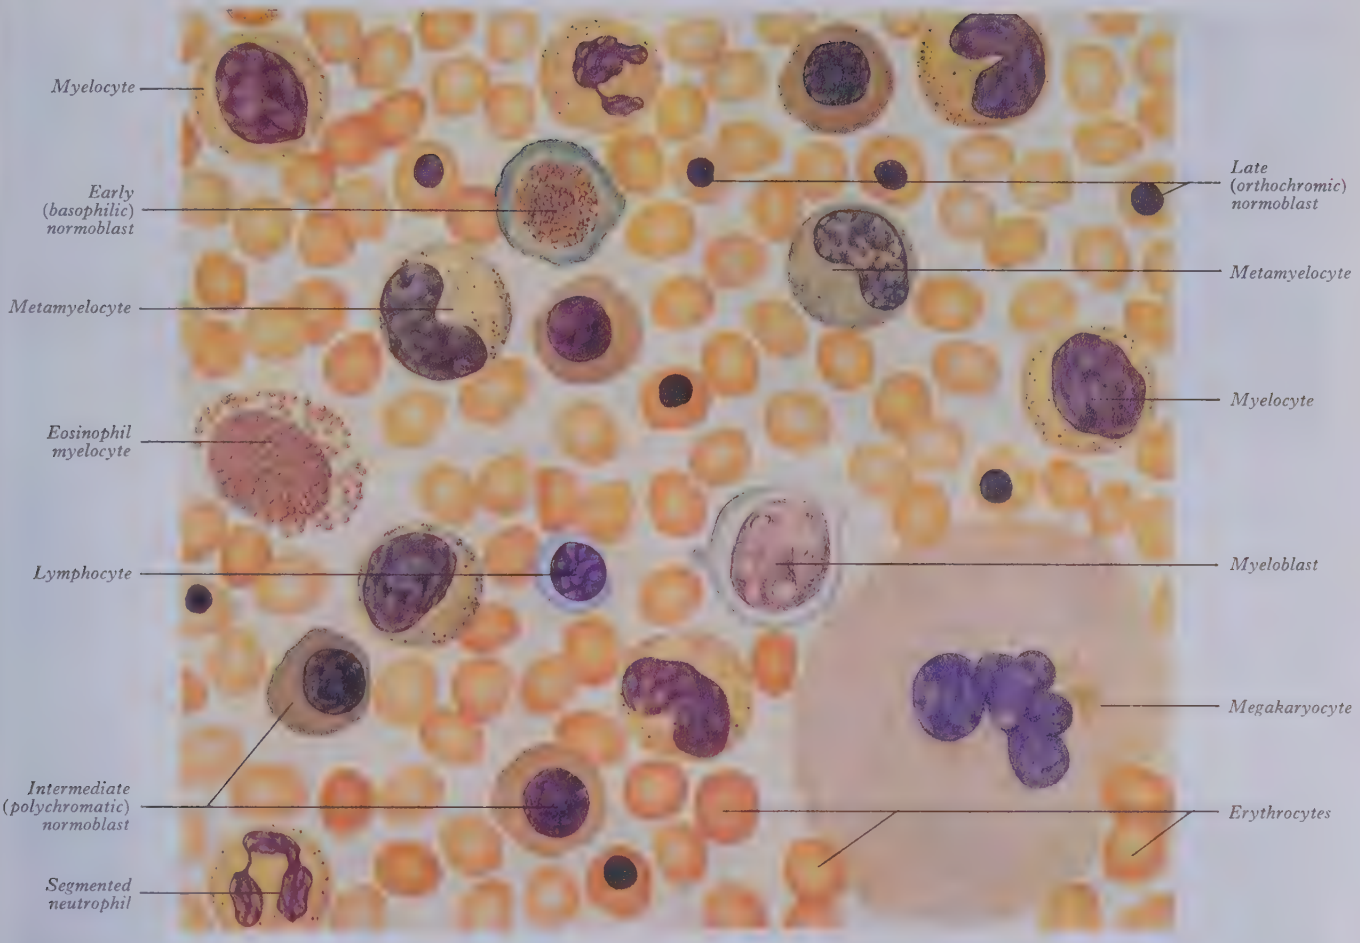
The red bone marrow consists of a network of loosely woven connective tissue, the *stroma*, supporting clusters of haemopoietic cells (*haemopoietic cords* or *islands*) and a rich vascular supply in which large, thin walled *sinusoids* are prominent (for reviews see Quesenberry & Levitt 1979, Tavasolli & Yoffey 1983, Weiss 1984, Golde & Takaku 1985). The stroma also contains a variable amount of fat, depending on age, site and the haematological condition of the body; small patches of lymphoid tissue are additionally present. Thus, the marrow consists of two major compartments, one vascular and the other extravascular. The whole assembly is enclosed within a bony framework, from which it is separated by a thin layer of bone lining cells (p. 295).

The stroma is composed of a delicate network of fine collagen (reticulin) fibres secreted by and adherent to highly branched *adventitial reticular cells* which appear to be a type of fibroblast and derived from embryonic mesenchyme. When haemopoiesis ceases, as in some limb bones in adult life, these adventitial cells become distended with fat globules, filling the marrow with yellow fatty tissue; but if there is a later demand for haemopoiesis, these cells can change back to their earlier stellate form. Also in the stroma are many *macrophages* attached to stromal fibres, some of them being embedded in the centres of haemopoeitic cell clusters. These cells are actively phagocytic of cellular debris created by haemopoietic development, especially the extruded nuclei of erythroblasts and remnants of megakaryocytes (vide infra).

Endothelial cells line the marrow sinusoids, the single layer of cells being supported by reticulin fibres on its basal surface. Endothelial cells are connected by tight junctions, which appear to be effective barriers between vascular and extravascular spaces. The passage of newly-formed haemal cells from the haematopoietic compartment into the blood stream occurs through temporary apertures (large fenestrae) formed in the endothelial cell cytoplasm, the migrating cell fitting tightly as it passes through, the aperture closing immediately behind it.

Haemopoietic tissue. Cords and islands of haematogenous cells consist of clusters of immature haemal cells in various stages of development, typically several different cell lines being represented at each focal group. One or more macrophages of a dendritic shape lie at the cores of each such group of cells, and may contain the iron-bearing molecules ferritin and haemosiderin. Besides the phagocytic functions already mentioned, there is evidence that such macrophages are important in transferring iron to developing erythroblasts for haemoglobin synthesis and may indeed exert control over the rate of cell proliferation and maturation of the neighbouring haemopoietic cells.

No lymph vessels have yet been demonstrated in either yellow or red marrow, as might be expected in a system of spaces enclosed in a rigid casing of bone. The vascular supply is derived from the nutrient artery to the bone and drained by the accompanying vein (p. 299). The artery ramifies in the bone marrow, its branches terminating in thin-walled arteries from which an extensive plexus of irregularly shaped sinusoids arises. These, in turn, drain into disproportionately large veins (Brookes & Harrison 1957). Many of these sinusoids are collapsed at any instant and are frequently but erroneously referred to as intersinusoidal capillaries.



HAEMAL CELL FORMATION

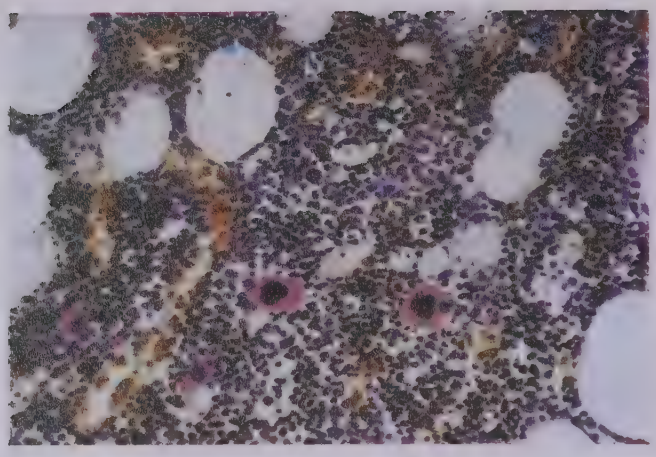
The initial stages of differentiation of haemal cells in mature marrow are far from clear. Early attempts to trace cell lineages in bone marrow preparations solely by histological examination of normal and abnormal tissue, led to much controversy about the origins and relationships of the various types of cell which could be observed. Some investigators considered it likely that all cell lines arose from a single type of stem cell (*haemocytoblast*) in adult tissue (the *monophyletic theory* of Maximow and others), whereas others favoured a multiple origin from many different types of stem cells (the *polyphyletic* theory, propounded by Ferrata and colleagues). Yet others have suggested compromise solutions (see Hardisty & Weatherall 1974). For many years it was also assumed that the lymphocytes arose exclusively in the peripheral lymphoid system and not in the bone marrow.

More recently, many experimental methods have been devised in an attempt to settle this issue; these include cell and organ culture, the replacement or transfusion of radiation-inactivated bone marrow with genetically or radioactively labelled haemal cells and the separation of stem cells from peripheral blood. The picture emerging still presents many uncertainties and applies mainly to rodent experimental models rather than directly to man. However, a brief outline of some recent findings will be attempted. It will be seen that haemopoiesis can best be described as a monophyletic or limited polyphyletic system, depending upon the stage in embryogenesis that is considered the starting point of differentiation.

Haemopoiesis in embryonic life commences at about the third week of gestation in the mesenchymal *blood islands* of the yolk sac, where only giant nucleated erythroid cells, *megaloblasts*, are formed. But these are soon replaced by *nucleated fetal erythroblasts* and these, in turn, are replaced by moderately large *anucleate, biconcave fetal erythrocytes* by about the fourth month of gestation. The adult type of erythrocytes are present by full term. Megakaryocytes, then granulocytes, lymphocytes and monocytes appear in that order between the second and fourth months of gestation. During the earlier developmental stages, stem cells occur in the yolk sac, liver, spleen and early bone marrow (p. 675) and these tissues can give rise to *all haemal cell lines* if they are transplanted to adult spleens (i.e. they are haemally 'totipotent'). Meanwhile, the lymphoid organs start to be colonized by stem cells which under normal circumstances only give rise to lymphocytes and hence appear to be already committed to that particular line of cells. However, the ability of these lymphoid tissues to carry out full haemopoiesis under certain pathological conditions suggests that some uncommitted stem cells have been retained in these sites but are normally suppressed.

In the *bone marrow* it appears likely that two types of *stem cell* have differentiated by early postnatal life; one type forms lymphocytes, whilst the other gives rise to erythrocytes, platelets, monocytes, neutrophils, eosinophils and basophils. The second of these stem cell types readily forms *haemal cell colonies* when transplanted to spleen cultures and each such cell is termed a *spleen colony forming unit* (CFU-S). The pluripotent CFUs are not numerous (about 0.5% of all haemopoietic cells in marrow), but they can circulate freely in the blood, where they appear as small lymphocyte-like cells, 7–10 μm across, with a large pale nucleus containing one or two nucleoli and bearing a narrow rim of cytoplasm.

6.9 Smear preparation of normal human red bone marrow, obtained by sternal puncture. This is a composite figure, drawn from a number of normal smears prepared by the late R L Waterfield, Guy's Hospital, and stained with a modification of Leishman's stain.



Next, we turn to the problem of the differentiation of such stem cells into the various cell lines of the blood. The early stages of these lines are difficult to distinguish since usually they cannot be recognized until well after they have begun to differentiate. In the cell line, however, a definite sequence of major stages can be recognized (or ascribed) (see **6**.8). These stages are: (1) the *final commitment* of a stem cell to a particular line of differentiation; (2) early cell *proliferation* to form a large pool of dividing cells; (3) *differentiation* as specific proteins characterizing the particular line are synthesized, accompanied by the gradual cessation of cell division; (4) final *maturation*, marked by the gradual closure of protein synthesis; (5) *release* of the cells from the bone marrow parenchyma into the circulation. In the case of some cell lines, cell division and protein synthesis may continue outside the bone marrow (e.g. monocytes or macrophages) and maturation may also be completed after release (e.g. erythrocytes).

The earliest 'committed' stages of each cell line are outwardly similar to the CFU-S, but at the next proliferative stage differences begin to emerge. In all, however, the initial picture is that of a rapidly dividing, relatively undifferentiated cell, in which the nucleus is large and euchromatic, with prominent nucleoli; the moderately basophilic cytoplasm contains unattached polyribosomes and the total cell size is large. As proliferation proceeds, the size of the cell usually diminishes as cell division outstrips cell growth. With continuing differentiation the ribosomes become numerous and the cytoplasmic basophilia increases as the specific RNAs begin to be synthesized, whilst the nucleus gradually becomes more heterochromatic and smaller, as DNA synthesis ceases; ultimately the nucleus becomes multilobed or pyknotic as protein synthesis terminates. The completed cell is then ready to be released, although the precise timing of its passage from the bone marrow varies with metabolic conditions and the 'demand' for more cells, so that relatively immature types of cell may be found in the circulating blood under abnormal conditions. This 'shift to the left' (a graphic convention of haematologists in which the cell is represented as maturing from the left to the right) is a useful concept in diagnostic haematology. These general features of development can be seen in several lines of haemal cells and underlie what appears at first sight to be a highly divergent series of progressions.

Erythropoiesis (**6**.8,9)

The earliest erythroid progenitor cells have not yet been identified, but the second stage includes cells which after some delay, can multiply very rapidly to form numerous erythroblast cells; they have therefore been named *burst-forming units of the erythroid line* (BFU-E). Third in this lineage is a cell which is sensitive to the hormone erythropoietin (p. 681), which induces it to further differentiation along the erythroid line. This is the *erythropoietin-dependent colony-forming unit* (CFU-E).

The first readily identifiable cell of the erythroid series is the *proerythroblast* (*pronormoblast*), a large (14–20 μm) cell with a large euchromatic nucleus and moderately basophilic cytoplasm. The latter already has small amounts of ferritin and bears some of the protein spectrin attached to its plasma membrane (p. 664); both are characteristic of this cell line and can be detected by electron microscopy. Proerythroblasts proliferate, and haemoglobin-RNA synthesis begins, as the smaller (12–17 μm) *basophilic* or *early erythroblast* (*basophilic normoblast*) appears, rich in ribosomes; shortly afterwards, haemoglobin synthesis commences so that the cytoplasm becomes partially eosinophilic (the *polychromatophilic* or *intermediate erythroblast/normoblast*) which has a diameter of 8–12 μm. At this stage, most of the RNA is lost and the nucleus, becoming intensely pyknotic, is finally extruded from the cell, thus forming the anucleate *reticulocyte*. At this point the cell is released into the circulation, losing its residual RNA

6.10 Photomicrograph of a section of bone marrow from a fetal human long bone. Note the heterogeneous collection of cell types including four large megakaryocytes. Magnification × 150.

in a few days to become a mature *erythrocyte*. The nucleus is removed by a macrophage. The whole process of erythropoiesis takes five to nine days; after release, reticulocytes typically sojourn for up to two days in the marrow sinusoids and then for an equal time in the spleen, perhaps because of their particularly adhesive cell coat. During this period, the remaining ribosomes add a further small amount of haemoglobin to the cell; then all the organelles are finally dismantled by a soluble cytoplasmic enzyme ('ubiquitin').

The cell lineage of normal erythrocytes is often called the *normoblastic series* to distinguish it from abnormal erythroid lines; too few divisions of the early proliferative stages may give rise to abnormally large erythrocytes (*macrocytes*), whereas too many divisions, or insufficient early growth, can lead to *microcyte* formation. Disturbances in haemoglobin synthesis can also give rise to a variety of anaemias and other pathologies.

Granulocytopoesis (6.8,9)

The details of this process are best known for the *neutrophil*, which will be described in some detail. Initially, the putative stem cells transform into the large (10–20 μm) *myeloblasts* which are similar in general size and appearance, though not in internal details, to the proerythroblast (vide supra). These proliferative cells differentiate into the larger *promyelocytes*, in which the first

6.11 Microscopic organization of bone marrow depicting a sinusoid in section, showing haemopoietic islands centred on macrophages (yellow), forming erythrocytes (red), various classes of leucocytes (blue), megakaryocytes (beige), adipocytes (orange), fibroblasts (brown) and endothelial cells (dark blue-purple) flanked by a basal lamina and reticulin fibres (white). A group of platelets (white) and various other cellular types are shown passing through apertures in the endothelial linings of sinusoids. An arteriole is also depicted (top left).

group of specific proteins is synthesized in the granular endoplasmic reticulum and Golgi apparatus, both of these organelles being quite prominent. The proteins are stored in large (0.3 μm) *primary ('non-specific') granules*, large lysosomes containing acid phosphatase and having azurophilic staining properties (p. 666). Next, in the smaller *myelocyte* —the last proliferative stage—the smaller *secondary ('specific') granules*, which contain a slightly different enzyme array, are formed in a similar manner, though released into the cytoplasm from the '*cis*' side of the golgi body, whereas the primary granules arise from the other *('trans')* side (see p. 28). The nucleus is typically flattened on one side in myelocytes. Subsequently, in the *metamyelocyte* stage the cell size decreases further, the nucleus becomes heterochromatic and horse-shoe shaped and protein synthesis practically ceases. Finally, as the neutrophil is released, the nucleus becomes heavily indented (the *juvenile* or '*stab*' form) and then partially divided into up to six lobes (the *segmented* or *mature neutrophil*). The whole process takes about seven days to complete: the mitotic period about three days and maturation four days. They may then be stored in the medulla for a further four days, depending on demand, before final release into the circulation.

Eosinophils pass through a similar sequence except that their nuclei never become as irregular as that of the neutrophil, and only one set of lysosomal granules is synthesized. it is not certain whether the eosinophil differentiates from the same myeloblast (or promyelocyte) stock as the neutrophil, or whether it is distinct from the colony forming unit (CFU) stage, which at present seems more likely (Zucker-Franklin 1985). In the case of *basophils*, it is not certain that they follow this general sequence at all; they may not even share the CFU as an ancestor.

Monocytes are also formed in the bone marrow, from stem cells of unknown structure; subsequently they pass through a proliferative *monoblast* stage and then form differentiating *promonocytes* in which small lysosomes begin to be formed (these may be demonstrated by neutral red staining). After further divisions, monocytes are released into the general circulation, and at least some are believed to pass to perivascular and extravascular sites, which they then populate as *mononuclear phagocytes* or *macrophages*. Monocytes and neutrophils appear to be closely related cells and arise from the same stem cell, the *colony forming unit for granulocytes and macrophages* (CFU-G/M) (the granulocytes in question being, of course, neutrophils).

Platelets, being fragments of cells, arise in a most unusual manner by the division of the cytoplasm of certain huge cells into many portions (Pennington 1979). The first detectable cell of this line is the highly *basophilic megakaryoblast* (15–50 μm); this is followed by a *promegakaryocyte* stage (20–80 μm) in which synthesis of granules begins; finally, the fully differentiated *megakaryocyte*, a giant cell (35–160 μm) with a large, dense, *polyploid, multilobate* nucleus, emerges. Once differentiation has commenced, mitoses proceed without cytoplasmic division and the chromosomes are retained within a single polyploid nucleus containing 8n, 16n or 32n chromosomes, depending upon how many nuclear mitoses finally occur. Under the electron microscope, the cytoplasm is distinguished by numerous centrioles and spindle microtubules, both of which reflect the repetitive *mitotic* activity. Meanwhile, differentiation proceeds in the cytoplasm with the production of free polysomes, smooth endoplasmic reticulum and fine basophilic granules. Cytomembranes within the cell fuse with one another and with invaginations of the plasma membrane to cut off portions of cytoplasm, which then break away from the parent cell to form platelets. The nucleus of the megakaryocyte eventually disintegrates.

Control of Haemopoiesis

The numbers of cells in the circulation are closely regulated, cell destruction being counterbalanced by cell replacement. How this system operates is known, at least in part, only for erythrocytes. Erythropoiesis is stimulated by a circulating protein *erythropoietin* synthesized by the tissues of the kidney and other parts of the body. The rate of erythropoietin synthesis is inversely proportional to the oxygen content of the tissues; hence low oxygen tensions, usually consequent upon lowered erythrocyte numbers, stimulate erythropoiesis whereas high oxygen tensions cause the withdrawal of the stimulus. At high altitude the lowering of the partial pressure of oxygen in the atmosphere leads to a raised erythrocyte count.

Many other factors also affect the rate of haemopoiesis, e.g. thyroid hormones, somatotrophic hormone, androgenic steroids and other hormones. In recent years it has also become clear that many other factors affect haemopoiesis, including substances released by T-lymphocytes, macrophages, neutrophils and other cells. The numbers of cells in the blood show a *diurnal rhythm*, probably because of hormonal fluctuations. Infection, haemorrhage and other clinical disturbances also affect the pattern of cell production, as do cytotoxic chemicals and ionizing radiations, to which the dividing cells of the bone marrow are particularly susceptible.

Blood Groups

Early attempts at transfusion of blood led to the discovery that erythrocytes bear antigens on their surface (see Race & Sanger 1975) which can interact with naturally occurring antibodies in the plasma of other individuals, causing agglutination and lysis of the erythrocytes. Such antigens, which are not shared with all members of a particular species, are termed *iso-antigens*; other iso-antigens are found amongst cells of other tissues (vide infra). Erythrocyte antigens are known as *agglutinogens* and the corresponding antibodies as *agglutinins*.

Erythrocytes from an individual can bear several different types of antigen, each type belonging to an antigenic system in which a number of alternative antigens are possible in different persons. So far at least 15 groups have been identified, which vary in their frequency of distribution amongst the various races of mankind, including the ABO, Rhesus, MNS, Lutheran, P, Kell, Lewis, Duffy, Kidd, Diego, Yt, Auberger, Ii, Xg and Dombrock systems. Clinically, only the ABO and Rhesus groups are of major importance. For a full description of blood groups in man, see the comprehensive account by Race & Sanger (1975).

All of these antigens are determined by genes carried by autosomes, except Xg which is borne by the X chromosome. Within each group the antigens are determined by alleles and inheritance is in accordance with simple mendelian principles. Thus, in the ABO system the genome may be homozygous and carry the AA complement, the blood group being A, the BB complement giving blood group B; or it may carry neither (OO), the blood group consequently being O. In the heterozygous condition the following combinations can occur: A B (blood group A B), A O (blood group A) and B O (blood group B). In Caucasians and Negroes group O is the commonest, being present in about 50% of the population, followed in frequency by groups A, B and AB in that order (Mourant 1975). In West Africans the Duffy determinant (Fy) is almost always absent, a lack which confers resistance to *Plasmodium vivax* malaria (Miller & Carter 1976).

The plasma in each case carries naturally occurring antibodies specific to the antigens which are not present on the erythrocytes in the same blood, so that in group A blood, anti-B antibodies are found. Similarly, present in group B blood are anti-A antibodies, in group O blood both anti-A and anti-B antibodies and in group AB blood there is neither type of antibody.

Transfusions succeed only if the recipient's antibodies do not correspond to the donor's antigens and cross-matching of blood antigens is therefore vitally important. Persons with group AB blood, lacking antibodies to both A and B antigens, can be transfused with blood of any group and are termed *universal recipients*; conversely, those with group O, *universal donors*, can give blood to any recipient, the donor's antibodies being diluted to insignificance. Normally, however, blood is only transfused between persons with precisely corresponding groups, since anomalous antibodies of the ABO system are occasionally found in blood and may cause agglutination or lysis.

Within the ABO system several subgroups exist (A_1, A_2, A_{1B}, etc.); the cross-matching of some of these is important in transfusions. The anti-ABO agglutinins, like all others (except those of

the Rhesus system), belong to the immunoglobulin M (IgM) class and do not cross the placenta during pregnancy.

The Rhesus antigen system, so-called because of its presence also in the erythrocytes of the Rhesus monkey, is determined by three sets of alleles, namely Cc, Dd and Ee, the most important clinically being Dd. The commonest condition in Britain is CDe and about 83% of the population is Rhesus-positive. Inheritance of the Rh factor obeys simple mendelian laws and it is therefore possible for a Rhesus-negative mother to bear a Rhesus-positive child. Fetal Rh antigens can, under these circumstances, stimulate the production of anti-Rh antibodies by the mother and since these belong to the immunoglobulin G group of antibodies they are able to cross the placental barrier and cause agglutination of fetal erythrocytes. In the first of such pregnancies little damage is usually caused, but in subsequent Rh-positive ones massive destruction of fetal red cells may ensue, causing fetal or neonatal death. Treatment is by exchange transfusion of the neonate infant or, prophylactically, by desensitizing the mother after the first Rh-positive pregnancy with Rh-immune serum, which appears to destroy the fetal Rh antigen in the maternal circulation before the processes of immunological memory can be entrained (see Clarke 1975).

Of the other antigenic systems known, some of which are occasionally of clinical importance, many are restricted to individual genic groups or even families; they can be of great value to anthropologists when tracing demographic relationships, as of course are the major systems described above (Mourant 1983).

Other antigenic systems such as MNS (shared with other tissues in the body) can be used in medico-legal investigations to establish identity of blood, or in parental identification. These antigens can remain intact long after death, and have been detected even in mummified tissues from Egypt over 4000 years old (Harrison et al 1969).

The genetics of blood groups is complicated by gene linkage with other characters which may be of some clinical importance; e.g. duodenal ulcers show a higher incidence in those with group O blood than in the general population.

Leucocytes also bear antigens and about 12 such groups have so far been identified, 10 of them belonging to the same complex system. These are similar to the *histocompatibility antigens* involved in graft rejection (vide infra).

Histocompatibility Antigens

Amongst important components exposed at the surfaces of most cells are the molecules which determine the individuality of tissues from different persons (the histocompatibility locus antigens) and which are intimately related to the functioning of the immune system. They also share the same region of one of the chromosomes, their genes being grouped together as the Major Histocompatibility Complex, expressed in the body as a number of distinctive proteins. This system has come into prominence because of its importance in tissue grafting and transplant surgery and to various other clinical approaches.

In humans, the major histocompatibility complex (MHC) genes lie on the short arm of chromosome 6 and are grouped in a linear sequence close to each other; crossing over during meiosis rarely or never occurs in this sequence, due to either their proximity to each other or some other intrinsic resistance to this process. The MHC region expresses a number of distinctive classes of molecules in various cells of the body, the genes being, in order of sequence along the chromosome: the Class I, II and III MHC genes. Class I consists of the HLA genes, subdivided into A, B and C subregions, A and B being represented by a number of different alleles; these genes are capable of generating throughout the cells of the body a distinctive set of gene products, expressed at the surfaces of most cells. These appear to be different in all individuals, conferring a unique chemical identity which is the basis of the immune reactions in the body, since lymphocytes recognize and attack cells bearing alien antigens mainly when these are present alongside characteristic 'self'-HLA molecules. This enormous range of possible alternatives is a result of the substructure of the genes coding for them, which are subdivided into many smaller units; these can be spliced together in many different combinations, in a manner resembling the mechanisms for creating diversity amongst antibodies or T-cell receptors (pp. 674, 675), although of course there is a fundamental difference in the outcome, since only one HLA sequence out of a great possible range is selected during development. The HLA sequence also has interesting diagnostic aspects because of chromosomal linkage to sites affecting the frequencies of certain diseases (vide infra).

The genes for Class II MHC molecules include three subdivisions termed DR, DQ and DP. Of their products, the MHC-DR molecules are best known; these occur on the surfaces of antigen presenting cells generally classed as macrophages (p. 673) and including various dendritic cells of lymphoid tissue (e.g. follicular dendritic cells, interdigitating cells) and the epidermis (Langerhans cells). These molecules are anchored into the membrane and like the HLA antigens are highly polymorphic (i.e. have different chemical structure in different individuals). They can bind to alien antigens which the cells have phagocytosed and partially digested, and this combination is presented to helper or cytotoxic T cells where they temporarily bind to the CD 4 molecules (T-cell receptors) present on the lymphocyte surface to activate that cell (p. 675). The genes for Class III MHC products are expressed in various components of the complement system, as well as some other, non-immune related proteins.

The HLA system has attracted much attention lately, because of its importance in transplant surgery and, in a quite different way, because of the association between certain of its subgroups and some types of disease. For example, the subtype HLA-B27 is present in nearly all cases of ankylosing spondylitis; the condition of haemochromatosis, a disturbance of iron metabolism, is strongly associated with $HLA\text{-}A_3$ and rheumatoid arthritis with $HL_4\text{-}D_4$. Other conditions that display a statistical correlation with the HLA system include diabetes in juveniles, Hodgkin's disease and multiple sclerosis. The reasons for these associations are not clear, but are thought to represent some type of loose *genetic linkage* between the HLA determinants and other alleles predisposing the body to a range of diseases. In mice, where this system has been widely investigated, genes that apparently control the responsiveness of the immune system to infection (the Immune related, or Ir genes) are situated between those genes that determine the major histocompatibility (H2) factors.

BLOOD VESSELS

Introduction

For life to be maintained, the composition and properties of the local fluid environment of the body's cells must remain constant within certain limits. This is ensured by the operation of interlocking homeostatic controls which depend for their effect upon adequate circulatory systems. These are composed of great numbers of cell-lined tubes and spaces which surround and permeate the tissues, providing a continuous perfusion of body fluids. The most extensive of these are the *blood-vascular system*, i.e. the heart and vessels in which blood circulates, and the *lymphatic system* of lymphatic vessels and nodes, which conduct the lymph; this definition also includes the isolated patches of lymphoid tissue, spleen, thymus and various pathways involved in a wider process of the formation and dissemination of lymphocytes (p. 670). Other, more restricted circulations are those of the cerebrospinal fluid, perilymph, various endocochlear fluids, ocular aqueous humour, synovial fluid and the fluids of the coelomic spaces—pericardial, pleural and peritoneal cavities. In this section only the blood-vascular and lymphatic systems are considered.

The rhythmically repeated contractions of the heart, which is essentially a *pair* of valved, muscular pumps arranged in *series* (vide infra), drives blood through the blood vessels to all tissues. Leaving the heart, it is distributed through large tubes, *arteries*, which divide and subdivide until minute vessels, various grades of *arteriole*, are reached; these again divide into dense networks of microscopic vessels, intimately in contact with tissues, which vary in structure and are termed *capillaries* or *sinusoids* depending upon their structure and function. Blood is collected from them via minute *venules* which unite repeatedly to form increasingly large *veins*, returning blood to the heart (**6**.12).

The terms artery, arteriole, capillary, venule and vein are essentially *anatomical* names, based on considerations of size, structure and topographical position. *Functionally* vessels may be classified as *distribution, resistance, exchange* and *capacitance* or *reservoir* types. Varieties of *shunt* vessels provide channels which can bypass capillary beds and sinusoids.

Distributing vessels are the low-volume, high-pressure system of large arteries which leave the heart, and their branches down to arteriolar level. They show gradually changing structural and functional features with increasing division and distance from the heart. As they leave the heart and branch, their walls contain much elastic tissue (*elastic arteries*); their repeated distension and recoil damps the effects of ventricular systole into smoother but still pulsatile flow throughout the arterial tree. Smaller branches, while retaining marked elasticity, display increasing amounts of non-striated muscle in their walls (*muscular arteries*), the tonus of which controls blood flow to large tissue masses in accord with the changing levels of activity. An alternative and perhaps more significant subdivision of arteries can be made into *conducting vessels* for major arteries with more highly elastic walls and *distributing vessels* for more muscular arteries down to the beginning of arterioles, the latter being termed *resistance vessels* (see Simionescu & Simionescu 1984).

Finer control of flow in microcirculatory units of various tissues (vide infra) is exercised by the muscular walls of arterioles and precapillary sphincters which provide the main peripheral resistance to flow. This factor, combined with the prevailing cardiac output, largely determines the general pressure in the arterial tree and, locally, modulates blood flow through the various capillary beds.

Capillaries, sinusoids and postcapillary venules are collectively termed *exchange vessels*: exchange between blood and the tissue fluid around cells, the essential function of circulatory systems, occurs through their walls. This exchange includes oxygen, carbon dioxide, nutrients, water and inorganic ions, vitamins, hormones, metabolic products, antibodies and defensive cells of various kinds.

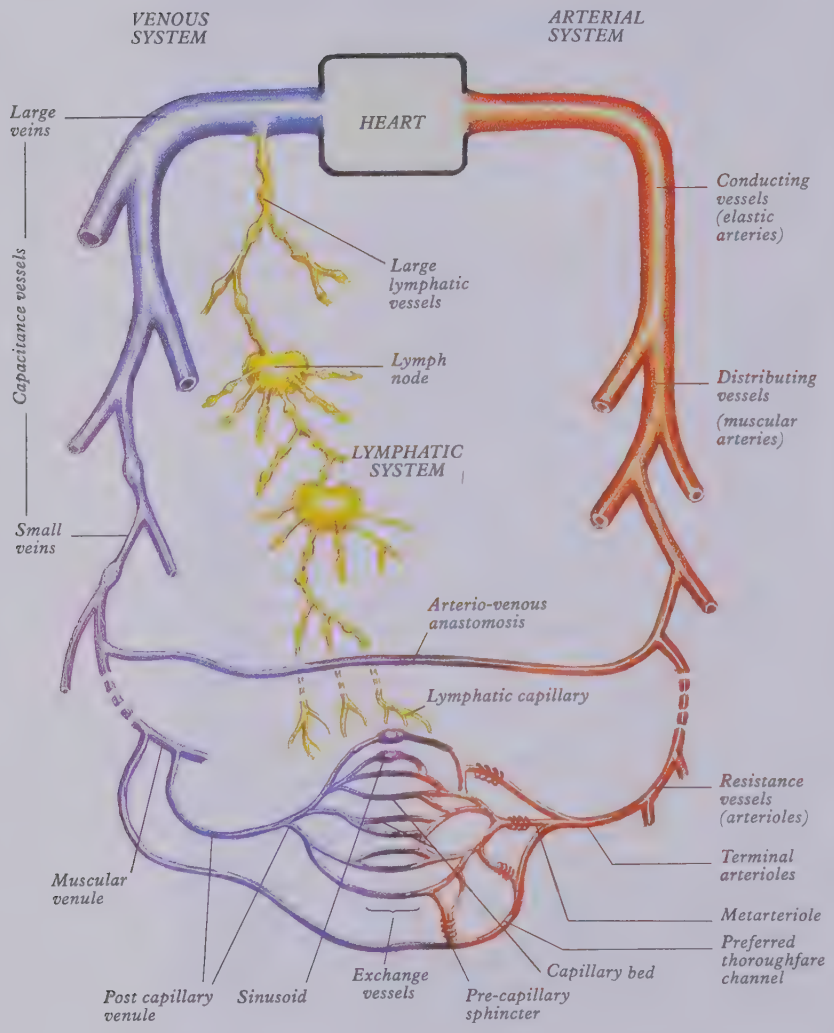
Larger venules and veins form a co-extensive but variable, large-volume, low-pressure array of *capacitance* or *reservoir vessels*, conveying blood back to the heart.

The heart has four chambers: *right atrium*, *left atrium*, *right ventricle* and *left ventricle*. (These somewhat misleading names are discussed on p. 698.) Each atrium leads into a corresponding ventricle, the right and left chambers being separated by *septa*. The right and left sides are thus twin pumps, *topographically combined* in a single organ but interposed *in series* in the vascular system, separating it into *systemic* and *pulmonary* circulations (constituting the so-called *double circulation* typical of birds and mammals, see p. 697). The course of blood from left ventricle through the body at large to the right atrium forms the *systemic circulation*, its passage from the right ventricle via the lungs to the left atrium being the *pulmonary circulation*. The relatively short pulmonary system offers much less peripheral resistance than the systemic circulation, as is reflected in the lower pressures in the pulmonary distribution vessels and in the thinner walls of the right ventricle (p. 698). The average output volume of blood from the right and left sides of the heart must, of course, be the same.

The superior and inferior venae cavae return to the right atrium blood which has become *deoxygenated*, has taken up carbon dioxide and been otherwise modified during circulation through the tissues of the body. This blood then enters the right ventricle, which expels it via the pulmonary trunk to the lungs. In the pulmonary capillaries blood is brought into close proximity to the inspired air, releasing some carbon dioxide and acquiring oxygen. This *oxygenated* blood, returned by the pulmonary veins to the left atrium, enters the left ventricle, which pumps it into the *aorta* for general distribution.

Blood traversing the spleen, pancreas, stomach and intestines is not carried back directly to the heart but passes through the *portal vein* to the liver. This vein divides like an artery, ending in the hepatic sinusoids drained by the *hepatic veins* to the inferior vena cava, whence blood is conveyed to the right atrium. This route is the *portal circulation*; its essential feature is that the blood supplied to the above-named viscera, traverses two sets of capillary vessels before reaching the inferior vena cava; the vessels are: (1) capillaries in the spleen, pancreas, stomach, etc., draining into the portal vein and (2) the hepatic sinusoids, draining into hepatic veins. Passage through these two sets of capillaries enables the blood to transfer the products of digestion directly from the alimentary canal to the cells of the liver. Another venous portal circulation connects the median eminence and infundibulum of the hypothalamus with the pars distalis of the adenohypophysis (p. 1451).

ENDOTHELIUM



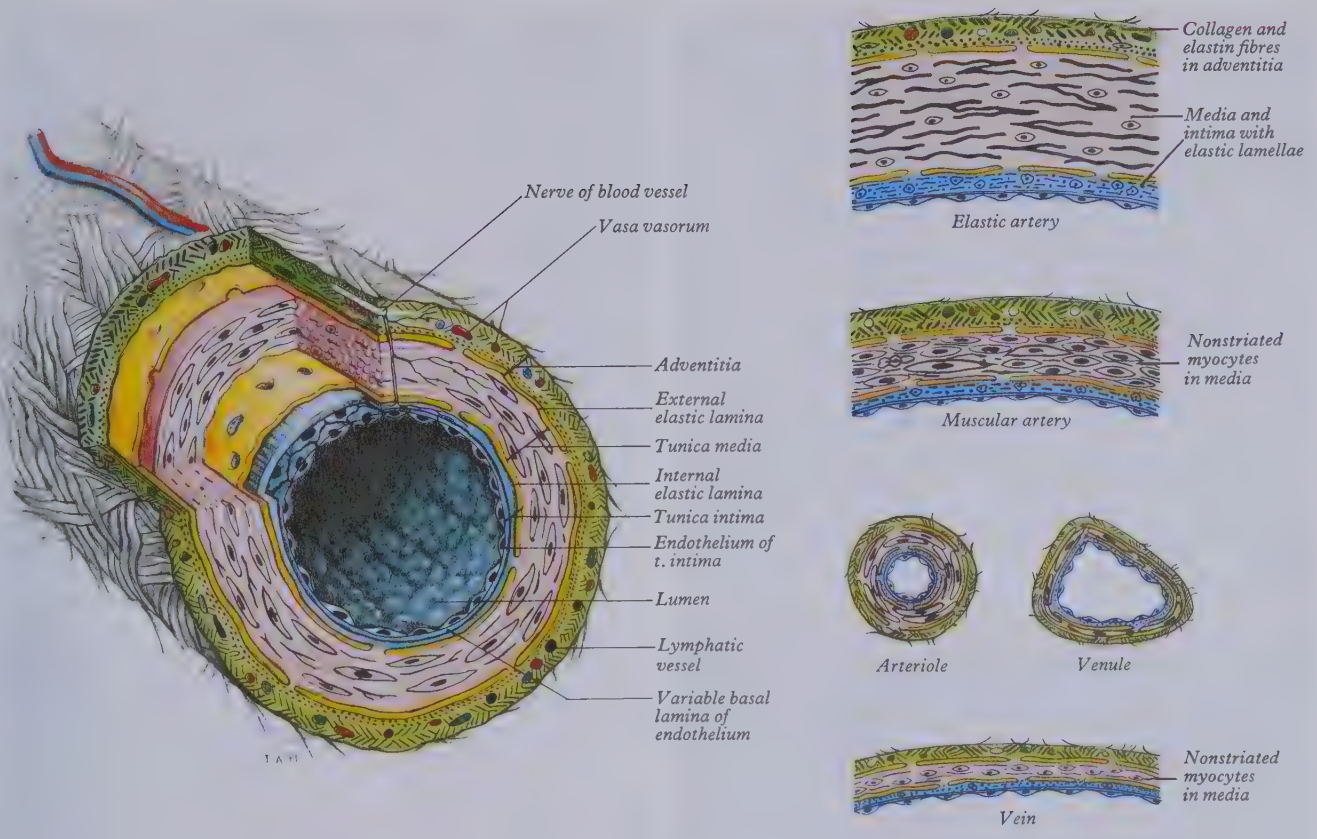
The surfaces of all blood vessels, the lymphatic channels and the inner surface of the heart are lined by endothelium, composed of a single layer of squamous, *endotheliocytes* (see Fishman 1982, Simionescu 1983, Simionescu & Simionescu 1984). The properties and activities of these cells are of great importance to the physiology of the vascular system. Although all endotheliocytes resemble each other in their general organization, considerable variations exist in their detailed structure and functions in different parts of the body.

Individual endotheliocytes are flattened cells, polygonal when viewed from the vessel lumen and usually somewhat longer, parallel to the longitudinal axis of the vessel. Typically their cytoplasm is thickened around the nucleus but is for the most part very attenuated, being as little as 0.2 μm in the capillaries. In arterioles and muscular arteries the nucleus and cytoplasm may bulge markedly into the lumen when the vessel is contracted, e.g. at post-mortem (see **6**.17D,E). Within the cytoplasm, organelles are sparse but include small amounts of granular and agranular endoplasmic reticulum, some free ribosomes and mitochondria and a pair of centrioles. Variable bundles of microfilaments and intermediate (vimentin) filaments are also present, presumably helping to determine cell shape (which may change when suitably stimulated in some cases) and reinforcing the cell mechanically. In arterial and arteriolar endothelia there are certain rod-like vesicles about 3 × 0.1 μm in dimension (Weibel–Palade bodies) which store a clotting factor (the von Willebrand component of factor VIII, Wagner & Marder 1984) which may be released after cell damage as part of haemostasis. A characteristic feature of many endothelial cells is the presence of great numbers of small vesicular invaginations (*plasmalemmal vesicles*) of the plasma membrane along both flat surfaces. These are believed to be important in shuttling materials across the endothelium and in some cases they may fuse to form complete open channels, grading into permanent fenestrae (p. 689). Such structures typify vessels engaged in rapid exchange of fluids or macromolecules between the vascular and extravascular spaces; but their frequency varies directly with vascular permeability, vessels in the brain having very few, and capillaries of the intestine, myocardium and kidneys having many. In some areas there are large gaps between cells, e.g. in linings of splenic sinusoids, which permit free access of plasma (and in the spleen, blood cells) to extravascular tissues.

Endothelial cells are linked to each other laterally by occluding (tight) junctions which may either form continuous belts to create permeability barriers (zonulae occludentes) and hold the cells together or in some cases discontinuous, spot-like contacts (Maculae occludentes), allowing some leakage between cells. Endotheliocytes are also linked to each other and often to other extravascular cells, such as non-striated myocytes, by gap (communicating) junctions, facilitating co-operation between cells connected in this way. They are limited externally by a typical

basal lamina, which may also affect the permeability of blood vessels, particularly fenestrated capillaries and sinusoids. In renal glomerula, this basal lamina is particularly important in determining transendothelial filtration (p. 1401).

Endothelial cells lining capillaries and venules are mainly passive, selectively permeable barriers, allowing the passage of water and small ions but retaining larger molecules and red cells within the vascular channels to varying degrees. Various substances in the body also may change vascular permeability, e.g. histamine, which causes a transient separation of intercellular junctions (see Simionescu et al 1982). However, endothelium also has many important metabolic functions and a variety of enzyme systems has been located within or at the surfaces of endothelial cells. The capillary bed of the lungs has been most fully investigated and it has been shown that various blood-borne substances are changed during their passage. These include Angiotensin I which is converted to the vasoactive Angiotensin II; many substances are also inactivated, e.g. serotinin, bradykinin, noradrenalin, various prostaglandins (e.g. A, E and F), testosterone, etc. (see Fishman 1982, Stalcup et al 1982). In addition, endothelium strongly inhibits the adhesion of platelets and other thrombus-initiating events; this may be partly due to the negative charge on the endothelial surface which repels other negatively charged cells, but the synthesis of anti-thrombogenic factors such as prostacyclins and similar prostaglandins appears to be important. If the endothelial surfaces of vessels are damaged, clotting soon occurs because of interactions of plasma-mediated haemostatic mechanisms with the underlying tissues, particularly their collagenous components, and also because of substances released by the damaged endothelial cells themselves. Such disturbances are obviously advantageous in limiting blood loss from breached vessels but also play a key role in thrombosis associated with arterial disease, especially atheroma and hypertensive damage.



6.12 Schema showing the nomenclature of the different vessels in the haemo-lymphoid system.

Angiogenesis

The microcirculation can readily change its form by adding new vessels and presumeably resorbing old, ill-used pathways. The development of new vascular pathways occurs during the developmental growth of tissues but remodelling continues at a diminishing rate throughout life. This is most clearly seen in wound healing and regeneration, where the repairing tissues are invaded by numerous vascular cords developed both by the migration and proliferation of existing endothelium and, where these are lacking, by the differentiation of connective tissue cells (probably persistent pluripotent mesenchymal cells). Having invaded as solid cords of cells, these canalize (develop a lumen) and join end to end to form vascular loops through which blood flows. Some vessels then acquire fibromuscular coats and innervation to become arterioles, venules and larger vessels. The stimuli for such angiogenetic activity is currently under active investigation; they appear to include various angiogenic factors released from macrophages, activated T cells and other sources (including mast cells), which create chemotactic gradients, stimulate mitotic activity and cause cellular differentiation and maturation (see Folkman & Klagsbrun 1987). Interestingly, some tissues lack an intrinsic network of vessels, e.g. cartilage, stratified epithelia; this may be partly due to active inhibition of vascular growth.

The Structure of Blood Vessels

Blood is ejected from the left ventricle during systole into the aorta, a single tube about 2.5 cm diameter in the adult (Wright 1969), with a wall thickness of about 1.5 mm. Having traversed numerous successive branchings of this trunk, the blood eventually enters a capillary bed in the tissues (**6.12**), consisting of millions of tubes each about 8 μm in diameter, with a wall in places less than 0.2 μm thick, and a total estimated length in adults approaching 60 000 miles (Zweifach 1961). It is often stated that this systemic *arterial tree* progressively divides to create a larger and larger total cross-sectional area; but the evidence in man is not clear, particularly proximal to the arteriolar level. However, there are many progressive changes in the structural and functional properties of arteries with increasing distance from the heart. There is both a geometric reduction of individual lumen cross-sectional areas and an increase in stiffness of the vessel walls. In *arteriolar* and *capillary* branching the total sectional area of vessels increases greatly, with a progressive reduction in the rate of blood flow and of systolic and pulse pressures. However, lining the interior of the whole system from the finest capillaries up to and including the heart, is a smooth, continuous single-layered endothelium. Larger vessels also have surrounding coats composed of non-striated muscle and connective tissue, arranged in characteristic layers. Though laminar organization of these varies greatly with vessel size and type, reflecting their functional roles, three analogous zones (coats or tunics) have classically been described in the walls of all vessels except for capillaries and sinusoids (Cliff 1976, Simionescu & Simionescu 1984). These are from inside outwards the *tunica intima*, *tunica media* and *tunica adventitia* (**6.13**). These coats confer on the vessels a number of important properties, including an endothelial lining low in friction and connective tissue components able to withstand longitudinal and circumferential stresses due to prevailing blood pressures; they provide elastic recoil for the progressive modification of pulsatile pressure changes or flow variations in arterial trees and the ability to vary vessel calibre by muscular action.

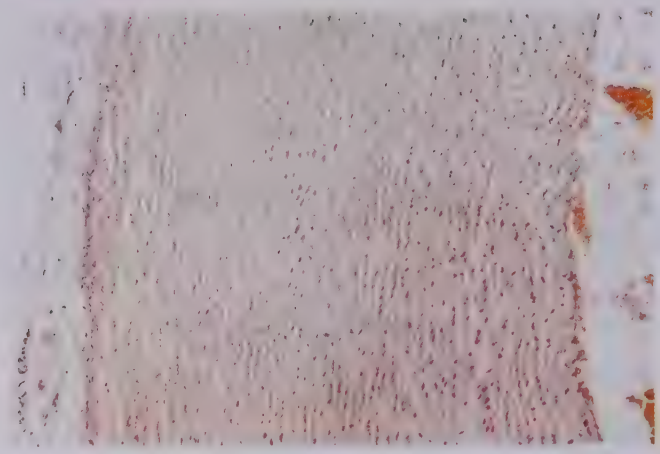
6.13 Diagram showing the principal architectural features of the larger blood vessels. On the *left* the major layers and associated structures are depicted; on the *right* the particular features of an elastic artery, muscular artery, arteriole, venule and vein are shown.

The *tunica intima* is generally a single layer of endothelial cells supported externally by fine subendothelial connective tissue of largely longitudinal arrangement. The fibromuscular *tunica media* extends from internal to external elastic lamina (*elastica interna* to *elastica externa*) and is circumferential. The *tunica adventitia*, surrounding the external elastic lamina, is again largely longitudinal or irregular in the orientation of its cells and fibres and blends at its outer limit with the connective tissue of the structures surrounding it.

Nutrient blood vessels, *vasa vasorum*, and lymphatics run in the adventitia and a few in the outer zones of tunica media in larger vessels. Nerve fibres may supply all three tunicae (vide infra). Arteries are enclosed in a thin, delicate *sheath* of loose connective tissue, which usually encloses the accompanying veins, perivascular nerves and sometimes major nerves in the vicinity.

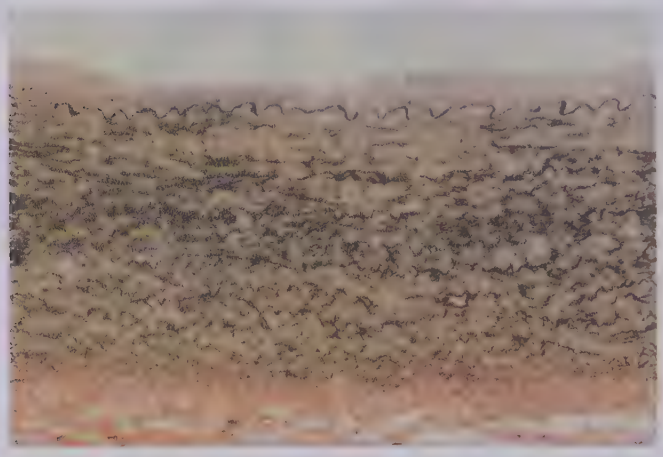
The thickness of vessel walls

The form and composition of blood vessel walls varies largely with blood pressure and, in arteries, with the nature of the pressure wave. Hence arterial walls are proportionately much thicker; and walls in arteries and veins inferior to the heart are in general thicker than those above it, due to the higher hydrostatic pressure in the lower regions when the body is erect. Systemic arteries have thicker walls than pulmonary arteries, reflecting the marked difference in pressure. Arteries within the cranium and vertebral canal (a 'closed box' system) have very thin walls relative to vessel diameter, the external and middle tunics being reduced in relative thickness as is also the condition in the medullary cavities of long bones. Where considerable external pressures or other mechanical forces act upon them, e.g. in coronary and carotid arteries, vessels often have thick muscular walls, mainly due to a wide tunica media.



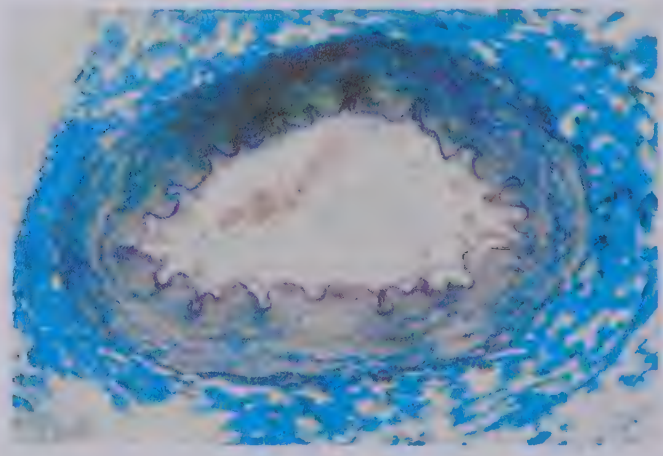
Elastic arteries usually have walls with a thickness of about one-tenth their calibre; this fraction in muscular arteries is about one-quarter, in arterioles approximately one-half and in veins the proportion is about one-tenth or less.

ARTERIES



The large elastic arteries (**6**.14A,B) include the aorta and its main branches, the brachiocephalic, common carotid, subclavian and common iliac arteries, and also the pulmonary arteries and their main branches.

In these vessels, the *tunica intima* is about 100 μm thick in young adults. The endothelium consists of flat, polygonal cells lying on a basal lamina and joined by intercellular junctions, including zonulae occludentes; their general features will be considered with capillary structure. The subendothelial tissue comprises: firstly, a layer of interlacing, mainly longitudinal, collagen and elastin fibres, with a few fibroblasts, non-striated myocytes and macrophages; secondly, a fenestrated elastic membrane, the *internal elastic lamina* of smaller arteries. In large arteries this is not sharply demarcated from the tunica media because both contain a series of similar elastic membranes (Dobrin 1978). Intimal thickness varies much with age and other factors: in children it may be almost insignificant, but in young adults intimal thickening is noticeable, perhaps due partly to migration and proliferation of non-striated myocytes from the tunica media, and otherwise to a variable deposition of lipid material, which often forms irregular fatty streaks. In young adults the tunica intima is about one-sixth of the total mural thickness but, after middle age, lipid deposits may grossly expand it.



The *tunica media* largely consists of circular, concentric, fenestrated elastic lamellae (up to 40 layers in the normal aorta), separated by fibrous tissue with a basophilic proteoglycan matrix permeated by bundles of collagen and elastin fibres, between which are circularly-orientated non-striated myocytes (Somlyo & Somlyo 1968). Most of these myocytes are typical of their cell type

but adjoining intima are often highly branched (Keech 1960), connecting adjacent lamellae. There is a strong correlation between the internal pressure of elastic arteries and the number of their elastic lamellae which, with associated myocytes, form '*lamellar units*' (Wolinsky & Glagov 1967a). The myocytes are responsible for the production of lamellae, collagen and proteoglycan components between them (Ross & Klebanoff 1971), an activity which is also shown by non-striated myocytes elsewhere, though to a lesser degree. At birth, the aorta is almost devoid of lamellae and is contractile but later lamellae increase greatly in number and individual thickness. They also multiply in hypertension due to added mechanical stress (see Cliff 1976).

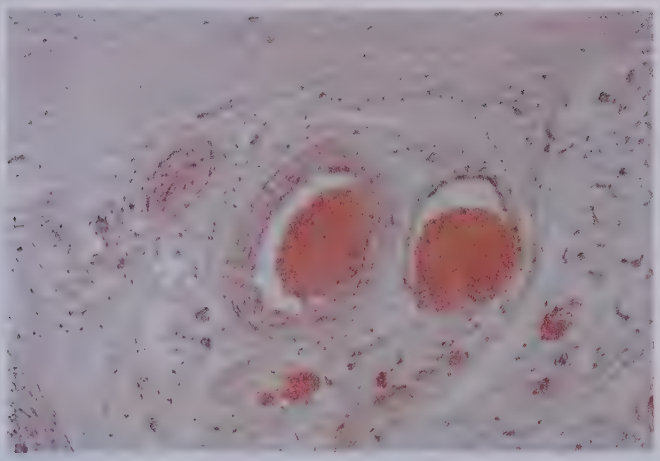
The arrangement of myocytes varies throughout the vascular system. In the elastic arteries nearest to the heart, they radially or obliquely interconnect the adjacent lamellae ('*Spannmuskeln*'), whereas more distally they are disposed circumferentially, individual cells lying end to end ('*Ringmuskeln*') (Benninghof 1927, Wolinsky & Glagov 1964); in both regions they are also slightly helical.

The *tunica adventitia* consists mainly of collagenous fibrous tissue containing a few elastic fibres; it is relatively thin and merges into the surrounding connective tissue.

From middle age onwards structural changes occur in elastic (and other) arteries, in addition to the intimal changes noted above, particularly in the aorta and arteries of the heart and brain. The content of elastin and collagen increases, while the muscle and water content decreases, leading to increased general stiffness. Calcium salts and lipid are also deposited in the intima and media, with splitting of the internal elastic lamina and various other alterations which may become overtly pathological.

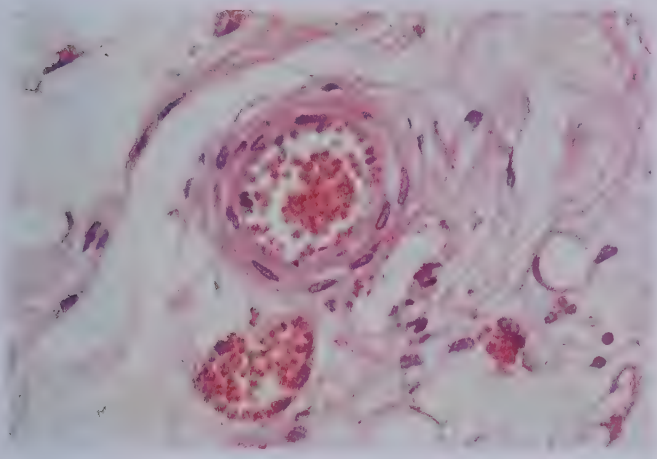
Medium and small muscular arteries (6.12,14C,15) have a *tunica intima* which is a single layer of elongate endothelial cells, longitudinally arranged; its external surfaces are covered by a typical basal lamina contiguous with the *internal elastic lamina*, a fenestrated elastic sheet seen in transverse sections as a brightly refractile zone usually undulated by the agonal contraction of the muscular tunica. Since the media contains less elastic tissue than in larger arteries the internal elastic lamina is prominent. Fenestrations in this lamina permit the diffusion of metabolites between the media and the lumen of the vessel.

In the coronary arteries, the internal elastic lamina is bounded by a specialized thick layer of longitudinal muscle and fibrous tissue, presumably enabling them to accommodate to the marked changes in length occurring during the cardiac cycle.



The *tunica media* consists mostly of non-striated myocytes with scattered elastic fibres and a small amount of collagen (mainly type III). The myocytes are generally disposed in tight helices around the circumference of the vessel, although in smaller ones their direction is mainly circular. Adjacent myocytes have communicating junctions which co-ordinate their activities, which are generally under neural and neurohumoral control. Longitudinal myocytes exist in both the intima and media of arteries subject to repeated bending, e.g. the carotid, axillary, uterine, cervicooccipital and palmar arteries. In the tunica media of umbilical arteries, longitudinal muscle occurs in the inner zone, circular in the outer.

The *tunica adventitia* consists of predominantly longitudinal collagenous and elastin fibres. Externally it is rather loosely arranged, merging into the surrounding loose connective tissue and thus allowing considerable movement between the artery and neighbouring structures. Adjacent to the tunica media the adventitia contains much elastic tissue, including the *external elastic lamina*, a feature of variable prominence.



ARTERIOLES, TERMINAL ARTERIOLES, METARTERIOLES AND PRECAPILLARY SPHINCTERS (6.12,16,17)

The smallest arteries terminate in *muscular arterioles* 100–50 μm in diameter, which branch into *terminal arterioles* less than 50 μm in diameter with merely one or two somewhat spiralized layers of non-striated myocytes in their walls (Rhodin 1971). *Metarterioles* (6.17E) are branches of terminal arterioles, 10–15 μm in diameter at their origin and decreasing over 50–100 μm to as little as 5 μm. Where they open into the capillary bed, they are surrounded by a strong circular layer of non-striated myocytes forming *precapillary sphincters*, which effect the final control of blood flow through the capillaries. Precapillary sphincters have been seen to open and close periodically with a cycle of 2–8 seconds.

Both muscular and terminal arterioles have a single layer of elongated endothelial cells, their long axes parallel to the flow of blood. These rest on a basal lamina; they are separated in places from the myocytes of the adjacent tunica media by patches of elastic tissue, homologous with the internal elastic lamina of

larger vessels. Elastin components decrease and finally disappear in the finest terminal arterioles. The tunica media of larger arterioles has a few circular layers of non-striated myocytes, the most external often being slightly helical. Myocytes form gap (communicating) junctions with overlying endothelium at points where the elastic lamina and basal lamina of the endothelium are lacking.

The adventitia of arterioles consist of a fine reticulum of collagen fibres with a few fibroblasts.

Arterial Nutrient Supply

Larger arteries have their own blood vessels, *vasa vasorum* (singular: *vas vasis*), often branches of the artery itself or of a vessel at

A. Low-power view of a group of vessels showing a small artery (mid-right) with an accompanying vein (mid-left) in transverse section. An obliquely sectioned vein is also visible (extreme right) and a lymphatic vessel is present on the upper left; the extravascular tissue consists mainly of irregular dense connective tissue. Magnification × 320.
B. Medium-power view of a transversely sectioned small artery, showing the thick muscular wall and the longitudinally ridged intima with erythrocytes adhering to the endothelial surface. The adventitia blends with the surrounding dense fibrous tissue. Magnification × 1000.
C. High-power micrograph of the cut end of a capillary with three erythrocytes visible. Note the extreme thinness of the endothelial wall (left) and the collagen fibres in the extravascular tissue. Preparations by Michael Crowder, Guy's Hospital, London. Magnification × 6000.

6.17D Transmission electron micrograph of a partially contracted small arteriole in transverse section, showing an outer zone of non-striated myocytes and an inner lining of endothelial cells. Erythrocytes are visible within the lumen. The specimen is from the uterus of a rat. Magnification × 4000.

some distance from their distribution; these ramify in the loose connective tissue of the outer sheath and form a dense capillary network in the adventitia and may, in larger vessels, penetrate the outer part of the tunica media. The remainder of the wall is supported by diffusion from blood from these vessels or from the vascular lumen; fenestrations in the elastic laminae are presumably important in allowing this to occur. Minute veins return blood from the adventitia into the artery's companion veins. Lymphatic vessels also occur in the adventitia and drain along parallel channels.

6.17E Transmission electron micrograph of a metarteriole fully contracted. The endothelial cells almost totally occlude the lumen. The dark cells around the periphery are pericytes. A biopsy specimen of human synovial membrane. Magnification × 6000.

Arterial Nerve Supply

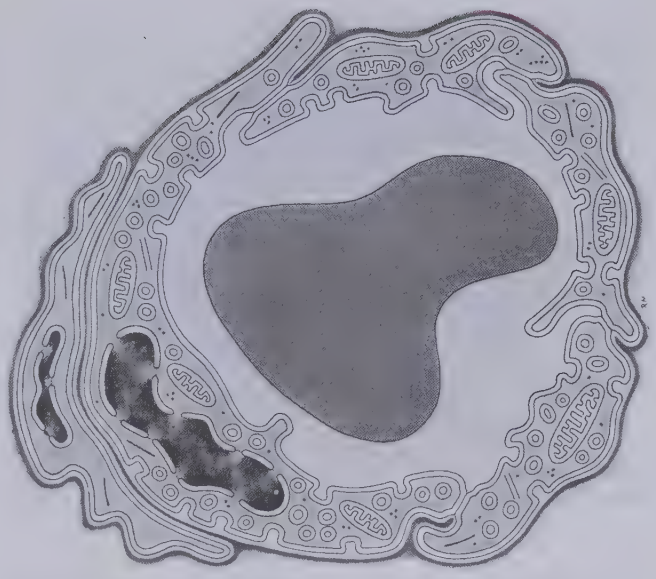
Arteries are innervated mainly by non-myelinated nerve fibres, which are largely efferent and vasomotor to the vessels and conduct a regular flow of impulses maintaining a variable 'vasomotor tone'. Light microscopical evidence of pericellular nerve nets in the tunica media has not been confirmed by electron microscopy, emphasizing the paucity of nerves in the media. Non-myelinated nerve fibres ramify in the adventitia and approach the external myocytes of the media through fenestrations in the external elastic lamina. Their terminals are extensive and contain clusters of mitochondria and numerous vesicles of 30–100 nm diameter, many in the mid-range being dense-cored and typical of noradrenergic synapses. Axons approach to within 60–400 nm of the myocytes (see p. 906) and may relate to several myocytes, each of which is possibly also innervated by more than one terminal (Appenzeller 1964, Lever 1965, 1968, Burnstock et al 1970). The neurotransmitter released from nerve terminals diffuses through the extracellular space and basal lamina to reach receptor sites at myocyte surfaces. A single myocyte may be electrically coupled to many others through gap junctions (p. 24, 562). Myelinated afferent fibres are distributed to the intima and adventitia; they have expanded and varicose endings. The functions of such fibres in the systemic arterial tree is uncertain; some may mediate pain, while in certain sites they are specialized as *baroreceptors* (pressoreceptors), recording general blood pressure (e.g. in the carotid sinus and aortic arch), or *chemoreceptors* responding to increased hydrogen ion and carbon dioxide concentration or decreases in oxygen tension (carotid and aortic bodies). Lamellated (Pacinian) corpuscles, which are mechanoreceptors, occasionally appear in the aortic adventitia.

Most blood vessels have no vasodilator innervation and neurogenic vasodilation follows a reduction of sympathetic

vasoconstrictor tone. However, neurally-induced vasodilation occurs: (1) in vessels of skeletal muscle which have a cholinergic sympathetic innervation; (2) in some exocrine glands, following secretomotor activity with secondary release of vasodilator bradykinin; (3) in skin following afferent nerve stimulation, collaterals of which ramify in neighbouring blood vessels as a structural basis for the so-called 'axon reflex'.

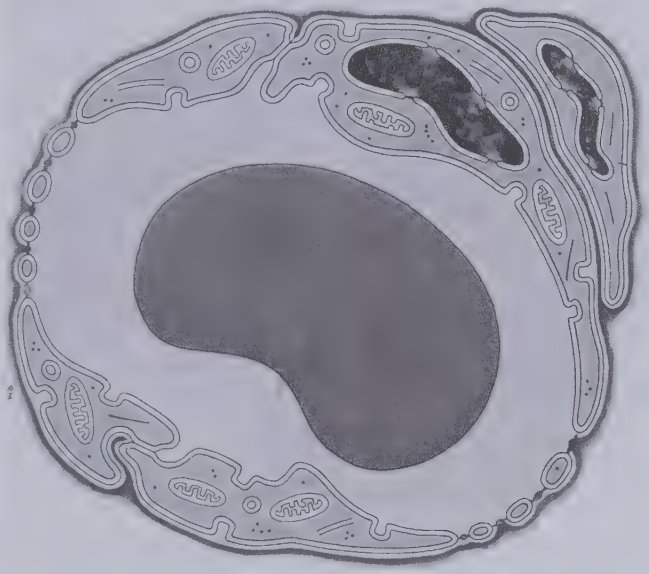
The largest arterial trunks receive direct branches from the sympathetic ganglia, but the supply for smaller arteries (brachial, femoral, etc.) is carried in the peripheral nerves and their rami (pp. 1124, 1156). Perivascular autonomic plexuses extend the whole length of the splanchnic arteries.

CAPILLARIES AND SINUSOIDS (6.18C, 19–21)



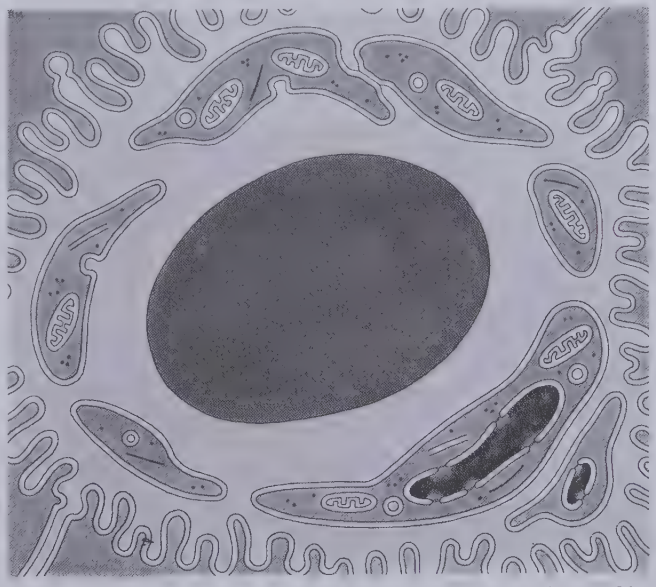
In many tissues (e.g. muscle, skin, lung, alimentary tract, brain, etc.) branches of terminal arterioles beyond the precapillary sphincters show a transitional zone of 50–100 μm; here a few, spiralling myocytes persist external to the endothelium, the vessels continuing as true *capillaries* of uniform diameter. These ramify and anastomose to create a capillary plexus (**6**.21), varying in form in different tissues (vide infra). In some sites (e.g. red bone marrow, spleen, liver, suprarenal and parathyroid glands, adenohypophysis, carotid and coccygeal bodies) the smallest vessels are *sinusoids*. These are lined by endothelium, supported externally by only a tenuous coat of connective tissue. They have a wider calibre than capillaries and their lumen may be irregular in cross section. Typically, the endothelium is incomplete or fenestrated, allowing relatively easy diffusion of larger molecules or of cells between the lumen and the adjacent tissues.

Electron microscopy (**6**.18–20) has revealed marked variation in fine structure among both capillaries and sinusoids (Bennett et al 1957, Rhodin 1962 a, b, Fawcett 1963, Florey 1966, Wisse 1970). Capillaries are tubes of a single layer of polygonal or lanceolate endotheliocytes varying in fine structure and intercellular junctions; external to them is a typical basal lamina, which splits to enclose flat or branching perivascular *pericytes*. An adventitial layer of fine reticular tissue is often associated with the capillary wall, with occasional fibroblasts and mast cells. Capillaries may be broadly classified as *continuous* and *fenestrated* types. Sinusoid endothelial linings are either fenestrated or *incomplete*.



Continuous capillaries (**6**.18A) occur, e.g. in skin, connective tissues, striated and non-striated muscle, lung and brain. The cytoplasm is more abundant near the oval nucleus. The cell presents a smooth luminal surface with occasional filopodia. Organelles are few but the cytoplasm contains fine actin and vimentin (intermediate) filaments (p. 30) and a little endoplasmic reticulum with attached and free ribosomes; the Golgi apparatus is small. The luminal and basal surfaces of the plasma membrane are often much invaginated by *caveolae* and the adjacent cytoplasm contains many vesicles, 50–70 nm in diameter. These are believed to form on one surface, detach, cross the cell to fuse with the opposite wall and discharge their contents. The cytoplasm around them is rich in phosphatases. At cell junctions plasma membranes may be simple or interdigitated; cells frequently overlap. A gap of about 20 nm, containing electron-dense material, usually separates plasma membranes; but sometimes these approach closely or fuse to form tight junctions (p. 24). True desmosomes are infrequent in human tissue.

Fenestrated capillaries (**6**.18B) occur in renal glomeruli, intestinal villi, endocrine glands and the pancreas. The cytoplasm on each side of the nuclear region in endotheliocytes is very thin, often approaching 40–60 nm, and apparently perforated at intervals by 'pores' varying greatly in number and size (diameters from 30–100 nm). Pores are often 'closed' by a thin electron-dense diaphragm which appears as a condensation of the basal laminal material. The mechanism of capillary diameter and blood flow is also obscure. Many believe that flow is determined only by the state of contraction of the arterioles and precapillary sphincters, others that endotheliocytes and some types of pericyte possess cytoplasmic contractile elements (Joyce et al 1985).



Sinusoids (**6**.18C) also vary locally in structure. Their calibre is larger and more irregular, their lining a variety of cell types and they may be *discontinuous, closed* or *fenestrated*. Fenestrated

sinusoids are typical of endocrine glands, having much the same ultrastructure as fenestrated capillaries, including the presence of a delicate, complete basal lamina. Sinusoids of the liver are lined by flat attenuated endothelial cells possessing numerous large fenestrations grouped in clusters, 'sieve plates' (p. 1392, **8.160D**). The sinusoids in the red pulp of the spleen provide an extreme example of *incomplete endothelium*, long slits between strap-like endothelial cells allowing blood cells free passage between lumen and peri-sinusoidal spaces (p. 830). Further details will be noted under individual organs (e.g. pp. 829, 1392).

VENULES

A variable number of capillaries form a *venule* (**6.13**), 20–30 μm in diameter and essentially a tube of flat, oval or polygonal endotheliocytes supported by basal lamina and a delicate adventitia of longitudinal fibres and fibroblasts (Rhodin 1968). Some observers (e.g. Simionescu & Simionescu 1984) distinguish between initial, *postcapillary venules* surrounded by pericytes (*pericytic venules*) and larger vessels partially enclosed in a muscular tunica media (*muscular venules*). Postcapillary venules are sites of fluid exchange and leucocyte migration; in lymphoid tissue of the gut and bronchi and in lymph nodes and thymus, postcapillary endotheliocytes are much taller and have intercellular junctions through which lymphocytes can readily pass into and from the extravascular tissue (p. 824). In other tissues these vessels are believed to be a major site of migration of neutrophils, macrophages and other leucocytes into extravascular spaces, and also a region of temporary endothelial attachment for neutrophils, forming *marginated pools* of these cells (p. 666).

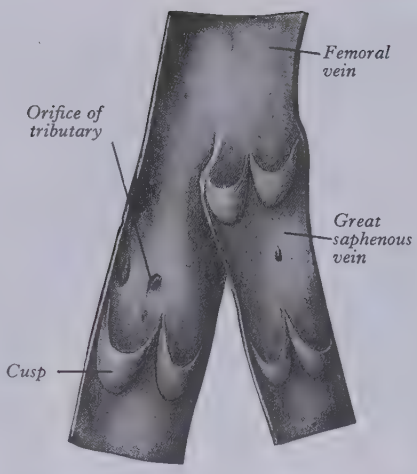
The intracellular junctions of venules are sensitive to inflammatory agents which increase their permeability to fluids and defensive cells (see e.g. Marchesi 1961, 1962).

PERMEABILITY OF CAPILLARIES AND VENULES

The capillaries and postcapillary venules form a vast area for *exchange* of nutrient substances, gases, metabolites and water between blood and tissues; this is also the chief route of leucocyte migration from blood to extravascular spaces. In general, the densities of capillary networks vary with the metabolic level of the tissues supplied; e.g. in the myocardium there are about 2000 capillaries per cubic millimetre, about 1000 in skeletal muscle, but only 50 in cutaneous connective tissue (Simionescu & Simionescu 1983). The total surface area is relatively large, as much as 2.4 metres^2 in skeletal muscle, about 4 metres^2 per 100 cm^3 in lung, with values of about 60 metres^2 for the total of all systemic capillaries and 40 metres^2 for the pulmonary circulation (Krogh 1959, Intaglietta & Zweifach 1971).

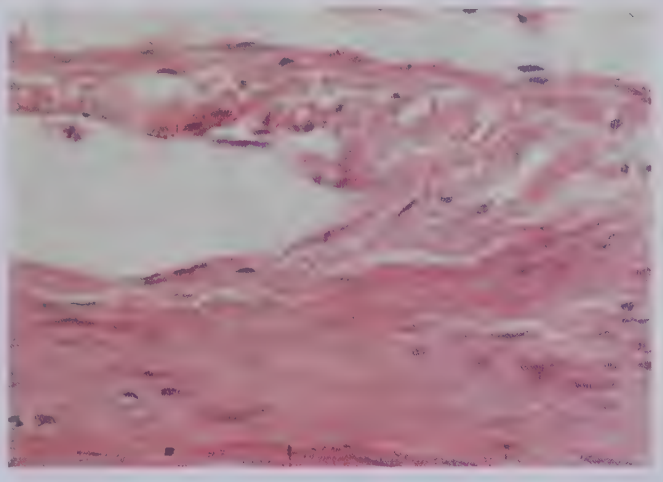
Capillary and venular permeability has been widely studied in various ways, ranging from physiological measurement of fluid composition to structural investigations with tracers, e.g. Evans' blue, horseradish peroxidase and ferritin (Karnovsky 1967, 1968, 1970). These techniques have shown that although vascular endothelium is a semi-permeable dialysing membrane, allowing water, gases and various ions to diffuse through, while being permeable to large molecules, there *is* some movement of colloids and even large water-soluble molecules through endotheliocytes. Measurements of the passage of large molecules, e.g. dextrans, through capillary walls have shown two types of diffusion, corresponding to hypothetical '*large pore*' and '*small pore*' channels (Grotte 1956, Landis & Pappenheimer 1963, see also Granger & Perry 1983). The precise structural basis of these is uncertain. Tracer studies show that large molecules, or molecular aggregates, cross endothelia in endocytic and exocytic vesicles; indeed, vesicles from both aspects may fuse into continuous channels (Bruns & Palade 1968). Such vesicular transport probably corresponds to 'large pore' diffusion, while 'small pore' diffusion is perhaps mediated by leaky intercellular junctions and perhaps endothelial fenestrae, when present, as in renal glomeruli (see Maul 1971).

Capillary permeability varies greatly among tissues and can be correlated partly with the local type of endothelium. In tissues



where large molecules pass easily (e.g. alimentary tract, endocrine glands) fenestrated endothelia exist, with numerous vesicles; intercellular junctions are either incomplete or 'leaky' (Simionescu et al 1972, 1973, 1975, 1980). Where barriers to diffusion of large molecules occur (e.g. brain, thymic cortex, testis and exocrine pancreas), endothelia are complete and not fenestrated, with efficient zonulae occludentes between cells; here, endocytic vesicles are few. Other tissues (e.g. skeletal muscle) show an intermediate condition.

VEINS



Venous walls, like those of arteries, have three layers: an endothelium-lined tunica intima, a muscular tunica media and an external tunica adventitia, which is mainly connective tissue (**6.13**, 17A). A major difference lies in the comparative weakness of the venous tunica media, which has a smaller content of muscle and elastic fibres, a condition related to the lower venous pressure.

In the smallest veins the three *tunics* are not distinct. Endothelium is supported on a membrane separable into two layers: the external one is thicker and a delicate membrane of collagen fibres and fibroblasts; the internal one is composed of interlacing longitudinal elastic fibres. In veins about 0.4 mm in diameter the middle tunic consists of collagen fibres and a few circumferential non-striated myocytes; connective tissue forms a recognizable *tunica externa*. In veins of medium size the endothelium is like that in arteries but its cells are shorter and broader, supported by a delicate network of branched fibroblasts, external to which is a network of elastic fibres in place of the fenestrated laminae of arteries. This constitutes the *tunica intima*. The *tunica media* is a thick layer of connective tissue with elastic fibres and, in some veins, circumferential non-striated myocytes. White fibres predominate; elastic fibres are less abundant than in arteries. The *tunica adventitia*, as in arteries, is loose connective tissue with longitudinal elastic fibres; in the largest veins it is much thicker than the tunica media and contains longitudinal non-striated myocytes, most numerous in the inferior vena cava, especially at its termination, in the largest portal, hepatic and external iliac, renal and azygos veins. In the inferior vena cava and in the renal and portal veins, myocytes appear throughout the adventitia but in the other veins mentioned, connective and elastic tissues form a layer external to the muscle. In the inferior vena cava, collagen fasciculi in the adventitia form an interwoven, diagonal meshwork spiralling around the vessel. This arrangement, together with the pressure of much elastin, allows it to lengthen and shorten readily with the movements of the diaphragm (Franklin 1937). Large veins entering the heart are encroached upon for a short distance by myocardium, and in the coronary sinus this covering is complete (Coakley & King 1959). Muscular tissue is absent in: (1) maternal placental veins, (2) dural venous sinuses and pial veins, (3) retinal veins, (4) veins of trabecular bone, (5) venous spaces of erectile tissue. Such veins consist of endothelium supported by variable amounts of connective tissue.

Most veins have *valves* to prevent reflux of blood (**6.22**). A valve is composed of an inward projection of the tunica intima, strengthened by collagen and elastic fibres and covered by endothelium differing in orientation on its two surfaces. Surface cells which are juxtamural are transversely arranged whereas on the luminal surface, over which the main stream of blood flows, cells are arranged longitudinally in the direction of the current. Most commonly, two such valves lie opposite one another, especially in smaller veins or in larger ones where smaller tributaries join; occasionally three valves lie in opposition; sometimes only one is present. The valves are semilunar (cusps) and attached by convex edges to the venous wall; their concave margins are directed *with* the current and apposed to the wall as long as flow is towards the heart but when blood flow reverses the valves close. Centripetal to each valvular flap the wall is expanded into a *sinus*, which fills when blood flow is reversed against a closed valve, giving a 'knotted' appearance to the distended veins, if these have many valves. In the limbs, especially the legs where venous return is against gravity, such valves are of great importance to venous flow, as blood is moved towards the heart by the intermittent pressure produced by contractions of the surrounding muscles.

6.22A The upper portions of the femoral and great saphenous veins laid open to show the valves. About two-thirds of the natural size.

6.22B Longitudinal section through a venous valve, showing intimal projections forming the valve leaflet. Magnification × 400.

Valves are absent in very small and in very large veins and in many tissues are rare or absent.

The venous return of blood is influenced by several factors. Smaller veins are filled by the overflow from capillaries. The deep veins in the limbs are massaged by the contractions of surrounding skeletal muscles, and venae comitantes are affected by arterial pulsation in the same way. This compression would drive blood in both directions along the veins, were it not for their valves which only allow flow towards the heart, when they are competent. The force of gravity in the veins of the head and neck and the negative intrathoracic pressure in veins near the heart are also important factors in venous return. Flow in veins is slower than in arteries and veins are larger and more numerous than corresponding arteries, a requirement for an efficient return of blood to the heart.

Walls of the larger veins, like the arteries, are supplied by *vasa vasorum* but these in veins may penetrate the wall deeply, perhaps because of the lower oxygen tension. Postganglionic sympathetic efferent and primary afferent nerves are distributed to the veins, as in arteries, but less abundantly.

Associations between Arteries and Veins

Arteries and veins usually accompany each other in fascial planes, visceral pedicles and neurovascular bundles. The vein may be single, but is often paired; such *venae comitantes* flank an artery, with numerous cross-connections, the whole assembly being enclosed in a single connective tissue sheath.

As noted, the proximity of an artery and vein probably aids venous return. Close apposition may also favour the

6.23 Diagram of a microcirculatory unit based upon descriptions in Zweifach (1959, 1961, 1973) and Reynolds & Zweifach (1959). Note the terminal arteriole, thoroughfare channels, true capillaries and the collecting venule. The distribution of non-striated muscle cells and precapillary sphincters is shown. See text for further description.

countercurrent exchange of heat or ions from incoming to outgoing blood, as exemplified by the blood supply of the testis, where tributaries of the testicular vein form a plexus around the artery, promoting heat transfer from arterial to venous blood and thus helping to maintain low testicular temperature (Evans 1949, Grant & Payling Wright 1971, also p. 1429). An analogous arrangement of arterial and venous sinusoids exists in the vasa recta of the renal medulla where countercurrent exchange retains sodium ions at a high concentration in the medulla (p. 1406), efferent venous blood transferring sodium ions to the afferent arterial supply.

Vascular Patterns

The distribution of systemic arteries is like a branching tree, its common trunk, the aorta, emerging from the left ventricle and smaller ramifications extending to viscera and other peripheral regions. The mode of arterial division varies: a short trunk may divide into several branches at one locus, e.g. coeliac and thyrocervical trunks; usually it gives off successive side-branches, continuing as the main trunk, as in arteries of limbs and the head and neck. A branch is smaller than its parent trunk; but where an artery bifurcates, the combined sectional area of the two vessels is almost always somewhat greater than that of the trunk; e.g. the sectional area of the aorta is greatly exceeded by the combined sectional area of all of its branches. These facts are basic to haemodynamics.

ANASTOMOSES

Arteries do not always end in arterioles and capillaries; they may unite, forming *anastomoses* (**6**.12,23,24). Anastomoses between arteries of equal calibre occur in the brain, where two vertebral arteries fuse to form the basilar artery and two anterior cerebral arteries are connected by the anterior communicating artery. A similar fusion is seen where intestinal arteries anastomose by their larger branches. In the limbs, anastomoses are prominent around joints, the branches of arteries proximal to a joint uniting with branches of the vessels below it; lateral anastomoses also form peri-epiphysial circles (p. 300). Arterial anastomoses increase in frequency with distance from the heart and smaller branches of arteries anastomose more frequently than larger ones. Between the smallest twigs, these anastomoses may be so numerous that they form a close network. Anastomoses can equalize pressure differences and provide alternative routes for blood flow, e.g. in peri-articular sites, where circulation may be temporarily impeded by movements of joints. Where arteries join end to end (e.g. palmar and plantar arches, intercostal arteries, gastric and intestinal arteries), section results in bleeding from both ends. In the case of restricted blood flow through an artery, an anastomosis channel may become enlarged (e.g. p. 766), providing a *collateral circulation* e.g. when a vessel is interrupted by accident, disease or ligation. This often develops rapidly. If the increased flow and pressure in the collateral channels are maintained, vessels enlarge, often tortuously, and finally provide a new arterial route, but

6.25 Human digital arteriovenous anastomoses prepared by intravascular perfusion of haematoxylin and subsequent clearing of a full thickness specimen of skin. The heavily stained, thick-walled, tortuous, anastomotic channels contrast with the central arterial stem and the thin-walled venous outflow channels. See text for further details. The specimens were prepared and provided by R T Grant, Guy's Hospital Medical School.

never in excess of functional needs. In some sites, sudden occlusion causes death of the region supplied, but gradual occlusion may allow the adequate dilatation of anastomosing channels. The collateral circulation develops more rapidly in the young. The mechanisms involved in the dilation of collateral channels are not fully understood; haemodynamic changes consequent on the fall of peripheral resistance, on anoxia, neural factors and the effects of accumulating metabolites have all been implicated in this phenomenon.

END-ARTERIES

In some regions arteries have no anastomoses and are hence *end-arteries*. If an end-artery is occluded, necrosis occurs in the tissues supplied by it, e.g. in the central artery of the retina where arterial occlusion is followed by permanent blindness. Though large arteries *outside* the brain form effective anastomoses, its central arteries in the substance of the brain, communicate only through capillaries, being virtually end-arteries, as are arteries in the spleen, kidneys, lungs and metaphyses of long bones. Branches of coronary arteries do anastomose to some extent, but this is often insufficient to provide an adequate collateral circulation. Occlusive arterial disease in organs with an end-arterial blood supply is hence most serious.

VASCULAR SHUNTS

These are communications between arteries and veins found in many regions of the body where the capillary circulation is bypassed by wider channels. They may be classified according to their dimensions, site and complexity as: (1) preferential thoroughfare channels, (2) 'simple' arteriovenous anastomoses, (3) specialized arteriovenous anastomoses or *glomera*.

Preferential 'thoroughfare' channels. In many tissues true capillaries arise not only as direct side branches of terminal arterioles but also as side branches of a main or 'thoroughfare' channel connecting the terminal arteriole and the venule (Zweifach 1937, 1959, 1961, Reynolds & Zweifach 1959, Maggio 1965, Grant & Payling Wright 1968, 1970). This *thoroughfare channel* has a larger calibre than true capillaries and in ultrastructure resembles typical continuous capillaries, except that widely spaced non-striated myocytes spiral round the endothelium. Each capillary side branch has at its origin a precapillary sphincter. Such a channel and its capillaries form a functional *microcirculatory unit* (**6**.23). When functional demand is low, blood flow is largely limited to the bypass channel, with most precapillary sphincters closed. Periodic opening and closing of different sphincters may irrigate different parts of the capillary net. With increasing demand, blood flow may increase greatly following the opening of many sphincters. The size of the micro-circulatory unit varies greatly, e.g. in skeletal muscle each channel give rise to 20–30 true capillaries, but in some glandular tissues only one or two may be given off. Detailed investigations in the cremaster muscle and biceps femoris tendon of the rat (Grant & Payling Wright 1968, 1970) have shown that, in these sites, bypass channels are confined to perimuscular and peritendinous connective tissues and absent from the muscle itself. The form of the capillary net also varies with the tissue, meshes being either round or elongated. Round or angular meshes are most common and prevail where networks are dense, as in the lungs, mucous membranes and skin. Elongated meshes occur in muscles and nerves, aligned parallel with their fibres. Sometimes capillaries are looped, as in the papillae of the skin and tongue. The number of capillaries and the size of their mesh determine the degree of vascularity; the smallest meshes occur in the lungs and the choroid of the eye.

Arteriovenous anastomoses (**6**.24) are direct connections between smaller arteries and veins (Grant & Bland 1931, Popoff 1934, Clark 1938). Connecting vessels may be straight or coiled, often possessing a thick muscular tunic of peculiar structure and a narrow lumen, about 10–30 μm across. Under sympathetic control through abundant non-myelinated fibres in its wall, the vessel is able to completely close, circulation being then via the capillary bed. When patent, the vessel carries blood from artery to vein, partially or completely excluding the capillary bed from the circulation.

Arteriovenous anastomoses of relatively simple type occur in the nasal, labial and aural skin, nasal and alimentary mucous membranes, coccygeal body, erectile tissue, tongue, thyroid gland, sympathetic ganglia and probably elsewhere.

In the skin of the hands and feet (especially digital pads and nail beds) anastomoses form a large number of small units termed '*glomera*'. They are deep in the corium; each '*glomus*' has one or more afferent arteries, stemming from branches of cutaneous arteries approaching the surface (**6**.24,25). These afferents arise at right angles from their parent vessels, which then continue into the dermal papillary layer, ending in a capillary plexus. A short distance from its origin an afferent artery gives off a number of fine 'periglomeral' branches and then immediately enlarges, makes a sinuous curve and narrows again into a short funnel-shaped vein opening at right angles into a collecting vein. This vein commences on the deep aspect of the glomus, curving round its superficial surface, whence it retraces its course, receiving venules from the dermal papillary layer. Finally, it joins a deeper cutaneous vein.

In the newborn child arteriovenous anastomoses are generally few and poorly differentiated, but they develop rapidly during the early years of life. In old age they atrophy, sclerose and diminish in number.

The vessels concerned in digital arteriovenous anastomoses are unusual (**6**.25). Where these enlarge, the afferent artery has small luminal endothelio-muscular projections but proximal to this structure it is typical. The connecting vessel has an endothelium supported by fine collagenous fibres but no internal elastic lamina. Longitudinal and circular muscle layers are not sharply differentiated but the muscular wall is thick; in sections myocytes appear pale and swollen, with central nuclei, and hence described as 'epithelioid'. The efferent vein has a thin wall lacking muscle but containing many elastic fibrils which pass into the tunica adventitia of the collecting vein.

The mechanisms by which arteriovenous anastomoses regulate local flow are poorly understood. Where they have circular muscle in their walls, epitheliocytes may help to narrow the lumen; where it is absent closure may be due to swelling of these epithelioid cells. Cutaneous arteriovenous anastomoses are essential to the control of general and local body temperature. When a rabbit's ear is raised above 40°C, muscle in the walls of the connecting vessels relax and increased blood flow at body temperature results, with a consequent cooling. When the local temperature is lowered below 15°C, the connecting vessels again relax and increased flow at body temperature then helps to raise local temperature, unless artificial cooling is intensified. When the animal's overall *body* temperature is raised experimentally, a general opening of all subcutaneous arteriovenous anastomoses results, with an increase in heat radiation and consequent drop in body temperature (Grant 1930). The cooling effect of panting in dogs also involves the opening of lingual arteriovenous anastomoses. The paucity and immaturity of arteriovenous anastomoses in the newborn and marked reduction in subcutaneous arteriovenous anastomoses with advancing years may be related to observed less efficient temperature regulation in these two extremes of age.

Arteriovenous anastomoses in alimentary mucous membranes fulfil a different function (Spanner 1931). An arteriole to a human villus has a direct connection with its corresponding venule and, when absorption is in abeyance, the connection is patent and helps to raise portal venous pressure; during alimentary absorption the anastomosis is closed and consequently blood traverses the capillary plexus.

Other suggested functions of arteriovenous anastomoses include regulation of blood pressure, secretion by epithelioid cells and pressor reception.

THE THORACIC CAVITY AND HEART

The thoracic skeleton is described on pp. 335–337. The total thoracic capacity does not correspond with that of the osseous thorax, because its lower part is encroached upon by the diaphragm and upper abdominal viscera. The capacity also varies with respiration, which also affects the positions and relations of the thoracic viscera. Its arbitrary upper limit is usually taken as the plane of the thoracic inlet but the pulmonary apices extend above this into the neck.

THE THORACIC INLET (**6**. 85,86,146)

Osseous boundaries are described on p. 336. Structures traversing the superior thoracic opening form two groups: those in or near the median plane, and those on each side closely related to the cervical parts of pleurae and lungs.

Near the midline, behind the manubrium, the lowest parts of the sternohyoid muscles enter the thorax, behind which are the sternothyroid muscles, thymic vestiges and inferior thyroid veins passing down to the brachiocephalic veins. In children particularly the left brachiocephalic vein itself may be *in* the thoracic inlet. Posteriorly, trachea and oesophagus, with the recurrent laryngeal nerves, occupy the median region; behind the left oesophageal margin the thoracic duct enters the neck. Anterior to the vertebral column are the prevertebral longus colli muscles and anterior longitudinal ligament.

On each side the upper part of the pleura and pulmonary apex occupy the inlet. Between the pleura and neck of the first rib, mediolaterally, are the sympathetic trunk, superior intercostal artery and ventral ramus of the first thoracic nerve passing superolaterally to the brachial plexus. Anteriorly, between pleura and first costal cartilage, the internal thoracic artery enters the thorax; medial to the artery its vein leaves the thorax.

On the right (**6**.85), the brachiocephalic artery leaves the thorax between the trachea and pleura. The vagus nerve, having passed between subclavian artery and vein, is between the pleura and the brachiocephalic artery at the inlet. The right brachiocephalic vein enters the thorax anterolateral to its artery; the right phrenic nerve crosses the internal thoracic artery and is lateral to the brachiocephalic vein behind the first costal cartilage.

On the left (**6**.86), the left common carotid and subclavian arteries leave the thorax between the pleura and trachea, the left vagus nerve descending lateral to the interval between them. Anterolateral to this is the left brachiocephalic vein. The left phrenic nerve crosses the internal thoracic artery at a higher level than on the right and, at the inlet, it is between the left brachiocephalic vein anterolaterally and subclavian and common carotid arteries posteromedially.

THE THORACIC OUTLET

This is wider transversely and slopes obliquely down and backwards, so that the vertical extent of the cavity is posteriorly much longer. The diaphragm (p. 592) closes the opening and forms a convex floor for the cavity; it is flatter centrally than at the periphery and higher on the right; in cadavers this side of the floor reaches the level of the fifth costal cartilage's upper border, on the left only to the sixth. (See p. 594 for further information on diaphragmatic shape and levels.) From the summit of each side the diaphragm slopes abruptly down to the costal and vertebral attachments; this slope is posteriorly much more marked and longer and the space between the diaphragm and the posterior thoracic wall narrows rapidly inferiorly.

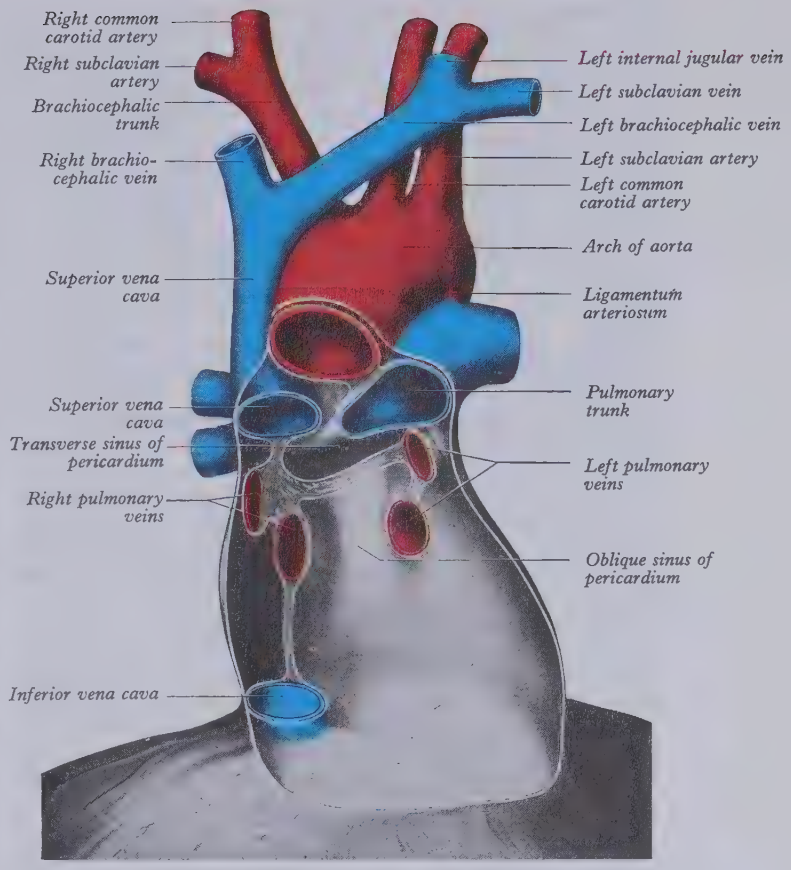
DIVISIONS OF THE THORACIC CAVITY

The thoracic cavity is divided by the *mediastinum*, the mass of structures between the lungs extending from the sternum to the vertebral column and from the thoracic inlet to the diaphragm. The heart is in the mediastinum, enclosed by the *pericardium*; the lungs occupy the right and left regions, each covered by a serous membrane, the *pleura*, which also lines the corresponding half of the thorax and additionally forms the lateral mediastinal boundary (**6**.27,29A).

For description the mediastinum is arbitrarily divided. The *superior part* extends from the thoracic inlet to an oblique plane passing through the lower edge of the manubrium sterni and lower border of the fourth thoracic vertebra. The *inferior part*, below this plane, is subdivided into an *anterior part* in front of the pericardium, a *posterior* behind this and the diaphragm, and a *middle*, containing the pericardium, heart and large vessels entering or leaving it. Detailed mediastinal contents are included with descriptions of respiratory organs (pp. 1248–1256), the heart (pp. 696–734) and the oesophagus (p. 1331).

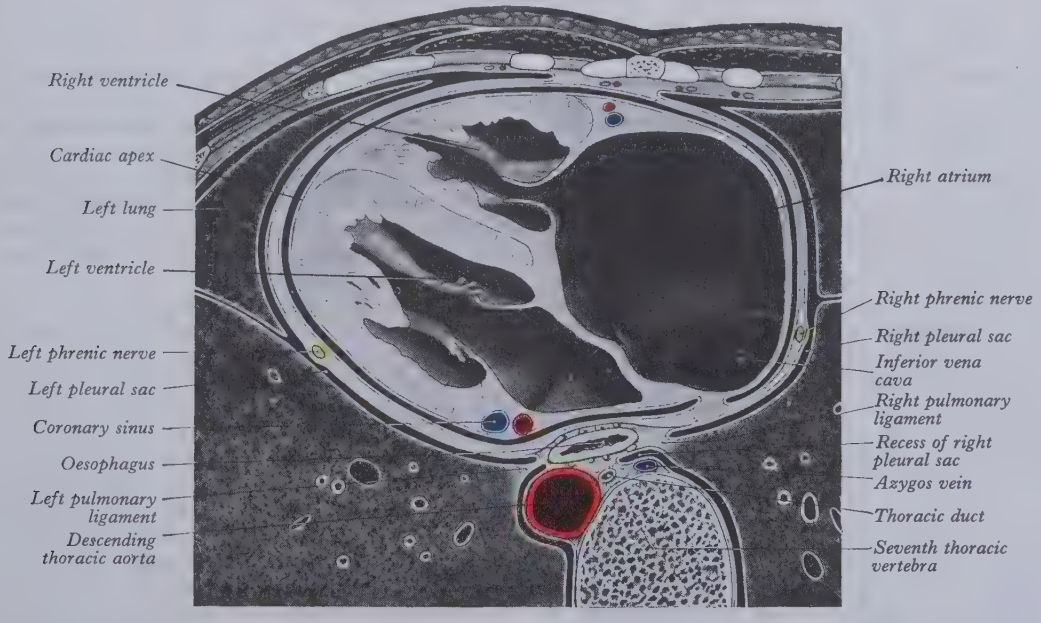
The Pericardium

The pericardium (**6**.26,27,29A) contains the heart and juxtacardiac parts of its great vessels. It is posterior to the corpus sterni and second to sixth costal cartilages and anterior to the fifth to eighth thoracic vertebrae. It consists essentially of two opposed



surfaces of serous membrane, separated by a film of fluid, providing a complete cleavage between the heart and its surroundings, which allows freedom of movement within the pericardium. This has an outer sac, *fibrous pericardium*, and an inner, double-layered sac, the *serous pericardium*, which lines the fibrous sac and covers the heart. The heart invaginates the serous sac from above and behind and fills its cavity, leaving only a potential circumferential space.

The *fibrous pericardium* is roughly conical, its apex continuous with the exterior of the great vessels and its base attached to the diaphragm's central tendon and a small muscular area of its left half. In some lower mammals the base is completely separate from the diaphragm or joined only by areolar tissue; its human diaphragmatic attachment is also of loose fibro-areolar tissue, easily cleft; but a small area of the central tendon and pericardium are fused. Above, the fibrous pericardium not only blends externally with the great vessels, but is continuous with the pretracheal fascia (p. 583). It is also attached to the posterior sternal surface by *superior* and *inferior sternopericardial ligaments* passing to the corresponding ends of corpus sterni. (In the experience of thoracic surgeons these 'ligaments' are extremely variable; the superior is often indetectible.) By these connections the pericardium is securely anchored and maintains the general thoracic position of the heart. Some say that it prevents 'over-distension' but this view is entirely speculative.



Anteriorly, the fibrous pericardium is separated from the thoracic wall by the lungs and pleurae; but in a small area of the lower left half of the corpus sterni and sternal ends of left fourth and fifth costal cartilages the pericardium is in contact with the thoracic wall. Until it retrogresses, the lower end of the thymus is anterior to the upper pericardium. *Posteriorly* are the principal bronchi, oesophagus, oesophageal plexus, descending thoracic aorta and posterior parts of the mediastinal surfaces of both lungs. *Laterally* are the pleurae and mediastinal pulmonary surfaces; the phrenic nerve with accompanying vessels descends between the fibrous pericardium and mediastinal pleura on each side. *Inferiorly* the pericardium is separated from the liver and gastric fundus by the diaphragm.

Vessels receiving prolongations of fibrous pericardium are the aorta, superior vena cava, right and left pulmonary arteries and four pulmonary veins. The inferior vena cava, traversing the central tendon, has no such covering.

Serous pericardium is a closed lining to the fibrous pericardium invaginated by the heart, with *visceral* and *parietal* layers. The visceral, or *epicardium*, covers the heart and great vessels and is reflected into the parietal layer, lining the fibrous pericardium. Early in development this reflexion occurs along a double line from the venous to the arterial end of the primitive pericardium, the attachment of the transient dorsal mesocardium (p. 208). With

6.26 Interior of the serous pericardial sac after removal of the heart (ventral aspect). See text for additional named recesses of the general serous pericardial cavity and of its transverse sinus.

6.27 Transverse section through the mediastinum at the level of the body of the seventh thoracic vertebra, viewed from above. Note the general disposition of cardiac cavities, their intervening septa (about 45° to sagittal and coronal planes) and, orthogonal to this, the plane of the atrioventricular valves. The oesophageal plexus of nerves is clear but not labelled.

the disappearance of the latter the parietovisceral lines of continuity are now restricted to two initially simple, perivascular tubes of inflexion, one periarterial and the other perivenous. This initial simplicity is progressively modified by folding and differential growth of the cardiac tube and great vessels. The serous reflexion is thus now arranged as two increasingly complex 'tubes', the aorta and pulmonary trunk enclosed in one and the superior and inferior venae cavae and pulmonary veins in the other; the latter continuation is J-shaped (**6**.26,31) and the cul-de-sac within its curve is behind the left atrium and termed the *oblique sinus*. The passage between the two so-called pericardial 'tubes' is the *transverse sinus*, which has the aorta and pulmonary trunk in front, the atria and great veins behind (**6**.36,59). In the foregoing simplified account of the serous pericardium, it is clear that, when the complex surface topography of the heart and its main vascular trunks is considered, the developmental analogy of two tubes is insufficient. The oblique and transverse sinuses and the main 'general' cavity are all affected by the development of complex three-dimensional *pericardial recesses* between adjacent structures. (For details, illustrations and bibliography see Vesely & Cahill 1986.) A list adopting their proposed terminology is given, although other apposite terminologies are easily envisaged. Recesses are grouped according to the siting of their orifices or 'mouths'. From the general serous pericardial cavity:

The postcaval recess projects towards the left behind the superior vena cava (atrial end), limited above by the right pulmonary artery and below by the upper right pulmonary vein. Its mouth opens superolaterally to the right. *The right and left pulmonary venous recesses* each project medially and upwards on the back of the left atrium between the superior and inferior pulmonary veins of their side; i.e. they indent the side walls of the oblique sinus; the mouths open downwards and laterally.

From the transverse sinus:

The superior aortic recess, its mouth inferior, ascends posterior to, then right of the ascending aorta to end at the level of the sternal angle.

The inferior aortic recess, its mouth superior, is a diverticulum descending between the lower ascending aorta and right atrium.

The left pulmonic recess, mouth under the fold of the left vena cava, passes to the left between the inferior aspect of the left pulmonary artery and upper border of the superior left pulmonary vein.

The right pulmonic recess lies between the lower surface of the proximal part of the right pulmonary artery and upper border of the left atrium.

A triangular fold of serous pericardium is reflected from the left pulmonary artery to the subjacent upper left pulmonary vein as the *fold of the left vena cava*; it contains a fibrous *ligament of the left vena cava*, a remnant of the obliterated *left common cardinal vein* (left duct of Cuvier, p. 208), which descends anterior to the left pulmonary hilum from the upper part of the left superior intercostal vein to the back of the left atrium, where it is continuous with the *oblique vein of the left atrium* (p. 221). The fold is often the anterior wall of a small recess, its mouth directed left. The *left* common cardinal vein may persist as a left superior vena cava, descending anterior to the left hilum then across the back of the left atrium to enter the right atrium, replacing both the oblique vein of the left atrium and the coronary sinus. Sometimes both common cardinal veins persist as right and left superior venae cavae; the transverse anastomosis between them, normally forming the left brachiocephalic vein, may be small or absent. When the left common cardinal vein persists it is joined by the left superior intercostal vein.

Vessels and nerves. Arteries of the pericardium are from the internal thoracic and musculophrenic arteries and the descending thoracic aorta; *veins* are tributaries of the azygos system. The nerve supply is from the vagus and phrenic nerves and the sympathetic trunks.

Structure. The fibrous pericardium is compacted collagenous fibrous tissue. The serous pericardium is a single layer of flat cells on a subserous areolar layer which blends with the fibrous pericardium and interstitial myocardial tissue, where it contains fat in greatest amounts along the ventricular side of the coronary sulcus, the inferior cardiac border and interventricular grooves. The main coronary vessels and larger branches are embedded in this fat, its amount being related to general body fat and gradually increasing with age.

Applied Anatomy. Pericardial puncture may be performed in the fifth or sixth left intercostal space near the sternum to avoid the internal thoracic artery, or at the left costoxiphoid angle, passing up and backwards into the pericardial sac. The serous pericardium extends on the pulmonary trunk, anterior to the transverse sinus, as far as the ligamentum arteriosum (p. 725).

THE HEART

General Introduction

All triploblastic organisms, including chordates, overcome the limitations of diffusion over long distances by circulating a fluid from regions of high oxygen tension and concentrations of nutrient substances to mesodermal and other cells remote from the external environment. The fluid and its mode of circulation vary amongst invertebrate phyla, but the majority are coelomates with closed vascular systems and some localized means of propelling 'blood' in a true circulation. (There are exceptions: some small annelid worms lack such a system and in some acoelomates, e.g. nematode worms, a body cavity (a *pseudocoel*) does occur but has no endothelium and merely permits tidal movement of contained fluid due to bodily movements. One nematode, *Ascaris*, has a haemoglobin in this fluid.)

In some coelomates, e.g. annelid worms, pulsatile sections of vascular tubes, usually multiple, occur in many regions; the larger of such 'hearts' may be valved and respond to neurogenic 'pacemakers'. In arthropods the single heart is dorsal and circulation 'open', i.e. vessels from the heart open into haemocoels around most organs. (Some small arthropods, e.g. mites, have no circulatory organs.) Aquatic arthropods, such as the *Crustacea*, respire through gill-like structures, the blood acting as the intermediary; but in the *Insecta*, where most of the species has emancipated from water, respiration is via intercellular tubes separated from the circulation. *Mollusca*, *Brachiopoda* and *Echinodermata* display an even wider variety of circulatory patterns. These facts are mentioned briefly as a contrast to the phylum *Chordata*, which displays a much more uniform circulatory pattern. Even in the most primitive, *Hemichordata* (acorn worms) and *Urochordata* (tunicates), the heart is single and in *Cephalochordata* (including the familiar *Amphioxus*) there is a *ventral* tubular 'heart' and a basically vertebrate circulation. The 'heart' is assisted by other pulsatile vessels.

The *vertebrate* heart is ventral to the gut—to the pharynx in fishes and embryos of land tetrapods, to the oesophagus in adults of the latter. Being evolved from a tube, it is a single pump in earlier forms. From the beginning (as in simpler extant forms) it is a succession of three or four enlarged segments: a collecting *sinus venosus* for principal veins, a pulsatile but thin-walled *atrium*, a thick-walled, muscular *ventricle* and a *bulbus cordis*, the latter being muscular or elastic and sometimes absent. From the ventricle's conical end (*conus arteriosus*), or bulbus cordis when present, major arteries start. Valves, usually of several flaps (sometimes serially repeated), separate successive cavities. The heart has its own *coronary* circulation (except in *Agnatha*) and is contained in a pericardial coelom, a separated part of the general body cavity. The pulsatile rhythm of vertebrate hearts is basically *myogenic*, but is coordinated with systemic demands by a nerve supply. With increasing specialization from fishes to birds and

mammals, 'nodes' and tracts of cardiac muscle differentiate as foci initiating contraction and rapid conductors for the dissemination of cyclic stimuli. (At particular loci the conduction is much slower introducing physiologically imperative delays.) In most vertebrates the cardiac tube outgrows the length of its pericardial sac, developing a sinuous bend; the 'venous end' (sinus venosus and atrium) becomes dorsal to the 'arterial end' (ventricle and conus); moreover, the heart becomes asymmetrical in position with the change from symmetrical cardinal to asymmetrical caval veins. The pericardial cavity is semi-rigid in some fish (e.g. elasmobranchs), being dorsal to the pectoral girdle; the resultant constancy of volume aids atrial filling by suction as the ventricle empties; in terrestrial and aerial vertebrates this effect is largely lost because of caudal 'migration' of the heart and less massive girdles.

In tracing cardiac phylogeny, especially in deriving mammalian from earlier forms of heart, no direct palaeontological data are available and comparison of existing arrangements in extant vertebrate groups is the only source of information. Such comparison can mislead unless allowance is made for several complicating factors. Firstly, hearts must function early in embryonic life, throughout development and into a greatly changed postnatal environment. Environmental demands in adults vary and, if they diminish for a more recent (presumably 'more highly evolved') group, actual cardiac retrogression may occur. For example, in *Dipnoi*, the lungfish (and in crossopterygians, if the extant coelacanth, *Latimeria*, is representative) the atrium is almost completely divided and the ventricle partly so, whereas in *Amphibia* the ventricle is single and the atrium fully divided only in anuran forms. Incomplete atrial division in urodele amphibians is considered structurally retrogressive, but must be a physiological advantage in this more active of these two subclasses. It is orthodox, indeed inescapable, to derive mammals from reptiles, but from no extant reptile can mammalian hearts be directly derived. Though in some reptiles (e.g. *Crocodilia*) hearts are fully divided, the relations of the pulmonary and systemic arteries to ventricles precludes such derivation. Reptiles ancestral to mammals must have had different arrangements. Avian hearts and their outflow vessels are much closer to those of extant reptiles.

A complete phylogenetic history is not available for vertebrate hearts; hence an elaborate comparison will not be attempted, but some evolutionary trends must be mentioned.

The sinus venosus, typically symmetrical in *Pisces*, is asymmetrical in *Cyclostomata*; its right duct only persists in lampreys, the left in hagfish. In *Dipnoi* the sinus opens into the *right* of a partly divided atrium, a condition persisting in subsequent vertebrate classes; in *Anura*, many *Reptilia* and all *Mammalia* this asymmetry is coupled with some retrogression of the sinus and absorption of its vestiges into the right atrium. With complete separation of atria a right-hand systemic venous return is thus established.

The 'arterial end', a *bulbus cordis* in vertebrate embryos (and some adults) or a contractile *conus arteriosus* in adult elasmobranchs, commonly has valve flaps, often in serial rows. Probably derived from these are the spiral valves in *Dipnoi*, which are more elaborate and efficient in *Amphibia*. This change is closely linked with the greatest era of transformation in cardiac evolution, the long series of adaptations which allowed vertebrates to spread from aquatic to terrestrial habitat. This is accepted as occurring in the Devonian Period of the Palaeozoic Era, a period of 50–60 million years, about 300 million years ago. At first were fish, which were chiefly dependent on branchial respiration but able to use, for aerial breathing, a pharyngeal diverticulum, the so-called 'swim bladder' (p. 1248); finally came amphibians, mainly dependent on pulmonary respiration, with lungs developed from some form of pharyngeal air sac, but also respiring through a wet skin. These respiratory changes, inseparable from cardiac and circulatory modifications, also demanded locomotor changes: the evolution of limbs, adapted from aquatic fins to terrestrial progression. For such reasons *Amphibia* are regarded as developed from crossopterygians related to extant *Dipnoi*.

During this transformation, occupying millions of years, an inherent duality already existed in circulations, both dipnoans and amphibians having a *systemic* 'portal', arterial circulation (through gills in one and subcutaneous vessels in the other) and also a parallel *pulmonary* 'portal' circulation through the walls of an air sac or, eventually, true lungs. These separate circuits already return blood to separate atria in dipnoans; and although the ventricle is only partly divided, mixing of atrial inputs is probably diminished by the highly trabecular internal ventricular surface. Of course, dipnoan *ventricular* output, although also largely separated into two streams by spiral valves in a large conus arteriosus, is all conducted to the gills; but blood is returned to the *right* atrium by a dorsal division of the ventral aorta to the more caudal gill clefts and hence largely to the air sacs or 'lungs'.

In amphibian circulation, with loss of the gills, the capillary beds supplying them disappear and respiration is mainly pulmonary. But an undivided ventricle (and only partial division of the atrium in some forms) may permit some mixture of systemic and pulmonary flows; presumably this is an advantage on the return to water for breeding, cutaneous respiration becoming predominant. Thus no sudden change, in structure or function, occurs in the slow cardiac adaptation from aquatic to terrestrial life, but rather a change of balance between two coexistent modes of respiration. Separation of cardiac flows is carried further in *Reptilia*. Though some forms have returned to an aquatic existence, respiration is entirely pulmonary, linked with a complete interatrial septum and at least a partial ventricular division, actually complete in *Crocodilia*; they are unusual in their triple arterial cardiac outflow which is pulmonary from the right ventricle and right *and* left aortic (systemic) arches, each from a contralateral ventricle. Aortic arteries hence cross and communicate at this point. In the cayman this allows an almost complete shunt into the left aorta, foreshadowing the mammalian condition.

In mammals, including mankind, cardiac division is complete and need not be described here; but in the embryo, stages occur (p. 206) very like the final arrangements in earlier vertebrate classes; arrested development at various stages leads to congenital defects resembling conditions in earlier vertebrate forms. However, the resemblance is modified, for the heart must function effectively at all but its initial stages of development. The foramen ovale, a feature of mammalian prenatal development, is a necessary shunt rather than an atavistic indication of earlier incomplete atrial septation. Hence, a persistent patent foramen ovale is due to disturbed *mammalian* rather than *vertebrate* development. Other cardiac abnormalities may be tentatively 'explained' as divergencies from ontogenetic development rather than by reference to phylogeny.

That every vertebrate heart must function in its own circulation from a very early stage, long before either has reached its final arrangement, accords with a continuous cardiac phylogeny, seen here in retrospect. A heart of single serial chambers has become a fully septated double heart, of two muscular pumps, topographically 'in parallel' though pumping in circulatory function 'in series', without departure from smooth evolution and achieved despite great changes from aquatic respiration through gills to wholly pulmonary breathing. This smooth changeover may be ascribed to the existence of *both* modes of respiration in a series of dipnoan and amphibian species over a long period of time. The double circulation, systemic through the gills and pulmonary through the lungs, has gradually evolved from a *parallel* supply by incompletely septated hearts to a *serial* supply with complete septation. Evolution in the vessels served by the heart has also occurred in a harmonious succession of adaptations. For further details consult *Embryology* in this volume, and for extensive bibliographies see Bolk et al (1931–9), Grasse (1954), Foxon (1955), Robb (1965), Romer (1970), Foxon & Bannister (1974).

There is no entirely logical progression in describing the heart; whatever standpoint is used this presumes subsequent details; the sequence adopted here is perhaps a good compromise. General organization precedes external features, surface anatomy and radiology, followed by internal structure, including flow tracts, valves, myocardium, fibrous 'skeleton', specialized conducting tissues and the cardiac cycle.

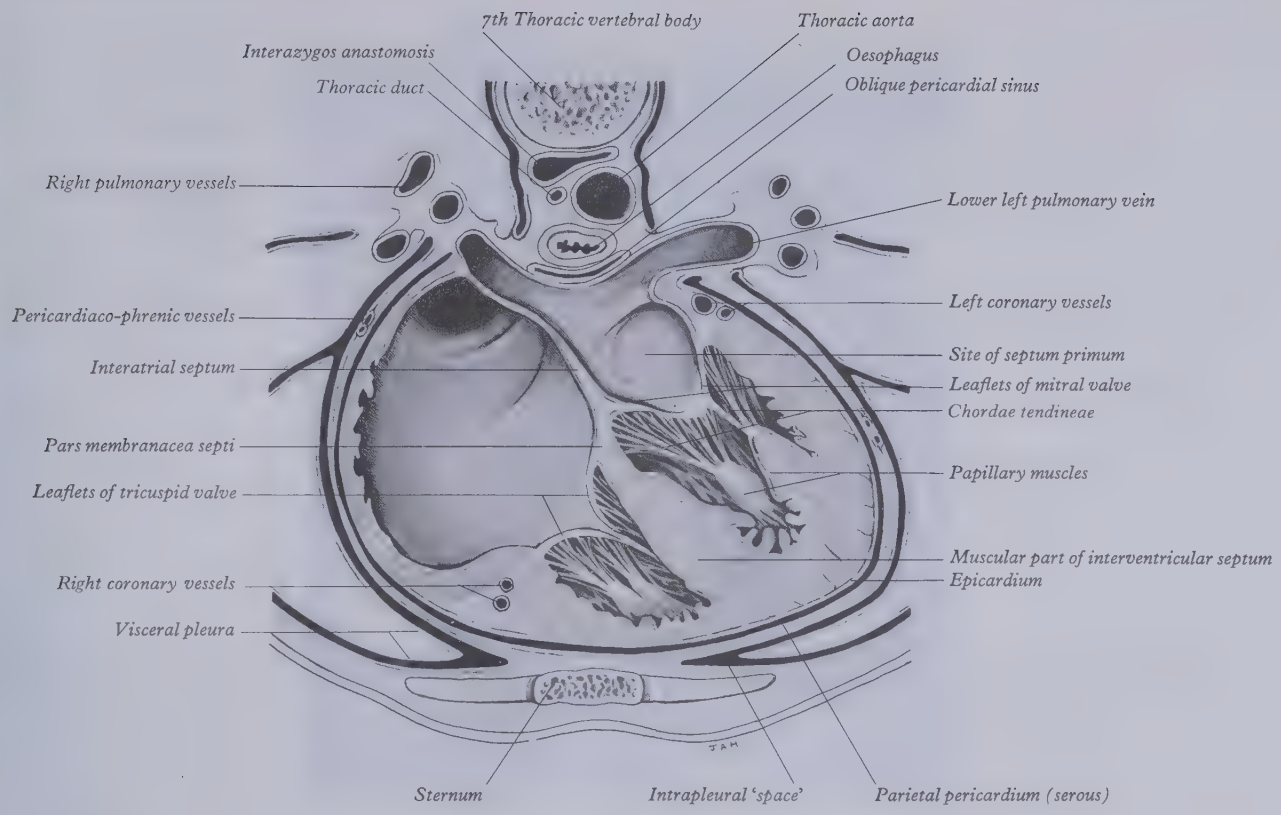
6.28 Coloured polyester resin luminal casts of a human heart. Blue = right atrium, ventricle, infundibulum, pulmonary root and valvular sinuses; red = left atrium, ventricle, aortic vestibule, root and sinuses. A. Sternocostal surface with right and left hearts in situ; B. isolated cast of right heart; C. isolated cast of left heart. Note the impressions made by the musculi pectinati, trabeculae carneae (spiralized in the left ventricle), the smooth areas related to the atrioventricular valve leaflets and the dilated sinuses in the walls of the aortic and pulmonary roots. Casts prepared by M C E Hutchinson, photography by Kevin Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School.

General Cardiac Organization

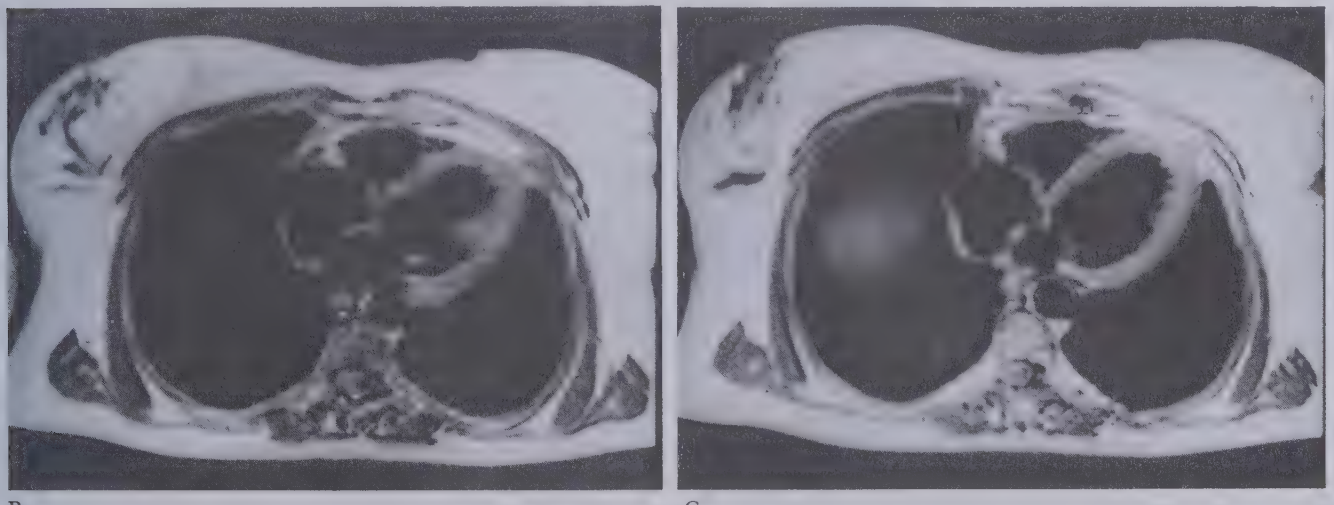
The human heart is a pair of valved muscular pumps combined in a single organ; but, while their fibromuscular framework and conducting tissues are structurally interwoven, each pump (so-called 'right' and 'left' heart) is physiologically *separate* and interposed *in series* at different points in the double circulation. Despite this *functional* serial disposition (vide infra), the two pumps are often described (vide supra) as *topographically* 'in parallel'; even this is an oversimplification, since they have contrasting haemodynamic roles and their outflow channels exhibit a *mutual spiral* of almost 180° as they discharge.

In the four cardiac chambers, two atria receive venous blood as weakly contractile reservoirs for final filling of the ventricles, and the two ventricles provide the powerful expulsive contraction forcing blood into the main arterial trunks.



The 'right heart' of clinical parlance consists of the *right atrium* receiving superior and inferior caval and main coronary inflow from the systemic circulation: this blood traverses the right *atrioventricular orifice*, with its *tricuspid valve*, to the *right ventricular inflow tract*, contraction of which finally closes the tricuspid valve and, with increasing pressure, reaches a level when ejection of blood through the *right ventricular outflow tract (infundibulum* or *conus arteriosus* and *pulmonary valve*) is achieved. (Pressure changes, time relations and valvular events are described below.) Note that the right ventricular outflow tract discharges into the pulmonary trunk and hence to the *relatively* low-resistance pulmonary vascular bed; many structural features of the 'right heart', including overall geometry, vectors of inflow and outflow, myocardial architecture (in particular thickness of wall) and construction and relative strengths of tricuspid and mitral valves all accord with this, being associated with comparatively low changes of pressure.

The 'left heart', in contrast, consisting of the *left atrium* receiving all pulmonary and some coronary venous inflows, contracts to complete filling of the *left ventricle* through the *left atrioventricular orifice* with its *mitral valve*. The valve is the entry to the left ventricular *inflow tract*, contraction of which rapidly raises its pressure, closing the valve (vide infra); this is followed at once by opening of the aortic valve and ejection via the left ventricular *outflow tract* via the aortic orifice into the aortic sinuses, ascending aorta and thence to the whole systemic arterial tree, including the coronary vessels. This vast vascular bed presents high peripheral resistance which, with large metabolic demands, especially the sustained requirements of the cerebral tissues, explains the structural organization of the 'left heart'—its geometry, flow vectors, parameters of mitral and aortic valves and the thickness of the left ventricular myocardium. The ejectional phase of the left ventricle is shorter but its pressure fluctuations are very much greater (**6**.55).



Because of its immense phylogenetic history, complex ontogeny (p. 206) and contrasting functional demands, the human heart is far from a simple pair of parallel pumps, structurally combined, even though the right and left ventricles must deliver the same volume with each contraction. The heart has a complicated, spiralized, three-dimensional organization, not obviously related to cardinal planes; hence terms such as 'left' and 'right', 'apex' and 'base', 'surface', 'aspect' and 'border' do not assist cardiac anatomy. Another source of confusion is the usual study of isolated whole or dissected hearts, with the subsequent difficulty in relating details to the heart in situ. The following preliminary description emphasizes such difficulties to circumvent certain misconceptions before proceeding to more detailed structure.

The principal features of cardiac anatomy can be illuminated by corrosion casts of normal hearts in which both sides have been filled with resins of contrasting colours (**6**.28A,B,C), and by horizontal mediastinal sections or scans at, or near, the seventh thoracic vertebral level (**6**.27,29A,B,C).

In illustrations **6**.28A,B,C the left (red) and right (blue) hearts are viewed from the *ventral aspect* in their normal relation (**6**.28A), followed by right (**6**.28B) and left (**6**.28C) hearts in isolation. Obviously their general forms contrast and unmodified terms are singularly inappropriate. The right heart, while forming a right

B C

6.29B,C Computed tomograms of the thorax: (B) through the body of the seventh thoracic vertebra; (C) through the intervertebral disc between the seventh and eighth vertebrae. Note the overall disposition of the heart, its apex, base, oblique interatrial and interventricular septa and, orthogonal to this, of the atrioventricular valves. Note also the atrioventricular septum, papillary muscles, trabeculae carneae, descending thoracic aorta and contrasting areas of right and left lungs and pleurae. Provided by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith.

aspect or border, follows a gentle curve (almost gastric in form) and covers most of the *anterior aspect* of the left heart (except for a left-sided strip including the apex). Thus, much of the right 'heart' in fact forms a majority of the *ventral surface*, its outflow tract ascending to the left until it terminates on the *left side* of the left ventricular outflow tract. Impressions of tricuspid and pulmonary valves are *widely separated* in different planes and the right ventricle's flat cavity (crescentic in section, vide infra) is splayed out between them. Conversely, the 'left' heart (except the left-sided strip and apex mentioned above) is largely *dorsal* in position and (as seen in **6**.28A) in ventral aspect is obscured by the right chambers. Note that the left ventricular inflow orifice (mitral valve) is *very close* to its outflow (aortic valve), the two being embraced by the wide divarication of the 'right' inflow and outflow orifices. Planes of the left ventricular orifices, though relatively inclined, are more nearly coplanar than those of the right. The left ventricular cavity is narrow, conical, with a spiral trabeculated interior. The conical left ventricular tip occupies the cardiac *apex*, most of the *anatomical base* being the left atrium.

The heart is placed *obliquely* in the thorax, as is clear in horizontal section (**6**.27, 29A) and scans (**6**.29B,C). The interatrial and interventricular septa are virtually in line but inclined *forwards and to the left* at about 45° to a sagittal plane; planes of mitral and tricuspid valves, though vertical and not precisely coplanar,

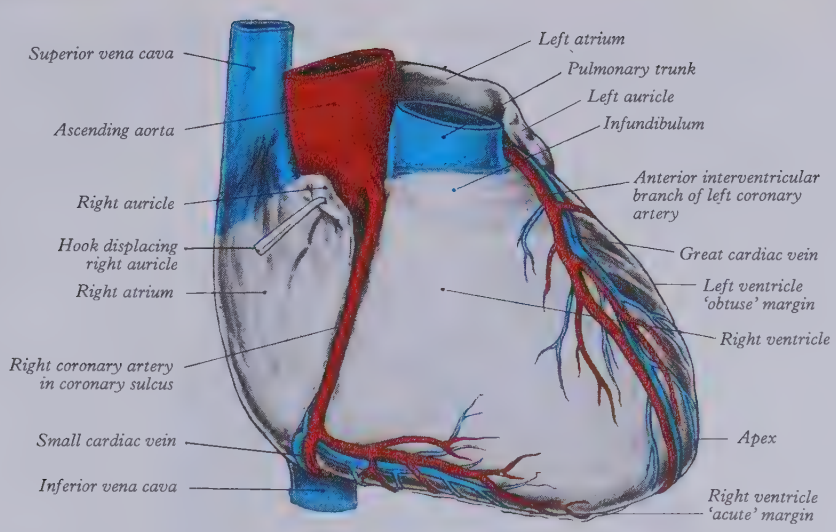
6.30A Dissection which displays the heart, the great vessels and the lungs in situ. The sternum and the sternal ends of the costal cartilages, together with the parietal pleura on each side, have been excised and the mediastinal pleura and parietal layer of the pericardium over the sternocostal surface of the heart have been removed. The lungs have been displaced to expose the heart and the epicardium dissected off the heart and roots of the great vessels.

On the right side, the inferior cardiac branch of the vagus nerve descends between the brachiocephalic artery and the right brachiocephalic vein. On the left side, a communication descends from the left superior intercostal vein and crosses the aortic arch and the left pulmonary artery to become continuous with the oblique vein of the left atrium.

are broadly at right angles to the septal plane. In brief, therefore, the right atrium is not only to the *right* but *anterior* and *inferior* to the left atrium (and also partly anterior to the left ventricle, an *atrioventricular septum* intervening). The right ventricle forms most of the *anterior aspect* of the ventricular part, only its inferior end being *right* of the left ventricle, its upper left extremity (outflow orifice) being *left and superior* to the aortic valve. The left atrium forms most of the *posterior aspect* supplemented by the right atrium, while the left ventricle is only prominent *inferiorly*, along the left margin and at the apex. The atria are essentially right of and posterior to their ventricles. These general dispositions are of the greatest importance in planning or interpreting radiographs, scans, angiocardiograms and echocardiograms.

Cardiac Size, Shape and External Features

The heart is a hollow, fibromuscular organ of a somewhat conical or pyramidal form, with a base, apex and a series of surfaces and 'borders' (**6**.28,29,30,31); it occupies the middle mediastinum between the lungs and the pleurae (**6**.27,29A,B,C), enclosed in the pericardium (p. 694). It is placed *obliquely* behind the corpus sterni and adjoining left costal cartilages and ribs; approximately one-third lies right of the midline.



An average adult heart is about 12 cm from base to apex, 8–9 cm transversely at its broadest and 6 cm anteroposteriorly. Its weight, in males, varies from 280–340 g (average 300 g), in females, from 230–280 g (average 250 g). Cardiac weight is said to be about 0.45% of body weight in males and 0.40% in females (Hudson 1965); adult weight is achieved between 17–20 years.

The heart's oblique position may be re-emphasized by the analogy of a rather deformed pyramid, with a base facing dorsally and right, the apex anteriorly and to the left. Thus a line from the apex to the approximate basal centre, projected antero-laterally, passes near the left mid clavicular line; projected posterolaterally it emerges near the right mid-scapular line. Some aspects of the cardiac 'pyramid' are flat, others more or less convex, these aspects merging along rather ill-defined 'borders'. Hence precise definition of surfaces and intervening 'borders' is difficult: in the following account official nomenclature (*Nomina Anatomica* 1983) *and* terms from clinical practice will be given as alternatives. The heart is described as having an (anatomical) base and apex, its *surfaces* designated sternocostal (anterior), diaphragmatic (inferior), right and left (pulmonary); its *borders* are termed upper, inferior ('acute' margin or border) and left ('obtuse' margin or border). Some persist in naming the right surface a 'border', despite its extent; the right surface is also as 'pulmonary' as the left. A further avoidable source of confusion is 'posterior' for such unambiguous terms as 'diaphragmatic'; if posterior is to be used for a cardiac surface it should be reserved for its base. Finally, as will be discussed more fully, there are a number of different usages of the term 'cardiac base'.

CARDIAC SURFACE GROOVES AND SULCI

Cardiac divisions into four chambers show externally as grooves or sulci, some deep and obvious, containing prominent structures; others are less distinct, even barely perceptible, sometimes completely obscured, in part, by the major structures crossing them.

Between the atria and ventricles is the *coronary* (*atrioventricular*) *sulcus* (**6**.30A,B, 31, 37A, 60, 61) containing the main coronary trunks; the sulcus is oblique and its position and plane are basic to cardiac anatomy. On the sternocostal surface it descends to the right, separating the right atrium (and its

6.30B The anterior or sternocostal surface of the heart.

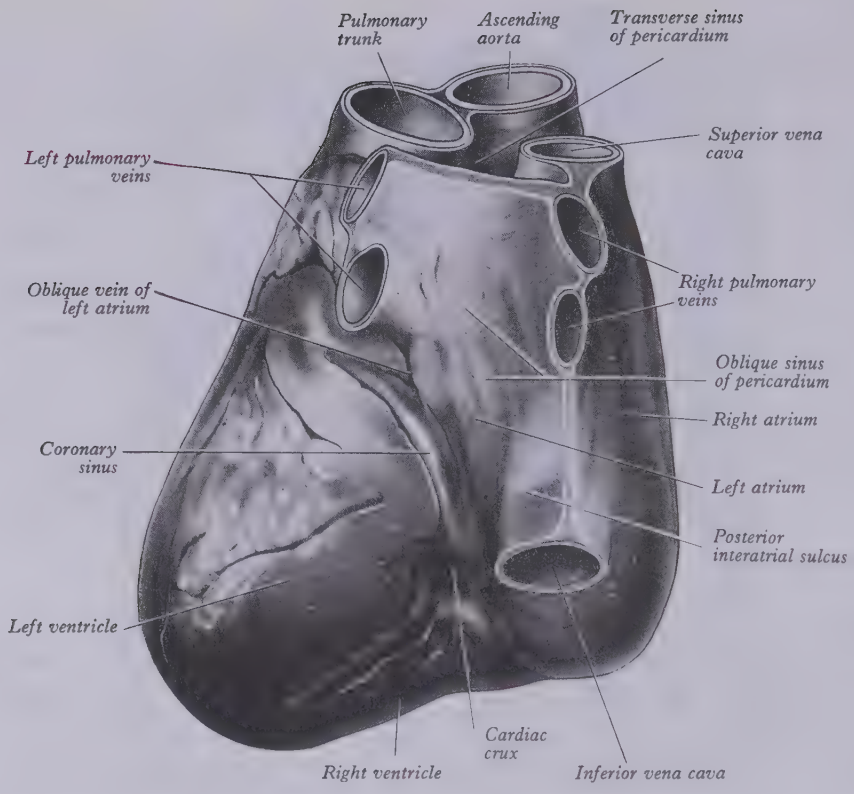
auricular appendage) from the oblique right margin of the right ventricle and its infundibulum; its upper left part is, however, obliterated where the root of the pulmonary trunk and, behind this, the aorta cross it. Continuing to the left, it curves around the heart's 'obtuse margin' and descends to the right, separating the atrial base from the diaphragmatic (ventricular) surface. Posterior and sternocostal parts of the coronary sulcus curve around the 'acute margin' at its lower right end to become confluent. Thus, both these parts of the sulcus pass from high on the left to the right but the posterior part is a little to the left of the sternocostal. Hence, a section which includes the coronary sulcus is at about 45° to the sagittal plane and at a greater but variable angle to the transverse and coronal planes; it approximately traverses the lines of attachment of the atrioventricular valves and (even less precisely) those of the aortic and pulmonary (**6.41,42**); a line at right angles to the centre of this plane will descend forwards and left to the cardiac apex.

Internally the ventricles are separated by the interventricular septum (p. 769), whose mural margins correspond to the *anterior* and *inferior (diaphragmatic) interventricular grooves*. The former, on the sternocostal cardiac surface, is near and almost parallel to the left ventricular obtuse margin but the latter, which is on the diaphragmatic surface, is nearer the acute border. Interventricular grooves extend from the coronary sulcus (i.e. ventricular 'base') to the *apical incisure* on the acute margin, a little to the right of the true cardiac apex.

CARDIAC BASE, APEX, SURFACES, BORDERS

The *posterior aspect* or *base* (**6.31**) is somewhat quadrilateral, with curved lateral extensions; it faces back and to the right, separated from the thoracic vertebrae (fifth to eighth in the recumbent, sixth to ninth in the erect posture) by the pericardium, right pulmonary veins, oesophagus and aorta. It is mainly formed by the left atrium and only partly by the posterior part of the right. It ascends to the pulmonary arterial bifurcation and descends to the posterior part of the coronary sulcus containing the coronary sinus and rami of the coronary arteries (p. 727). To the right and left it is limited by the rounded surfaces of the corresponding atria; these are separated by a shallow vertical *interatrial groove*. Where the coronary sulcus, interatrial groove and inferior interventricular groove meet is often picturesquely termed *the crux of the heart* (**6.31**). Two pulmonary veins on each side open into the left atrial part of the base: into the upper part of the right atrial basal region open the superior vena cava, and the inferior vena cava into its lower part. The area of the left atrium between the openings of right and left pulmonary veins forms the anterior wall of the oblique pericardial sinus (p. 696). This description applies to the *anatomical base* with the heart in situ. Some confusion is entailed by other current usages of the term: some apply it to the ventricular aspect seen after section through the coronary sulcus (**6.47**); this should be termed the *base of the ventricles* . In clinical practice auscultation in or near the parasternal parts of the second intercostal spaces is often regarded as applied to the *clinical 'base'* (in contrast to the *clinical 'apex'*). These applications, while unfortunate, seem likely to persist.

The cardiac apex is really the apex of the conical left ventricle, directed down, forwards and left; the left lung and pleura overlap it. It is located most commonly behind the fifth left intercostal space, near or a little medial to the mid-clavicular line.



The anterior, sternocostal surface (**6.30A,B**) faces forwards and upwards, with both right and (more pronounced) left convexities; it consists of an atrial area above and to the right and a ventricular part below and left of the coronary sulcus. The atrial area is almost entirely the right atrium; the left atrium is largely hidden by the ascending aorta and pulmonary trunk (**6.30B,60**); a small part of its auricle, however, projects forwards, left of the pulmonary trunk. Of the ventricular region about one-third is the left and two-thirds the right ventricle; their septum is indicated by the anterior interventricular groove. The sternocostal surface is separated by the pericardium from the corpus sterni, sternocostales and third to sixth costal cartilages; owing to cardiac bulging to the left, more of this surface is behind the left costal cartilages than behind the right ones. It is also covered by pleurae and thin, anterior edges of the lungs, except for a triangular area due to cardiac incisure of the left lung; both lungs and pleurae are variable in their degree of overlap.

The inferior, diaphragmatic surface (**6.31**), is largely horizontal but slopes down and forwards a little towards the apex. It is formed by the ventricles (chiefly the left), resting mainly upon the central tendon but also, apically, on a small area of the left muscular part of the diaphragm. It is separated from the base by the coronary sulcus carrying the coronary sinus and is traversed obliquely by the inferior interventricular groove.

The left surface, facing up, back and left, consists almost entirely of left ventricle, but with a small part of the left atrium and its auricle contributing above. Convex and widest above and crossed here by the coronary sulcus, it narrows to the cardiac apex. It is separated by serous pericardium from the left phrenic nerve and accompanying vessels and by the left pleura from the left lung's deep concavity, antero-inferior to its hilum.

The rounded right surface is formed by the right atrial wall, separated from the mediastinal aspect of the right lung by the serous and fibrous pericardium and the mediastinal and visceral pleurae. Its convexity merges below into the short intrathoracic part of the inferior vena cava and above into the superior vena cava. The sulcus terminalis curves approximately along the junction of the sternocostal and right surfaces of the right atrium.

The cardiac upper border is atrial (principally the left atrium); anterior to it are the ascending aorta and pulmonary trunk. The superior vena cava enters the right atrium at its right extremity.

6.31 The base and the diaphragmatic surface of the heart. The serous pericardium is in situ and its cut edge is seen around the great vessels; its disposition is highly schematic (recesses omitted). See text for additional details.

The rounded so-called *right 'border'*, the right atrium's convex profile, approaches the vertical but is obvious on radiographs.

The *inferior border* or *'acute margin of the heart'* is sharp and thin and nearly horizontal; it extends from the lower limit of the right border to the apex. It is formed mainly by the right ventricle but by the left ventricle near the apex.

The *left border* or *'obtuse margin of the heart'* separates the sternocostal and left surfaces; it is round and mainly formed of left ventricle but, to a slight extent above, is formed by the left auricle. It descends obliquely from the left auricle, convex to the left, to the cardiac apex.

The borders, as indicated above, apart from the inferior ('acute') one, are rounded and cannot be precisely defined, being 'aspects' rather than borders. The right and left surfaces are referred to as pulmonary but much of the sternocostal is also related to the lungs. Right and left profiles of the cardiac *shadow* in a postero-anterior radiograph are the radiologist's right and left borders.

Cardiac Chambers and Internal Features

The right and left cardiac chambers will be described seriatim in terms of general form, walls and internal features. They have much in common, such as the structure of valvular leaflets, chordae tendineae, papillary muscles of atrioventricular (inflow tract) valves and the cuspal architecture of pulmonary and aortic (outflow tract) valves. Repetition will be minimized.

THE RIGHT ATRIUM (**6**.30A,B,31,32,36,54)

General and External Features

The *interatrial (atrial) septum* is oblique, so the *right atrium*, a roughly quadrangular chamber, is anterior as well as right of the left atrium, also extending inferior to it. Its walls form the right upper sternocostal surface, the convex right (pulmonary) surface and a little of the right side of the base. The superior vena cava opens into its upper posterior aspect and the inferior vena cava into its lower posterior part. A small, muscular pouch, *the auricle*, projects to the left from its upper anterior part, overlapping the right side of the ascending aorta; the auricular margins are notched, its interior encroached on by an irregular muscular reticulum. In well-fixed hearts the lateral wall is marked externally by a shallow *sulcus terminalis*, extending between the right sides of the two vena caval orifices; posteriorly a vertical interatrial groove descends to the crux.

Anteriorly, the right atrium is related to the anterior part of the mediastinal surface of the right lung, separated from it by pleura and pericardium, and *laterally* also to the mediastinal surface of the right lung but anterior to its hilum and separated by the pleura, right phrenic nerve and pericardiacophrenic vessels and pericardium. *Posteriorly* and to the left (**6**.13B,15), the right atrium is separated from the left atrium by the septum (its mural attachment indicated by the posterior interatrial groove); posteriorly and to the right are the right pulmonary veins. *Medially* are the ascending aorta and to a lesser extent the root of the pulmonary trunk.

The right atrial interior (**6**.32,34,54) presents two main aspects: a posterior and an anterior.

The posterior part, where the great veins end, is derived from the absorbed right cornu of the sinus venosus (p. 209); it has smooth walls and is the *sinus venarum*. *Anterior* to this is a ridged region derived from the embryonic *atrium* proper and is continuous anteriorly with the *auricle*.

The *sinus venarum* includes the posterior and lateral wall forwards as far as the crista terminalis (p. 703). Opening into it are the following vessels:

(1) The *superior vena cava* (**6**.30A,B,31,54), returning blood from the body's upper region, opens into it superoposteriorly. Its orifice faces infero-anteriorly and has no valve.

(2) The *inferior vena cava* (**6**.31,32,34,54), larger than the superior, returns blood from the lower body into the lowest part of the atrium near its septum. Anterior to its orifice is a rudimentary semilunar *valve of the inferior vena cava*, its convex margin attached to the orifice's anterior margin. Its concave edge ends in two *cornua*, the left continuous with the anterior edge of the limbus fossae ovalis; the right cornu is lost on the lateral atrial wall

becoming continuous with the lower end of the crista terminalis. The valve is a fold of endocardium enclosing a few muscular fibres. It is prenatally large, directing flow from the *inferior vena cava* into the *left atrium* through the septum's *foramen ovale*. The valve varies in size, being sometimes cribriform or filamentous and occasionally absent.

(3) The *coronary sinus* (**6**.31,32,34,54). This returns the majority of blood from the heart itself, opening between the inferior caval orifice and the atrioventricular opening, protected by a thin, semicircular *valve of the coronary sinus* (**6**.32,34,54) covering the lower part of the orifice. It prevents regurgitation into the sinus during atrial contraction. It may be double or cribriform.

(4) The *foramina venarum minimarum* are the orifices of *venae cordis minimae* which return a small fraction of blood from the heart (p. 792). They are most numerous on the septal wall. The anterior cardiac veins and sometimes the right marginal may enter the atrium (p. 793).

The *intervenous tubercle*, small and variable, projects on the posterior wall below the superior caval orifice; it is distinct in quadrupeds but in man often scarcely visible. In utero it is more prominent and may direct blood from the superior vena cava towards the atrioventricular opening.

The *atrium proper* and the *auricle* are separated from the sinus venarum by the *crista terminalis*, a smooth, muscular ridge, mainly on the lateral wall; it begins on the upper septum and, passing anterior to the superior caval orifice, skirts its right margin to reach the right side of the inferior caval orifice, where it joins the right end of the inferior caval valve. It is the site of the embryo's *right venous valve (sinuatrial valvula*, p. 209), corresponding externally to the sulcus terminalis (p. 702). It marks the junction of the cardiac parts derived from the right cornu of the sinus venosus and the original atrium. Superiorly the crista terminalis accommodates the sinuatrial node (p. 720); its remainder is regarded by some as the route of the posterior internodal tract (p. 722).

The *musculi pectinati*, almost parallel muscular ridges extending anterolaterally from the crista terminalis in the right atrium, incline towards the atrioventricular orifice. In the auricle they interconnect to form a network.

The septal wall presents the *fossa ovalis* (**6**.32,54), an oval depression low on the wall, above and to the left of the inferior caval orifice. Its floor is originally the fetal septum primum (p. 209). The *limbus fossae ovalis* is its prominent margin, representing the edge of the septum secundum (p. 210). It is most distinct above, and deficient inferiorly; its anterior edge is continuous with the left cornu of the inferior caval valve. A small, valvular slit sometimes exists at the fossa's upper margin, ascending beneath the limbus to the left atrium; it is a remnant of the foramen ovale.

Antero-inferior in the right atrium is the large, oval *atrioventricular orifice*, its margin approximately the line of attachment of the *tricuspid valve*.

A triangular zone (*triangle of Koch* **6**.34,54) exists between the base of the tricuspid valve's septal leaflet, the anteromedial margin of the coronary sinus orifice, and the round, collagenous, palpable, subendocardial *tendon of Todaro*, which curves from the '*right fibrous trigone*' *(central fibrous body*, p. 657) to the medial cornu of the inferior caval valve; it is a landmark of surgical import, indicating the septal site of the atrioventricular node and associated juxtanodal bundles (p. 657). Dorsal to the septal leaflet of the tricuspid valve, the septal wall is an extension of the *pars membranacea septi*, which is here *atrioventricular*, intervening between the right atrium and left ventricle.

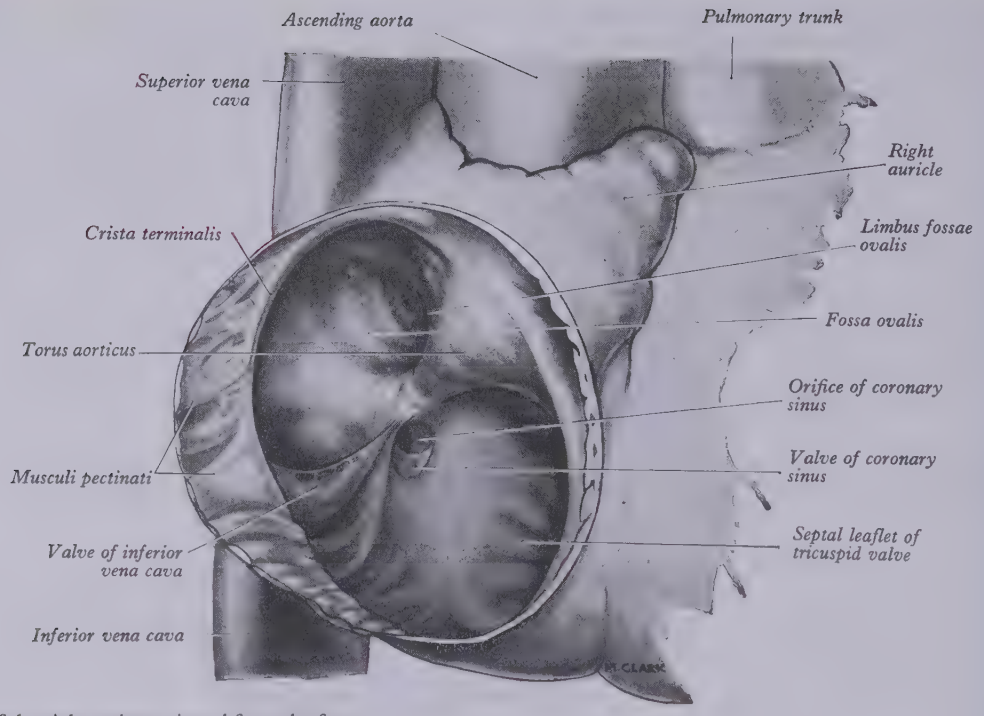
The septal wall bulges in its anterosuperior area into the right atrial cavity as the *torus aorticus*, due to the proximity of the right posterior (non-coronary) aortic sinus and its cusp (p. 711).

THE RIGHT VENTRICLE

The right ventricle extends from the right atrioventricular (tricuspid) orifice nearly to the cardiac apex; it then ascends to the left as the *conus arteriosus (infundibulum)*, reaching the pulmonary orifice. Thus it has an inflow orifice and tract leading at an obtuse angle to an outflow tract and orifice. Some prefer to include an intermediate 'body' but this view will not be followed here. External features will be followed by considerations of inflow and outflow tracts, the tricuspid valvar complex, pulmonary valve and brief functional allusions.

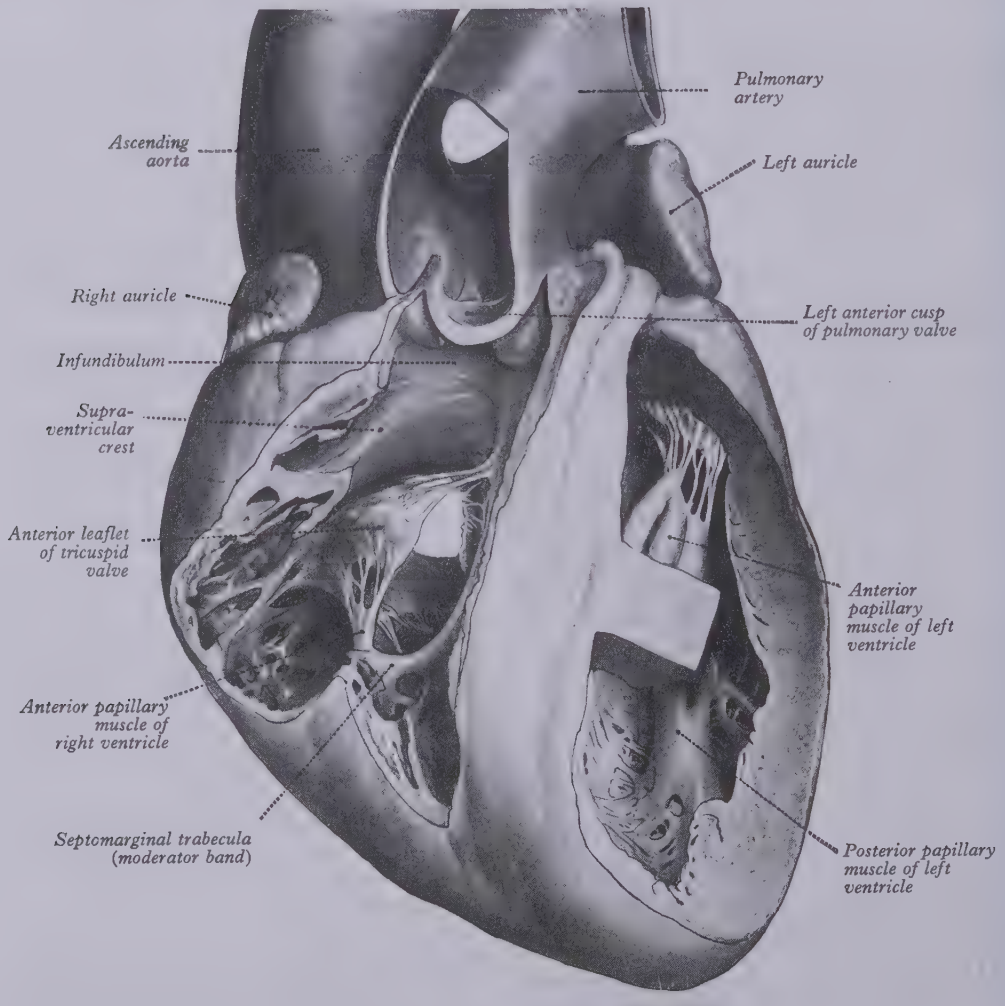
External features. The convex *anterosuperior surface* is a large part of the sternocostal aspect of the heart, separated from the thoracic wall only by pericardium; the left pleura and, to a lesser extent, the anterior margin of the left lung are interposed above and to the left (**6**.30A,41). The *inferior surface* is flat and mainly related to the central tendon and also a small adjoining muscular part (left cupola) of the diaphragm, separated by pericardium. The *left and posterior* wall is the ventricular septum which bulges into the ventricle, so that in sections across the cardiac axis the right ventricular outline is crescentic (**6**.35). A collagenous band (6.47,48), the *tendon of the infundibulum (conus ligament)*, connects the pulmonary annulus and muscular infundibulum posteriorly to the root of the aorta, where it blends with the wall and margin of its right posterior (non-coronary) sinus (p. 712); inferiorly this tendon blends with the membranous ventricular septum (p. 709). The ventricle's wall varies much in thickness (vide infra) but is thinner (3–5 mm on average) than the left, in a ratio of about 1 to 3; it is thickest at its atrial end and gradually thins towards its apex.

Internal features. The internal surfaces of inflow and outflow tracts are in complete contrast, the transition between the two being superiorly at the supraventricular crest and antero-inferiorly near the ventricular apex at the septomarginal trabecula (vide infra). The *supraventricular crest*, a massive muscular arch between the right atrioventricular and pulmonary orifices (**6**.33), is oblique, curving forwards and right from the interventricular septum ('*septal limb*') to the right anterolateral ventricular wall ('*mural or parietal limb*'). Its concavity is between these limbs in the line of the crest; at right angles to this, i.e. between the valvar orifices, it is convex. To it posteriorly the anterior tricuspid leaflet is partly attached. Its septal limb often fuses with the septal end of the septomarginal trabecula (vide infra).



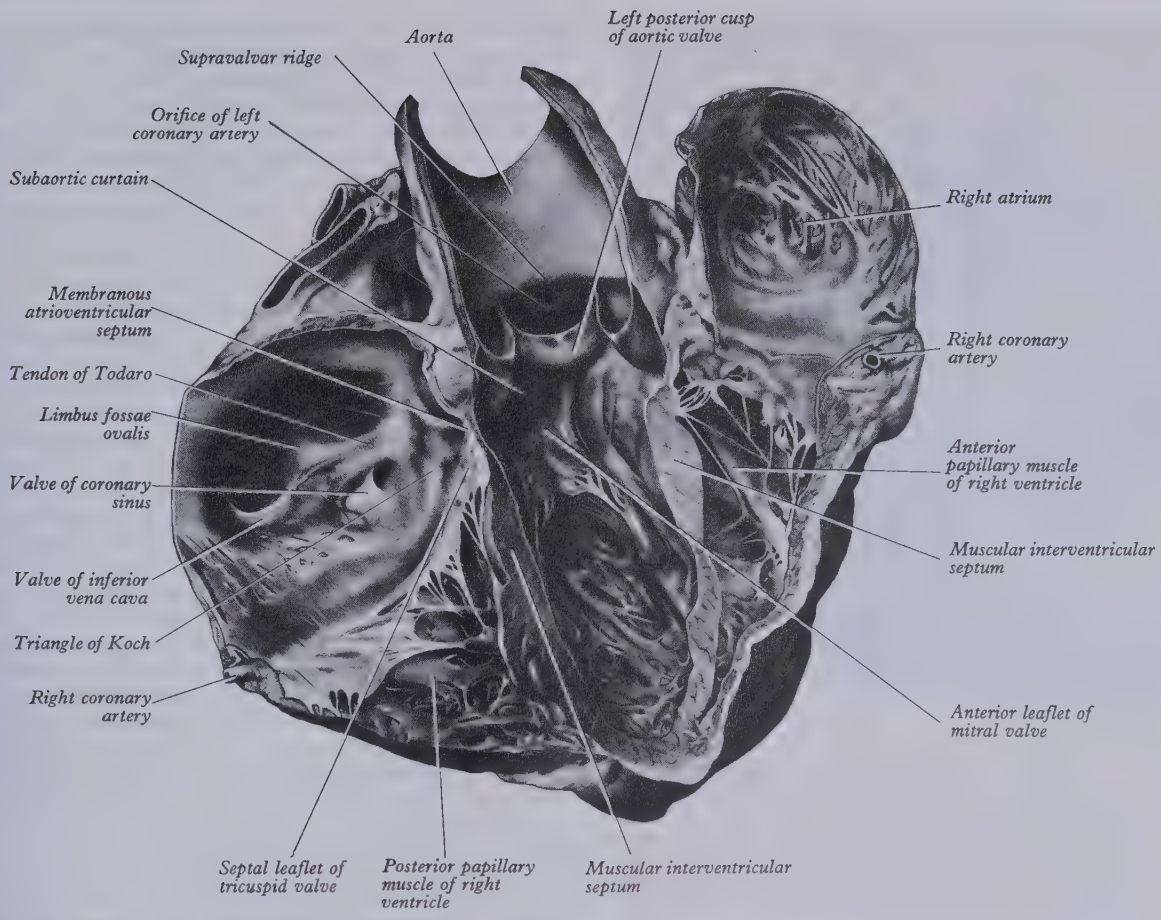
The inflow tract has walls roughened by the *trabeculae carneae*, irregular muscular ridges, columns, bands or protrusions covered with endocardium which project into the cavity; these and intervening depressions greatly vary myocardial thickness. Trabeculae are (1) mere ridges, (2) fixed at the ends but free between, or (3) *papillary muscles*, the latter continuous basally with the ventricular wall and at their apices with the *chordae tendineae*, glistening collagenous cords which, with the muscles, are part of the tricuspid valvar complex. The *septomarginal trabecula*, a curved muscular band from the lower part of the interventricular septum to the base of the anterior papillary muscle, forms the lower limit of the inflow tract and contains a continuation of the right bundle-branch of conducting tissue (p. 722). Its alternative name, 'moderator band', records an old idea that it prevents ventricular 'over distention'.

The outflow tract, conus arteriosus (infundibulum), with smooth walls, ascends to the left and posteriorly to the *pulmonary orifice*. In cadavers its lower limit cannot be identified externally but it is the free rounded border of the supraventricular crest (**6**.33) and upper border of the septomarginal trabecula near the ventricular apex. The infundibulum is a persistent part of the bulbus cordis incorporated in the right ventricle; and its persistence as the right outflow channel is attributable, in part, to the support it provides for the pulmonary valve during diastole. It has been shown (in dogs) that, when subjected to increased backward pressure, the pulmonary valve becomes incompetent more readily than the aortic, suggesting that the muscular infundibulum retains contractile tonus throughout ventricular diastole, thus supporting the valvar cusps (Brock 1955).



Trabeculated walls of the inflow tract may assist in slowing entry of blood during early diastole; their contraction and interdigitation may increase the *volumetric efficiency* of ventricular emptying. Smooth walls in the outflow tract are presumed to increase the *velocity* of ejection. Similar considerations apply to the left ventricle.

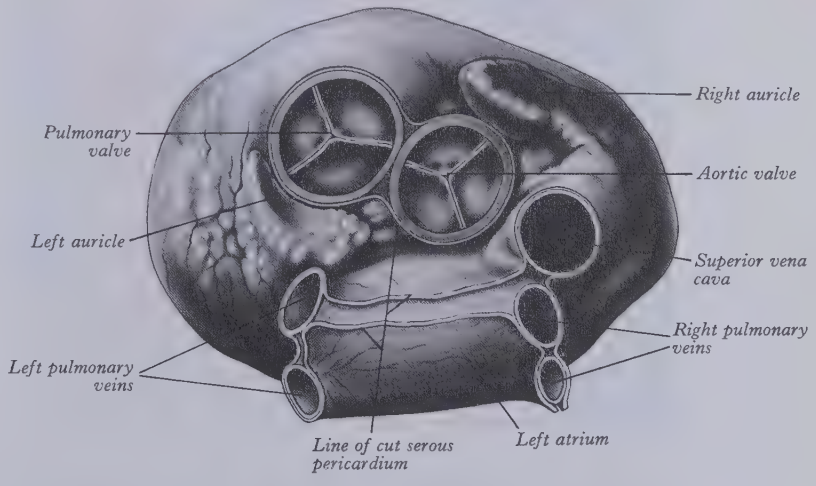
THE TRICUSPID VALVAR COMPLEX



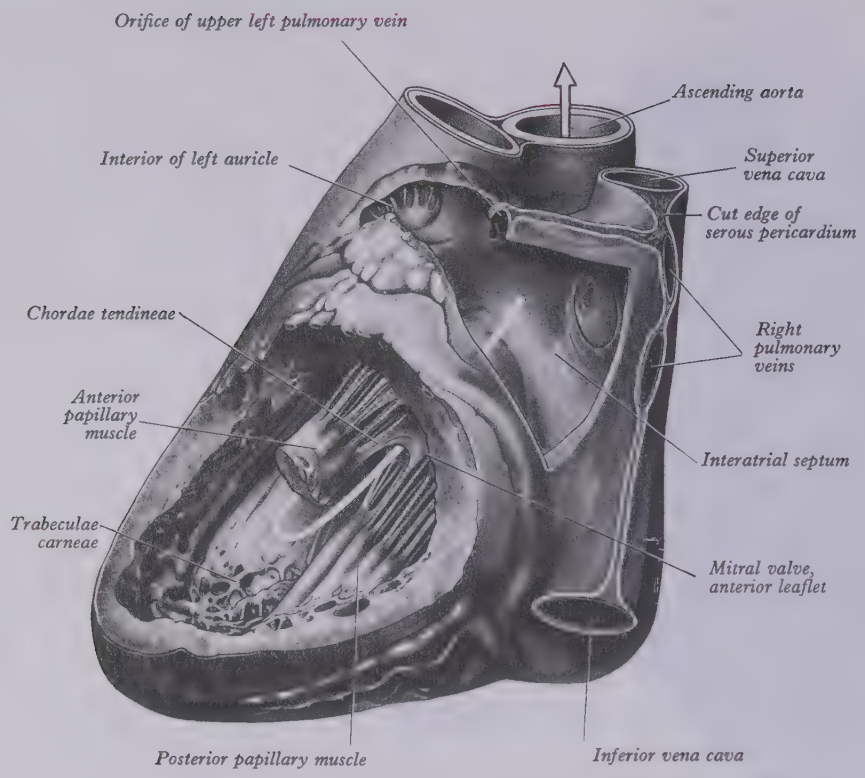
It is undesirable to describe tricuspid and mitral valves as isolated structures, since they are parts of functionally integrated

6.32 The interior of the right atrium, viewed from the front.

 6.33 A dissection opening the ventricles, viewed from the front.



6.34 The interior of the heart revealed by incising it along its right and lower surfaces and excising the pulmonary trunk and infundibulum. The rest of the front of the heart has been turned over to the left.



complexes. The *tricuspid valvar complex* comprises: (1) the so-called *tricuspid atrioventricular 'orifice'* and its associated *annulus*, (2) *valvar leaflets* or *cusps*, (3) *chordae tendineae* of various types, and (4) *papillary muscles*. Harmonious interplay of all these together with the atrial, ventricular and septal myocardium (p. 717), depends on the conducting tissues (p. 720) and mechanical cohesion provided by the cardiac fibro-elastic 'skeleton'. All parts change substantially in position, shape, angulation and dimensions during a cardiac cycle, the in vivo condition being the result, at all times, of the state of myocardial activity balanced against internal changes in pressure and blood flow. Qualitative or

6.35 Transverse section through the ventricles of the isolated heart, viewed from below. Note that in this illustration the heart is *not* positioned as it would be in situ: in the latter position the crescentic 'right' ventricle overlaps most of the *anterior* surface of the 'left' ventricle.

6.36 The heart viewed from above. The two continuous white lines which enclose the pulmonary trunk and aorta on the one hand and the pulmonary veins and the superior vena cava on the other, indicate the continuation of the parietal layer of the serous pericardium with the serous epicardium. The floor of the transverse sinus is seen from above, with the left coronary artery running in it. This diagram, from an earlier edition, has been retained for its pericardial details. However, in some respects it is misleading: the aortic and pulmonary valves are *not*, as shown, coplanar; the pulmonary valve is distinctly higher than the aortic valve; furthermore the planes of the valves 'face' approximately at right angles to each other.

6.37A Dissection showing the interior of the left side of the heart. The white arrow indicates the course of blood flow from the left atrium through the left ventricle to the aorta.

quantitative studies of dead hearts, fixed or unfixed, removed or in situ, may be most misleading; similar strictures apply *equally* to observations during cardiac surgery where a diseased heart has been subjected to severe haemodynamic interference.

The *tricuspid valve 'orifice'*, the largest valve orifice, (circumference 11.4 ± 1.1 cm in males and 10.8 ± 1.3 cm in females according to Silver et al 1971), is best seen from its atrial aspect (**6**.47); it has a *clear* line of transition from the atrial wall or septum to the bases of the valvar leaflets (valvulae). It is not a true orifice, becoming so only after leaflet removal; deep to its endocardium are various components of the valvar annulus. This artificial orifice has been described as almost circular, oval or roughly triangular with rounded angles, doubtless reflecting differences in age, normality, preparation and inspection. As detailed below, its margins are not precisely in a single plane; but for present purposes, a near approximation is almost vertical but at about 45° to the sagittal plane and slightly inclined to the vertical, so that it 'faces' (on its ventricular aspect) anterolaterally to the left and somewhat inferiorly. When roughly triangular, its margins are described as anterior, posterior and septal, corresponding to the bases of the valvar leaflets. (The term septal is unambiguous; *anterior* and *posterior*, though simple, are misleading, because of the near-vertical plane of the orifice; right superolateral and right inferolateral would be more accurate although cumbersome.)

The *tricuspid valve annulus* is an ill-defined term used without uniformity. Elementary accounts often describe all four valvar orifices as surrounded by *uniform rings* of collagenous tissue, the rings interconnected by dense masses of collagen; and as providing topographical lines of attachment for the bases of valvar flaps, fusing with their lamina fibrosa and, in mitral and tricuspid valves, situated precisely at the atrioventricular junctions (i.e. separating the myocardia of the cavities). But only some of these assumptions have proved true; in atrioventricular valves, though connective tissue *does* separate atrial and ventricular myocardium completely round the associated 'orifice', it varies in density and disposition around the circumference and with sex and age (Walmsley & Watson 1978). The topographical 'attachment' of the *free* valvar leaflet (valvula) does not *wholly* correspond to the internal level of attachment of the valve's lamina fibrosa to the atrioventricular connective tissue (though it does in much of its extent). Some limit the term *annulus* to the line of free leaflet attachment; but the collagenous central stratum of the leaflet may pass basally and subendocardially for some distance before merging with this atrioventricular connective tissue, which will be considered to be the valvar annulus in this account. In the tricuspid valve this includes: (*a*) an angled line across the membranous septum, (*b*) the tricuspid aspect of the right fibrous trigone, (*c*) the tapering, dense, fibro-elastic 'anterior' and 'posterior' *fila coronaria* from the trigone, and (*d*) the tenuous sulcal connective tissue completing the annular circumference between the tips of the fila, which will be described below and are illustrated in **6**.48.

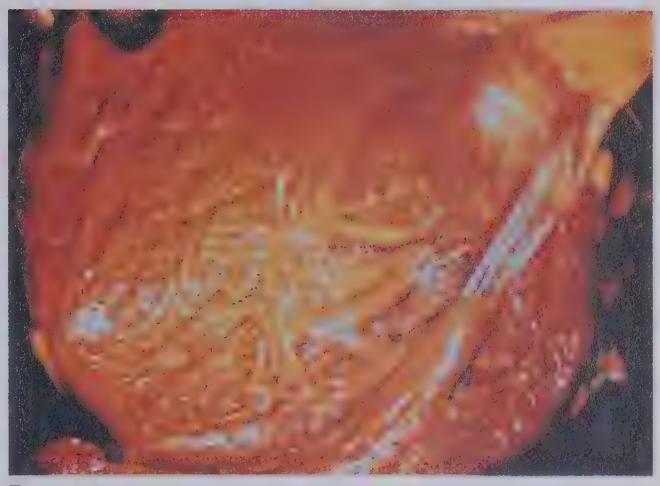
Tricuspid valve leaflets, usually three and hence the name, are *septal*, *anterior* and *posterior*, corresponding to the marginal sectors of the atrioventricular orifice so named (vide supra); each is a reduplication of endocardium enclosing a collagenous *lamina fibrosa*, continuous marginally and on its ventricular aspect with diverging fascicles of chordae tendineae (vide infra) and basally confluent with the annular connective tissue. Earlier descriptions of small 'accessory' valvulae, or 'islands of leaflet tissue' between the major leaflets have been modified (Silver et al 1971). Valvular tissue of the tricuspid (and mitral, p. 649) valves is now regarded as a *continuous curtain* arising from or near the annulus, descending into the ventricle but with three principal marginal grades of indentation, dividing it into definable parts. The deepest indentations are bays towards the basal attachment of the main, smoothly arched, *valve commissures*, separating the main leaflets and therefore termed anteroseptal, posteroseptal and anteroposterior. Thus a region may be designated, e.g. 'the anteroseptal half of the septal leaflet'. Commissures are usually well defined (but not as clearly as in the mitral valve) by their attached chordae tendineae and other adjacent features (Silver et al 1971). Intermediate indentations or '*clefts*', with smaller chordae, divide the posterior leaflet into three 'scallops'; one small '*notch*' usually exists on the margins of both septal and anterior leaflets. Thus, from either the atrial or the ventricular aspect, the true valvar orifice is highly irregular.

Palpation, transillumination and histology reveal that (except for parts extending on to the membranous septum) all tricuspid leaflets possess, passing from the free margin, *rough, clear* and *basal zones*. The *rough zone* is relatively thick, opaque and uneven on both aspects, particularly the ventricular, where most chordae tendineae are attached, its atrial, 'inflowing' aspect making contact with another leaflet during full valve closure. The *clear zone* is smooth and translucent, receives few chordae and has a thinner lamina fibrosa. The *basal zone*, extending about 2–3 mm from its peripheral attachment, is again thicker, with more connective tissue, is vascularized and frequently contains atrial myocardium.

The *anterior leaflet* (*valvula*, flap or lacinia) is the largest and is attached chiefly to the atrioventricular junction on the posterolateral aspect of the supraventricular crest but extends along its septal limb to the membranous septum, ending at the anteroseptal commissure; one or more notches indent its margin. The *septal leaflet* is smallest; its attachment passes from the posterior ventricular wall across the muscular septum and then angles across the membranous septum to the anteroseptal commissure. The *posterior leaflet* is wholly mural in attachment. Diagram **6**.38A, based on Silver et al (1971), summarizes the main features of the tricuspid leaflets, attachments and chordae; the heart is incised along its acute margin, opened and the annulus severed at the anteroposterior commissure and laid flat, with the base–apex ventricular axis vertical. The posterior leaflet and posteroseptal half of the septal leaflet are horizontal, whereas the latter's anteroseptal half and the anterior leaflet slope up to meet on the membranous septum at the anteroseptal commissure. The distribution of commissures, clefts, notches, zones and the pleated form of the septal leaflet are drawn to scale (**6**.38A).

Chordae tendineae are white fibrous collagenous cords; as in the left ventricle most are *true chordae* of the atrioventricular valvar complex. *False chordae*, merely connecting papillary muscles to each other or to the ventricular wall including the septum, or passing directly between points on the wall (and/or septum), are irregular in numbers and dimensions and of doubtful significance;

they will not be further discussed here. (However, see brief comments on false chordae associated with the *left* ventricle, also structures designated *left ventricular bands* and a bibliographical source, p. 709. Comparable *right ventricular bands* also occur.) *True chordae* usually arise from small projections on the tips or margins of the apical thirds of papillary muscles but sometimes from papillary bases or general ventricular (including septal) walls; they are attached to some aspect of the leaflets, their clefts, commissures or bases. They were classified by Tandler (1913) into first, second and third order chordae, according to the distance of attachment from margins: subsequent authors have usually concurred, although the schema has little functional or morphological merit. In an extensive study of the mitral valve, Lam et al (1970) proposed a new and more useful classification, applied with additions by Silver et al (1971) to the tricuspid, in which five classes of chordae are described: *fan-shaped, rough zone, free edge, deep* and *basal*.

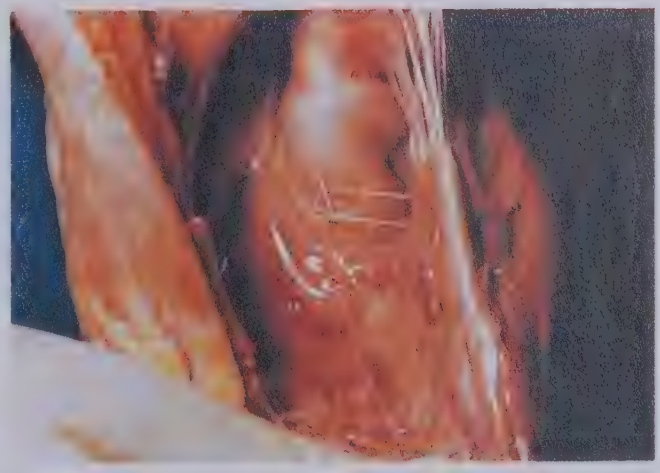


Fan-shaped chordae have a short stem from which branches radiate to attach to margins (or the ventricular aspect) of main commissures (*commissural chordae*) and to the ends of adjacent leaflets, smaller ones having a like attachment to the clefts between the 'scallops' of the posterior leaflet (*cleft chordae*). *Rough zone chordae* arise from a single stem which splits into three: one cord is attached to the free margin, another on the ventricular aspect of the rough zone at its outer limit (the line of valvular contact in full closure); the third to some intermediate point. *Free edge chordae* are single, threadlike, and often long, passing from either the apex or the base of a papillary muscle into a marginal attachment, usually near the mid-point of a major leaflet or one of its scallops. *Deep chordae*, also long, pass beyond the margin and, sometimes bi- or tri-furcating, reach the more peripheral rough zone or even the clear zone. *Basal chordae*, the most variable, being round cords, flat ribbons, long and slender or short and muscular, arise from the smooth or trabeculated ventricular wall and attach to the basal 2 mm of a leaflet. (The references quoted above give quantitative details and bibliographies.)

Papillary muscles in the right ventricle comprise two principal, *anterior* and *posterior*, and smaller, variable, *septal* muscles. The *anterior papillary muscle* is largest; its base arises from the right anterolateral ventricular wall below the anteroposterior commissure and blends with the right end of the septomarginal trabecula (vide supra); to its apex, occasionally bifid, are attached (apically and subapically) chordae tendineae which extend to the *corresponding zones* of anterior *and* posterior tricuspid leaflets. The *posterior papillary muscle* arises from the ventriculoseptal myocardium below the posteroseptal commissure; it is frequently bifid or trifid, its chordae distributed to the septal and posterior leaflets, their commissure and clefts. 'Accessory' *septal papillary muscles* may be absent or merely irregular fibrous cords; more often a group of small papillary projections arise from the infundibular septal wall below the crista supraventricularis and reach the apical aspect of the anteroseptal commissure, tethering adjacent parts of the anterior and septal leaflets; the highest muscle is often termed the *papillary muscle of the conus*.

In closure the tricuspid valve has much in common with the mitral; since evidence with regard to the latter is clearer, they will be considered together (p. 714).

THE PULMONARY VALVE



The pulmonary valve, the outflow valve of the right ventricle (**6**.33), surmounts the infundibulum, is separated a little from the other three cardiac valves and is anterosuperior to them. Its general plane faces superiorly to the *left* and slightly posteriorly. It has three semilunar *cusps (valvules)*, attached by convex bases to a *trilunate (triple-scalloped, tricrenate, 'coronet-like'* are alternative names) fibrous thickening in the wall of the pulmonary trunk at its junction with the ventricle forming a *valvar annulus* (p. 717 and **6**.48); the cuspal free borders project into the vessel. Two cusps are anterior (right and left), the third posterior. (Cusps of the pulmonary and aortic valves are named here from their approximate in situ positions in adult hearts; this differs from *Nomina Anatomica* where they are named according to the fetal position *before rotation*.) Each cusp is a fold of endocardium, with

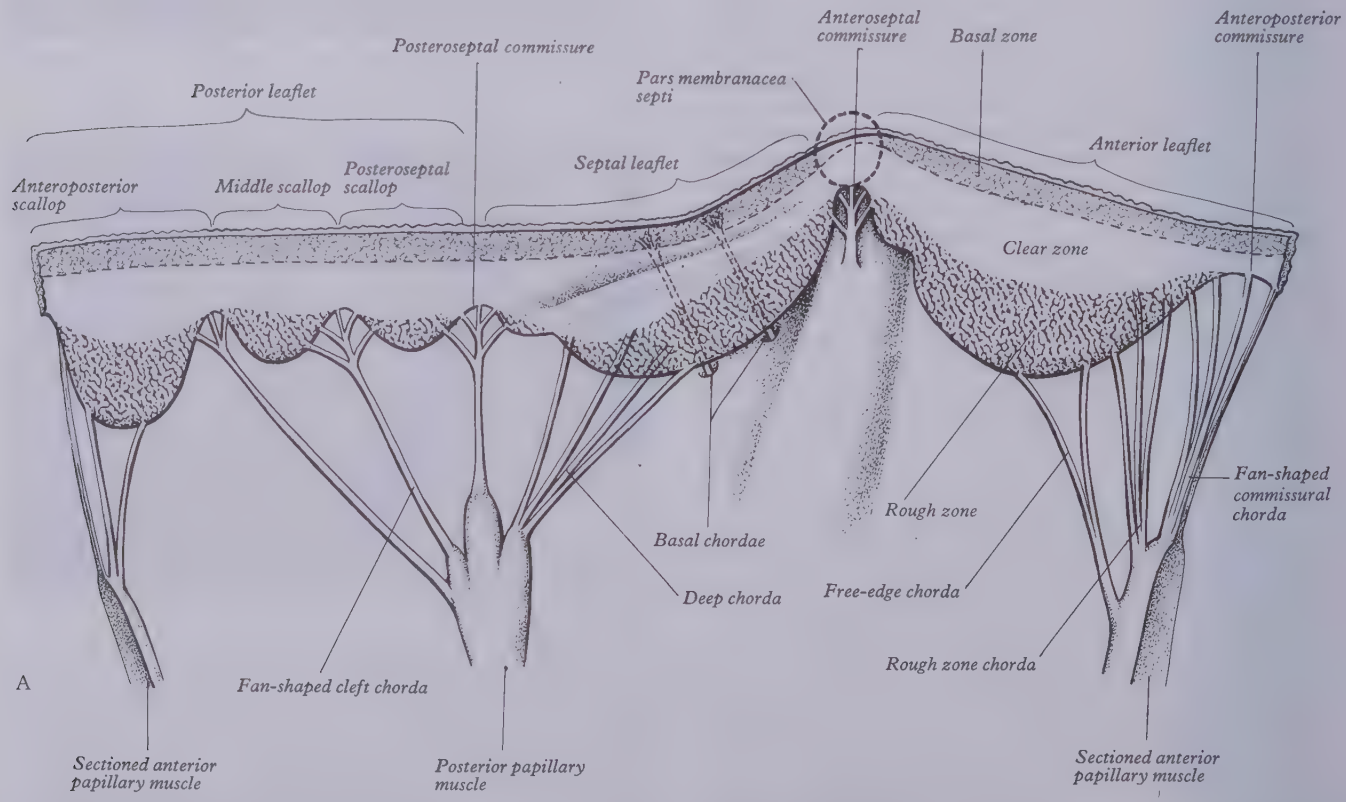
The latter in (B) is single, long, slender and between two mural attachments; in (C) between papillary subapex and ventricular wall passing obliquely; in (D) two cross the ventricular cavity horizontally between papillary muscles mid-belly and ventricular septum. Supplied by Blanka Darazs, Faculty of Internal Medicine, University of South Africa. (See also text and Darazs & Taylor 1988.)

an intervening, regionally variably developed *lamina fibrosa*; the lamina is substantial along both free and attached borders and at the latter blends with the fibrous 'annulus'. Central in each cuspal free margin is a localized thickening of collagen, the *nodulus* (Arantii), from which fibres radiate through the lamina to reach the annulus; on each side of a nodule, the collagen is much reduced in the narrow *lunules*. Opposite the semilunar cusps the arterial wall presents three *sinuses* (of Valsalva), whose walls are thinner than elsewhere; although predominantly collagenous near the annulus, their content of elastic tissue increases rapidly in their upper zones. Except for differences in time relation and pressures, opening and closure of the pulmonary valve has much in common with that of the aortic valve (p. 712, **6**.53).

THE LEFT ATRIUM

Though less in volume than the right, the *left atrium* has thicker walls (3 mm on average); its cavity and walls are largely formed by the proximal parts of pulmonary veins incorporated during development (p. 209). (The only clear derivative of the left part of the embryonic atrium is the auricular appendage.) The left atrium is roughly cuboidal and extends *behind* the right atrium, separated by the oblique interatrial septum (p. 702 and **6**.27,29A,B,C). Thus the right atrium is in front, lying anterolateral to the right part of the left atrium; its left part is concealed ventrally by the commencements of the pulmonary trunk and aorta, with part of the transverse pericardial sinus between it and these arteries. Anteroinferiorly and to the left it adjoins the left ventricular base, where the left atrioventricular orifice is sited (vide infra). Its posterior aspect forms most of the cardiac anatomical base and is approximately quadrangular, receiving the terminations of (usually) two pulmonary veins from each lung; it forms the anterior wall of the oblique pericardial sinus (p. 696). This surface ends at the shallow vertical interatrial groove that descends to the cardiac crux.



The left *auricle* is constricted at its atrial junction; it is longer, narrower, and more curved than the right, its margins being more deeply indented. It turns forwards left of the pulmonary trunk and overlapping its commencement. (Relations of the auricle to the left coronary artery are described on p. 730).

The **interior of the left atrium** (**6**.37A,55) presents several features: the four *pulmonary veins* open into its upper posterolateral surfaces, two on each side; their orifices are smooth, oval and not valved; the left pair frequently end via a common opening. The *left atrioventricular orifice* is fully described below. *Foramina venarum minimarum* are orifices of venae cordis minimae, returning blood from the myocardium. *Musculi pectinati*, fewer and smaller than in the right atrium, are confined to the left auricle. On the atrial septum a lunate impression may appear, bounded below by a crescentic ridge, concave upwards, marking the site of the ostium secundum (p. 209). (Its ridged margin is derived from the septum primum and its floor the septum secundum. Sometimes there are multiple impressions.)

THE LEFT VENTRICLE

General and External Features

In contrast to the right ventricle, construction of the left ventricle accords with its role as a powerful pump to sustain pulsatile flow in high-pressured systemic arteries. Variously described as half-ellipsoid or cone-shaped, it is longer and narrower than the right, extending from its base in the plane of the coronary sulcus to the cardiac apex. Its long axis descends forwards and to the left. In transverse section, at right angles to the axis, its cavity is oval or nearly circular (**6**.35), with walls about three times thicker (8–12 mm) than in the right ventricle. It forms part of the sternocostal, left and inferior (diaphragmatic) cardiac surfaces. Except where obscured by the aorta and pulmonary trunk, the base of the ventricular cone is superficially separated from the left atrium and auricular appendage by part of the coronary sulcus; anterior and

6.38 Diagrams of the tricuspid (A) and mitral (B, facing page) valves, laid flat after division of their fibrous annuli with the atrioventricular axis placed vertically, showing the relative shapes, dimensions and zones of the leaflets and their subdivisions; also the varieties of chordae tendineae. Drawn to scale: A after Silver et al (1971); B after Lam et al (1970). See text for further details.

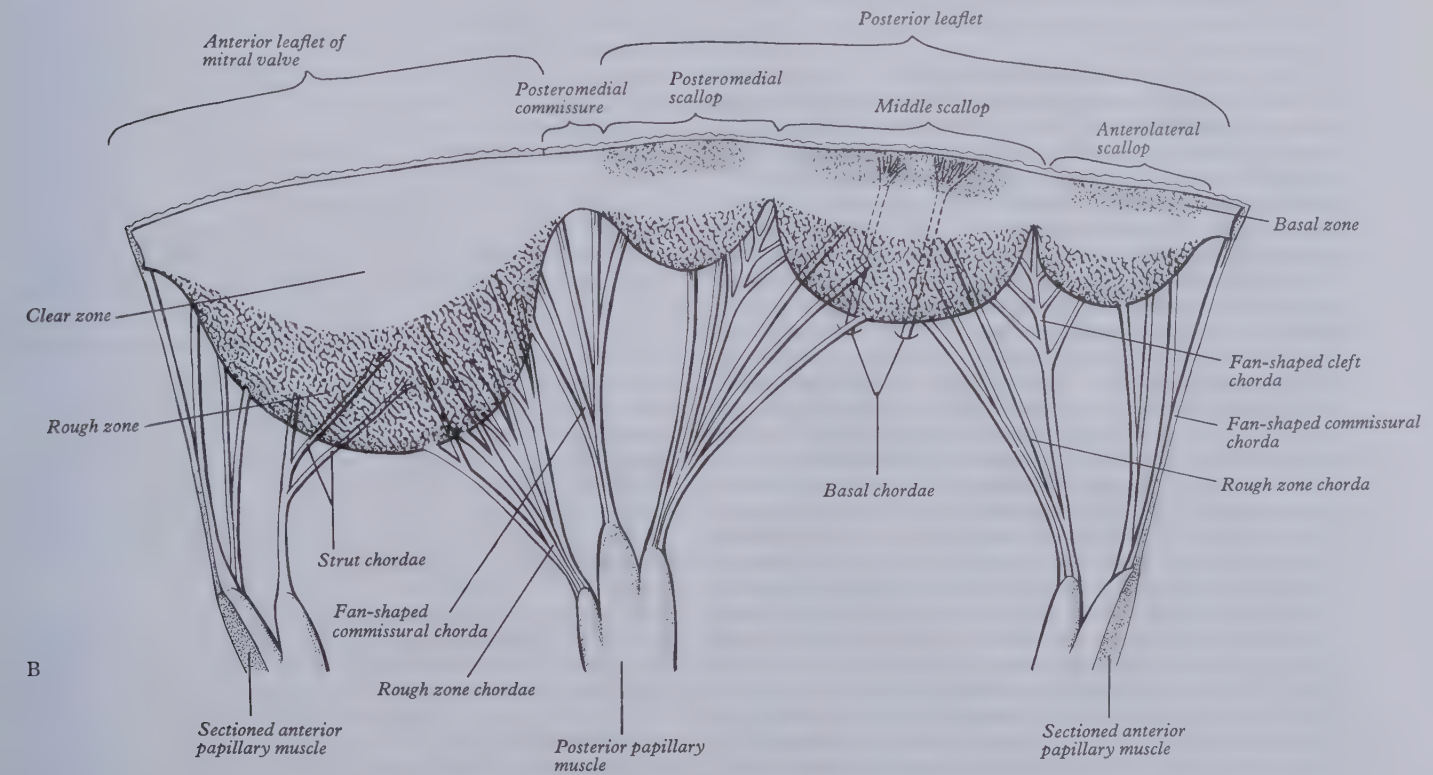
inferior interventricular grooves indicate the lines of mural attachment of the interventricular septum and the limits of the left and right ventricular territories. The ventricle's sternocostal surface curves bluntly into the left surface at the 'obtuse' margin.

Internal Features (6.33,35,37A–D)

Like the right, the left ventricle has an *inflow orifice* and *tract* continuous with an *outflow tract* and *orifice*, with attendant valvar complexes. The left atrioventricular orifice, with its mitral valve, admits atrial blood during diastole, flow being towards the cardiac apex (*inflow vector*). After mitral closure and throughout the ejection phase of systole (**6**.55), blood is expelled from the apex through the aortic orifice, defining the *outflow vector*. In contrast to right ventricular orifices, the left inflow and outflow orifices are in *close contact*, in part separated only by the subaortic curtain (intervalvar septum, vide infra) and anterior mitral valve leaflet; thus inflow and outflow vectors are acutely angled.

The anterolateral wall is the interventricular septum (i.e. septal wall as distinct from 'free' ventricular wall) which is mostly (but not exclusively) thick and muscular. The *muscular septum* is concave to the left, its convexity being the posteromedial profile of the right ventricle as seen in section; it thus completes the left ventricle's circular outline (**6**.35). Towards the aortic orifice the septum becomes the thin, collagenous *pars membranacea septi*, an oval or round area below and partly confluent with the fibrous supports of the anterior (right coronary) and right posterior (non-coronary) aortic cusps (pp. 711, 717 and **6**.34,48).

Between the lower limits of the free margins of the mitral valve leaflets and the ventricular apex, including the apical two-thirds of the interventricular septum, the muscular walls are intensely trabeculated. These *trabeculae carneae* are larger and more intricate than in the right ventricle but show the same varieties: mere ridges; terminally attached but centrally free; or papillary muscles. They form a very dense labyrinth towards the apex. Endocardial walls of the outflow tract (as in the right ventricular infundibulum) are smooth; subendocardial tissue in its final part, the *aortic vestibule*, is increasingly fibrous and less muscular.



THE MITRAL VALVAR COMPLEX

Many *general* comments already made in respect to the tricuspid valve apply equally to the mitral; to avoid repetition, remarks will be confined to features of the following components of the mitral complex: (1) the *mitral atrioventricular 'orifice'* and its *valvar annulus*, (2) *leaflets (valvulae)*, (3) varieties of *chordae tendineae* and (*d*) *papillary muscles*.

The *mitral atrioventricular orifice*, a well-defined transitional zone between the atrial or aortic wall into the bases of the leaflets, is best viewed from the atrial aspect; it is smaller than the tricuspid (mean circumference: 9.0 cm in males, 7.2 cm in females, according to Ranganathan et al 1970, in a study of 50 Caucasian hearts from 15–85 years). In diastole the orifice, approximately circular, is almost vertical and at 45° to the sagittal plane but with a slight forward tilt; its ventricular aspect faces anterolaterally to the left and a little inferiorly, i.e. towards the left ventricular apex. It is almost coplanar with the tricuspid orifice but postero-superior to it, whereas it is postero-inferior and slightly left of the aortic orifice. All three orifices are intimately connected by the cardiac fibrous skeleton (p. 714).

The *mitral valvar annulus* is again *not* a simple fibrous ring, but comprises elements varying greatly in consistency, with which the valvular laminae fibrosae become continuous. These variations are of the greatest functional significance, allowing major changes in the annular shape and dimensions at different stages of the cardiac cycle, ensuring optimal efficiency in valvular actions of the mitral complex and its equally important role in controlling inflow/outflow patterns through the left ventricle. Such structural variations around the valve's periphery are sometimes accentuated, particularly with age.

The mitral annulus is shown in **6**.47,48. It includes internal aspects of parts of the left and right fibrous trigones and,

B

extending from the latter, the anterior and posterior fila coronaria: tapering, fibrous, subendocardial tendons partly encircling the orifice at the atrioventricular junction. Between the filar tips the atrial and ventricular myocardia are separated by a more tenuous sulcal sheet of deformable fibro-elastic connective tissue. Spanning between the trigones, the lamina fibrosa of the central part of the anterior mitral leaflet is a continuation of the fibrous *subaortic curtain (intervalvar septum)*, which descends from the adjacent halves of the left posterior (left coronary) and right posterior (non-coronary) cuspal regions of the aortic annulus; the curtain is specially thick where it passes to the base of the free leaflet. Since the valvar line of connective tissue attachment comprises sequentially a malleable fibrous sheet, bordered by two dense collagenous masses, then two tapering 'tendons' and finally delicate fibro-elastic areolar at different locations, the usual term 'annulus fibrosus' is inappropriate but is deeply engrained and will serve until a more suitable substitute is minted.

Mitral valve leaflets (valvulae), since the earliest descriptions, have been 'two in number'; hence the name *bicuspid valve* is more explicit, though erroneous (the leaflets are *not* cuspid in form) and surely less picturesque than the clinical 'mitral'. However, confusion, controversy and difficulties in quantitation have arisen because one or more small accessory leaflets between the two major ones often occur. Problems have apparently been resolved by the quantitative studies of Lam et al (1970) and Ranganathan et al (1970). The mitral valve is now described as consisting 'of a continuous veil attached around the entire circumference of the mitral orifice' (Harken et al 1952); its free edge bears indentations, two being deep and regularly positioned and receiving unique fan-shaped commissural chordae tendineae (vide infra); the tips of the papillary muscles are guides to them (Rusted et al 1952). These indentations are the *anterolateral* and *posteromedial commissures*; the valvar tissue may therefore be allocated to the two *commissural areas* mentioned and termed *anterior* and *posterior leaflets*. (Names of tricuspid commissures are derived from those of the adjacent cusps, whereas mitral commissures are positionally named. Their official terms, anterior and posterior, though simple, are misleading because of the valve's obliquity; many prefer alternative names (vide infra). General mitral anatomy, with the valve opened and laid flat, is diagrammed in **6**.38B (after Ranganathan et al 1970).

The *anterior leaflet* (aortic, septal, 'greater' or anteromedial, Chiechi et al 1956) is large, semicircular or triangular, with few or no marginal indentations. Its lamina fibrosa is peripherally continuous, beyond the margins of the fibrous subaortic curtain, with the mitral aspects of the right and left fibrous trigones, between these with the fibrous curtain itself and beyond the trigones with the trigonal roots of the fila coronaria (**6**.48). The leaflet has a deep crescentic *rough zone* receiving various types of chordae tendineae (vide infra); the ridge limiting the rough zone's outer margin indicates the maximal extent of surface contact with the posterior leaflet in full closure; from the rough zone to the valvar annulus is a *clear zone*, devoid of chordal attachments, though its lamina fibrosa carries extensions from chordae attached in the rough zone. The anterior leaflet has no basal zone. Hinging on its annular attachment and continuous with the deformable subaortic curtain, it is critically placed *between* inflow and outflow tracts, the whole mechanism having been dubbed the *aortic baffle*. During passive ventricular filling and atrial systole, its smooth atrial surface is important in directing a smooth flow of blood towards the trabeculated ventricular body and apex. After the onset of ventricular systole and mitral closure the ventricular aspect of its clear zone merges into the smooth surface of the subaortic curtain which, with the remaining fibrous walls of the subvalvular aortic vestibule, forms the smooth boundaries of the terminal outflow tract. Dimensions of the anterior leaflet are: mean central vertical height 2.4 cm in males, 2.2 cm in females; mean basal width 3.6 cm in males, 2.9 cm in females; the mean vertical height of the rough zone is 0.9 cm in males and 0.8 cm in females (according to Ranganathan et al 1970, who include further details and analysis of the data of Rusted et al 1952 and Chiechi & Lees 1956).

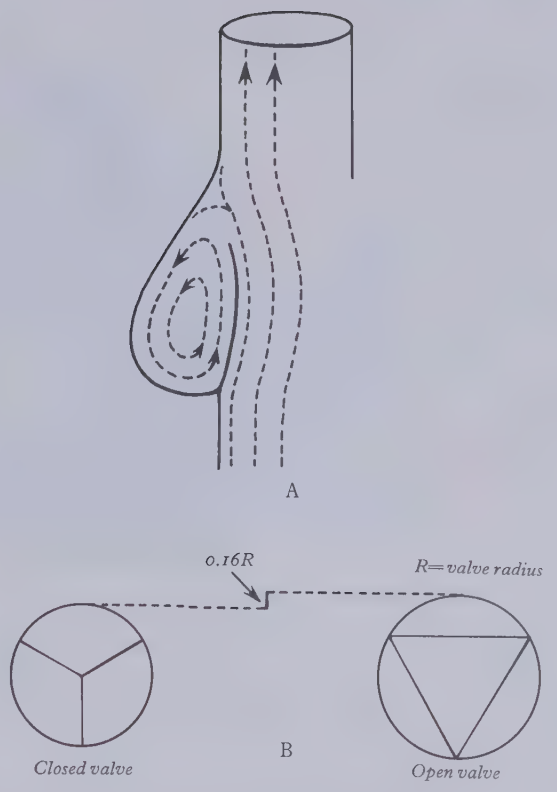
The *posterior leaflet* (ventricular, mural, 'smaller' or posterolateral) has usually two minor indentations or 'clefts'. Lack of definition of a major intervalvular commissure and of other details, has previously led to disagreement and confusion concerning the territorial extent of the posterior leaflet and the possible existence of an accessory one. Lam et al (1969), however, have provided precise definition of the commissural chordae (vide infra), showing that the posterior leaflet is best regarded as all valvular tissue posterior to the anterolateral and posteromedial commissures. Thus defined, it has a wider attachment to the annulus than the anterior (mean values are 5.4 cm in males, 4.3 cm in females). There are typical cleft chordae tendineae (vide infra) and clefts divide the posterior leaflet into a relatively large *middle 'scallop'* and smaller *anterolateral commissural* and *posteromedial commissural 'scallops'*. Each scallop has a crescentic, opaque rough zone, receiving chordal attachments on its finely serrated margin and ventricular aspect, defining the area of valvular apposition in full closure. From the rough zone to within 2–3 mm of its annular attachment is a membranous *clear zone* devoid of chordal attachment; the basal 2–3 mm is thick, vascular and receives chordae tendineae. The ratio of rough to clear zone in the anterior leaflet is about 0.6, in the middle 'scallop' of the posterior leaflet 1.4; thus, much more posterior leaflet is in apposition with the anterior during mitral closure.

Mitral chordae tendineae resemble those in the right ventricle; false chordae are also irregularly distributed as in the right ventricle. *False chordae*, as noted, may interconnect papillary muscles, extend from the latter to a point on the ventricular wall or interconnect two points on the ventricular walls. They are ignored in many accounts and when mentioned considered of little or no functional significance; further, many names have been applied, confusing rather than clarifying the topic. There has been a recrudescence of interest in structures having these anatomical dispositions and connections; a general name, *left ventricular bands*, has been re-adopted and they are being reinvestigated by Darazs & Taylor (1988), see also Gerlis et al (1984). Their main summary emphasizes: they are defined as discrete fibromuscular bands crossing the left ventricular cavity and having the connections mentioned. They are common, occurring in about 50% of human hearts, and often cross the outflow tract. Many contain Purkinje myocytes. Often left ventricular bands can be identified by two-dimensional echocardiography. Their normal role in cardiac conduction and haemodynamics has still to be determined. A positive association between the presence of left ventricular bands and the occurrence of a vibratory systolic auscultatory murmur has been claimed. The colour photographs **6**.37B,C and D, kindly provided by Dr B Darazs, are of the interior of the left ventricle showing varieties of trabeculae carneae, papillary muscles, true chordae tendineae and left ventricular bands. (As mentioned previously, comparable *right ventricular bands* also occur.) *True chordae* of the mitral complex may first be divided into *interleaflet* or *commissural chordae* and varieties of *leaflet chordae*; of the latter those of the anterior leaflet are *rough zone chordae*, including special *strut chordae*; those of the posterior leaflet include *rough zone chordae*, *cleft chordae* and *basal chordae*. Most true chordae divide into branches from a single stem soon after its origin from the apical third of a papillary muscle, or proceed as single cords dividing into multiple fine cords near their attachment.

Anterolateral and posteromedial *commissural chordae* arise near the tips of papillary muscles by a single stem fanning out at once into radiating strands attached to the smooth free margin of the commissure; some enter the lamina fibrosa of their adjacent leaflets and continue to their annular attachment. Branches of the posteromedial commissural chorda are longer, thicker and spread more.

Rough zone chordae divide into three soon after their origin from the papillary muscle; one cord is attached to the free leaflet margin, one beyond it on the ventricular surface at the line of closure and one between these. Such chordae occur in posterior and anterior leaflets; peculiar to the anterior are two which are the thickest and strongest in the mitral complex; they come from the tips of the anterolateral and posteromedial papillary muscles to attach near the line of valvar closure posteromedially ('4–5 o'clock' position) and anterolaterally ('7–8 o'clock' position). They are *strut chordae*, visible in over 90% of hearts examined by Lam et al (1970); their zone of attachment was earlier termed the *critical point of tendinous insertion* of the anterior leaflet (Brock 1952).

Cleft chordae, like miniature fans, have small branches radiating to the free margins of clefts between 'scallops', the deeper branches passing to the ventricular aspect of the adjacent rough zones.



Basal chordae are confined to the posterior leaflet (usually the large middle 'scallop' and one of the two smaller); they arise directly from the mural ventricular myocardium as a single strand which flares into minute branches before attachment to the ventricular aspect of the valvular basal zone. Sometimes basal chordae are partly or wholly muscular.

The *two left ventricular papillary muscles* vary in length and breadth and may be bifid. The *anterior papillary muscle* arises from the sternocostal mural myocardium, the *posterior* from the diaphragmatic region. Chordae tendineae arise mostly from the tip and apical third of each muscle, but sometimes near its base. They diverge and are attached to corresponding points (i.e. points in close apposition in valvar closure) on *both* mitral leaflets.

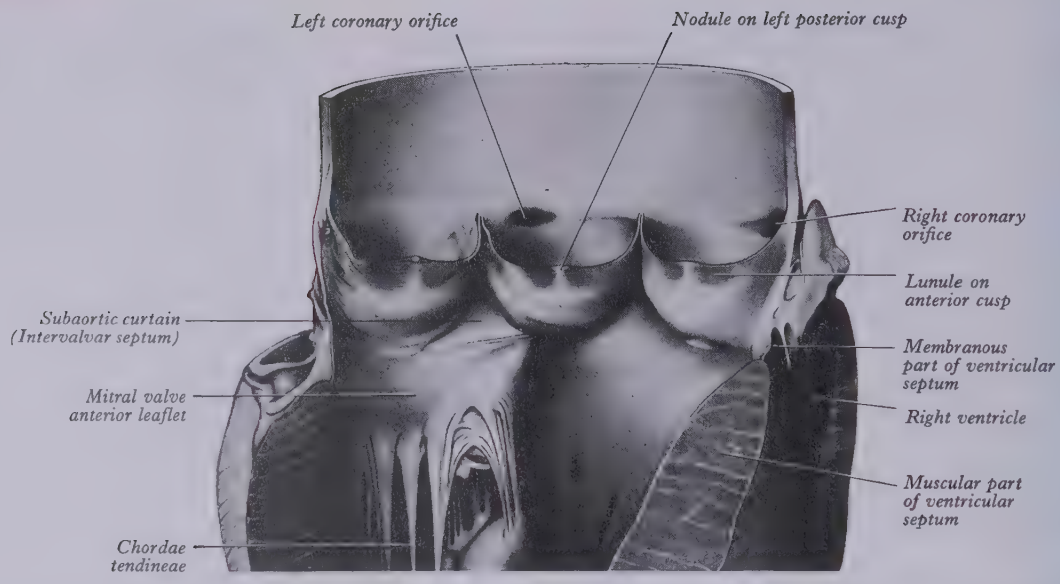
Opening of the mitral valve at the onset of diastole is passive but rapid, leaflets parting and projecting into the ventricle as left atrial pressure exceeds left ventricular diastolic pressure. Passive ventricular filling proceeds as atrial blood pours to the apex, directed by the pendent anterior mitral flap. Leaflets begin to float passively together, hinging on their annular attachments and partially occluding the ventricular inflow orifice. Atrial systole now occurs, jetting blood apically and causing transient valvar reopening. As maximal filling is reached, the leaflets again float rapidly together, ventricular systole follows, starting in the papillary muscle and followed rapidly by general mural and septal contraction. Co-ordinated papillary contraction raises tension in the chordae and coaptation of the corresponding points on opposing cusps. With general mural and septal excitation and contraction, left ventricular pressure rapidly rises (**6**.55); the leaflets 'balloon' towards the atrial cavity and the atrial aspects of the rough zones come into maximal contact. Precise papillary contraction and increasing tension in their chordae prevent valvular retropulsion into the atrium, maintaining valvar competence. The *biphasic* nature of mitral closure thus described is vividly apparent in a normal echocardiogram (**6**.46). With the fast drop in ventricular pressure following the ejective phase of systole and the onset of diastole, the leaflets part and the next cycle begins.

It is assumed that, apart from differences in timing and pressures, the general form of activity is similar in the tricuspid valve.

Both atrioventricular orifices and valves undergo large changes in position, form and area during a cardiac cycle. Both valves move anteriorly and to the left during systole, and the reverse in diastole. The mitral valve (for which data are more complete) reduces its orificial (annular) *area* by as much as 40% in systole; its shape also changes from circular to *crescentic* at the height of systole, the annular attachment of its anterior leaflet being the concavity of the crescent; the attachment of its posterior leaflet, although remaining convex, contracts towards the anterior.

6.39 A. Diagram of the vortices formed within an aortic sinus during the ejection phase of left ventricular systole. Note the position of the valve cusp and sinus wall. B (left). The general position of the apposed valve cusps during diastolic closure of the aortic (and pulmonary) valve. B (right). The open position of the aortic (and pulmonary) valve during the ejection phase of ventricular systole. Note the increase in diameter of the arterial trunk root at the level of the valve commissures and the *triangular* form of the open valve. Consult text for further discussion.

THE AORTIC VALVE (**6**.38A,B,40,48)



The smooth left ventricular outflow tract, or aortic vestibule, ends at the aortic orifice and valve, whose attached margins continue into the aortic root. Although stronger in construction, the aortic valve resembles the pulmonary (p. 707), consisting of a complex fibrous 'annulus', three semilunar cusps (or valvules) attached to it and three dilatations of the aortic wall, the aortic sinuses, one corresponding to each cusp.

Because the annulus is complex, it is difficult to define a valvar 'plane'. Some choose apices of intercuspid commissures as reference points, others select the deepest and most proximal points on the attached cuspal margins, i.e. three nadirs of the fibrous annulus. Approximately the valve faces up, right and a little anteriorly; it is anterosuperior to and slightly right of the mitral orifice; it is like a truncated cone.

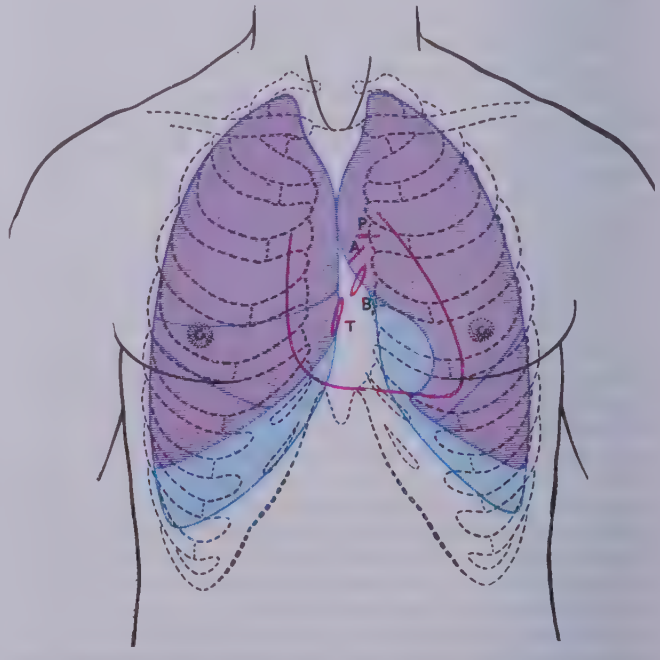
The *aortic annulus* consists of three almost semicircular condensations of collagen forming three scallops (or 'crenations'—an indifferent name), the whole encircling the trilunate vestibuloaortic junction like a three-pronged coronet; the 'prongs' point distally; apically the prongs form the fibrous commissural framework between adjacent cusps (vide infra and **6**.48). The luminal aspect of each scallop fuses with the valvular lamina fibrosa at the attached border of its cusp. The proximal (ventricular) aspect of the annulus is thickened at its nadirs (p. 716), while the triangular intervals between the proximal aspects of the scallops' ascending limbs are filled and fuse with extensions of the aortic vestibule's largely fibrous walls, special regions of which include the subaortic curtain (intervalvar septum) and part of the *pars membranacea septi*. The distal, deeply concave aspect of each scallop or crenation is the lower limit of, and continues into, the wall of an aortic sinus. Some maintain that, though largely fibrous, the aortic vestibular walls contain myocardial strands, some crossing the fibrous annulus as fine irregular strands in the walls of the sinuses.

The three aortic *semilunar cusps (valvules)* (**6**.40) are folds of endocardium with a central lamina fibrosa specially thickened in places. With the valve half-open, each cusp equals slightly more than a quarter of a sphere, an approximate hemisphere being completed by the corresponding sinus. Each cusp has a thick basal attached border, deeply concave on its aortic aspect, and a horizontal free margin, which is only slightly thickened except at its mid-point where it has an aggregation of fibrous tissue, the *valvular nodule* (Arantii); fine collagenous bundles radiate from this to the attached border, where the basal fibrous thickening blends with its corresponding annular scallop. At the apices of commissures a few transverse collagen fibres pass between adjacent cusps, but longitudinal fascicles enter the ascending limbs of the annular scallops (p. 716, **6**.48). Flanking each nodule the lamina fibrosa is tenuous, forming the *lunules* of translucent and occasionally fenestrated valvular tissue. The aortic surface of each cusp is rougher than its ventricular (outflow) aspect; endocardial cells are elongated in the direction of blood flow (Clarke & Fink 1974).

Three sets of names for the aortic cusps (valvules) are current. Official terms in *Nomina Anatomica* (1980) refer to fetal positions before full cardiac rotation has occurred; they are *posterior, right*

6.40 The aortic orifice opened from the front to show the cusps of the aortic valve, their nodules, lunules, commissures and the triple-scalloped line of annular attachment. Also shown is the continuity of the subaortic curtain with the mitral anterior leaflet (i.e. 'aortic baffle') and the coronary orifices.

and *left*. Here, terms based on the approximate positions in maturity are retained: *anterior*, *left posterior* and *right posterior*. But a widespread clinical terminology links cusps and sinuses to the origins of the coronary arteries; thus the anterior is *right coronary*, left posterior is *left coronary* and right posterior *non-coronary*(!)



The *aortic sinuses* (of Valsalva) are more prominent than those in the pulmonary trunk; both are dilatations of the arterial wall above the attached base of each cusp. The upper limit of each sinus reaches considerably beyond the level of the free cuspal border and is a well-defined complete circumferential *supravalvar ridge* viewed from the luminal aspect (**6**.34). Coronary arteries usually open near this ridge from the *upper* part of their sinus of origin, the ostium of the left often being a little lower (p. 727). Walls of sinuses are largely collagenous near the annulus, but thence the amount of collagen diminishes and that of lamellated elastic tissue increases; strands of myocardium may enter this fibro-elastic wall. At sinus mid-level its wall is about half the thickness of the supravalvar aortic wall and less than one-quarter of the supravalvar ridge; at this level the mean luminal diameter of the aortic root is almost double that of the ascending aorta's beginning (Reid 1970).

All such details are functionally significant in the valvar mechanism. During diastole the closed aortic valve supports an aortic column of blood at high but slowly diminishing pressure (**6**.53); each sinus and its cusp form a hemispherical chamber; the three nodules are apposed and the margins and lunular parts of adjacent cusps are tightly apposed on their ventricular aspects. From the aortic aspect the closed valve is tri-radiate, three pairs of closely compressed lunular segments radiating to commissures. As ventricular systolic pressure rises it exceeds aortic pressure and the valve is passively opened. The fibrous wall of sinuses nearest the aortic vestibule (i.e. at the nadirs of annular scallops) is almost inextensible; but in the upper parts of sinuses, at the level of the valvular commissures, the wall is fibro-elastic; under left ventricular ejection pressure, the *radius* here increases about 16% in systole. Hence commissures move apart, making the fully open orifice *triangular*, the free margins of cusps becoming almost straight lines between commissures. But they do *not* flatten against the sinus walls, even at maximal systolic pressure, which is probably an important factor in subsequent closure. During ejection most blood enters the ascending aorta, but some enters the sinuses, forming vortices which help to maintain the triangular 'mid-position' of the cusps during ventricular systole and probably initiate their approximation as systole ends; tight, full closure ensues with the rapid drop of ventricular pressure in diastole; commissures narrow, nodules aggregate and the valve reassumes its tri-radiate form. Experiments indicate that about 4% of ejected blood regurgitates through a valve with normal sinuses, while 23% regurgitates through a valve without them (Bellhouse 1968). Normal aortic sinuses may also promote non-turbulent flow into the coronary arteries.

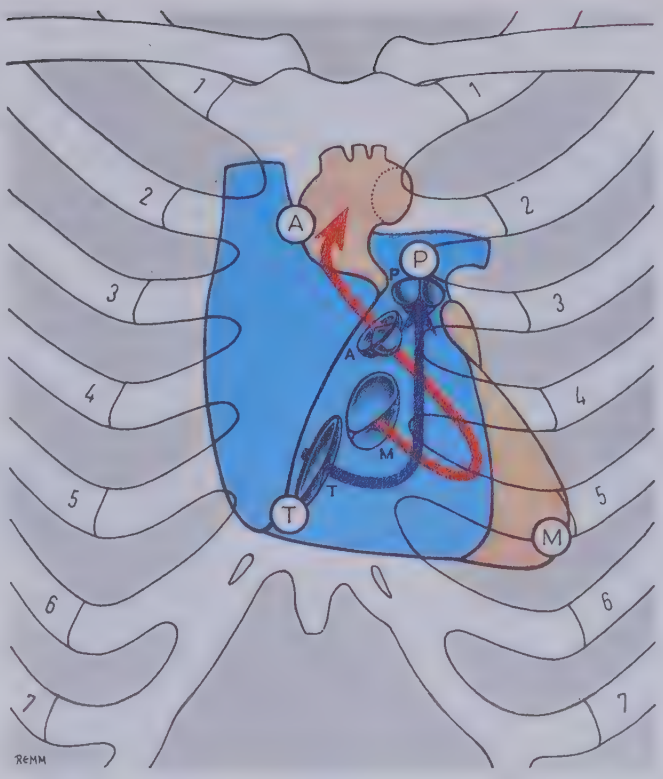
Similar events must occur in the pulmonary valve, though more leisurely, the pressure profiles being less extreme (**6**.53) and valvar structure less substantial.

CARDIAC SURFACE ANATOMY (6.41,42)

The surface projection data set out below apply to an average adult; they are considerably modified by age, sex, stature and proportions, respiration and position. Surface projections of valves are *not* the best sites for *auscultation* (**6**.42).

6.41 The front of the thorax, showing the surface relations of the bones, lungs (purple), pleurae (blue) and heart (red outline). Compare **6**.42 for further cardiac detail. A = orifice of aorta; B = left atrioventricular (mitral) orifice; P = orifice of pulmonary trunk; T = right atrioventricular (tricuspid) orifice.

The cardiac *apex* almost corresponds to the *apex beat*, which is usually visible and always palpable a little inferomedial to the left male nipple, in the fifth intercostal space, slightly medial to midclavicular line, about 9 cm from midline in average adult males. (The *apex beat* is the most inferolateral point at which a pulsation can be felt, whereas the *true cardiac apex* is a short distance further inferolaterally, does not contact the thoracic wall in systole and its position is seen in profile in appropriate X-rays and scans.)

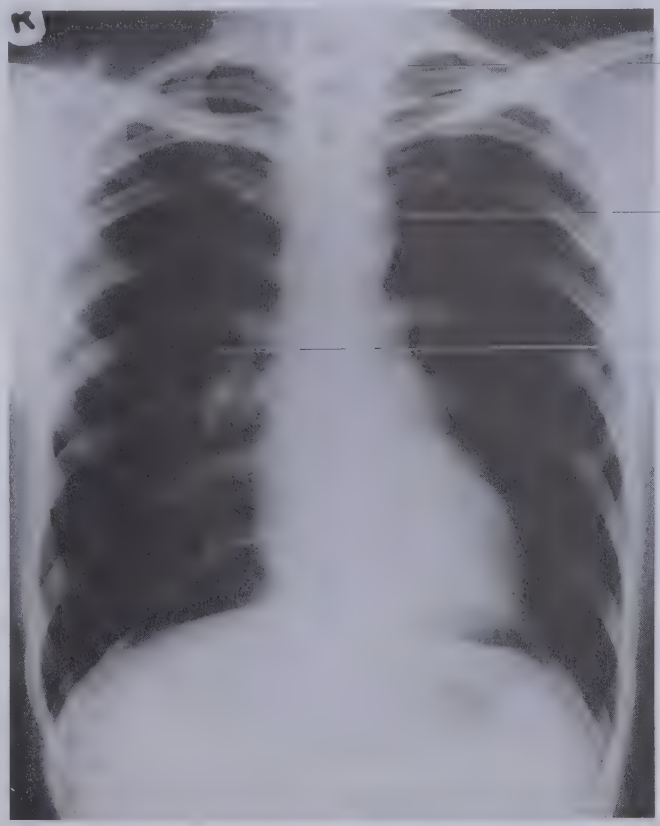


The cardiac sternocostal surface, projected to the anterior thoracic wall, is an irregular quadrangle. Its *right border* (**6**.41,42) corresponds to a line from the right third costal cartilage's superior border, 1.2 cm from the right sternal margin, to the sixth costal cartilage, convex to the right and maximally distant from the midline (about 3–4 cm) in the fourth intercostal space; it represents the right atrium's lateral profile. Upward continuation of this line marks the right border of the superior vena cava and downward that of the inferior vena cava. The *lower border* of the surface projection is a line joining the right border's lower end to the apex beat; it passes over the xiphisternal joint, corresponding largely to the lower (acute) margin of the right ventricle but includes the apical part of the left ventricle. The *left border* is marked by a line from the apex beat to the lower border of the left second costal cartilage 1.2 cm from the sternal margin; it is convex upwards and to the left, corresponding to the obtuse margin of the left ventricle and left auricle above. The surface projection is completed by a sloping line joining the upper ends of the right and left borders, approximating to the upper atrial limits. Left and right borders can be identified by heavy percussion. The surface projection of the anterior part of the *coronary sulcus* is an oblique line joining the sternal ends of the third left and sixth right costal cartilages. This line separates the atrial and ventricular areas; also, although in different planes, the projections of the cardiac valves are sited along this line or are near it. (They are *not* the preferred areas for auscultation.)

The *pulmonary orifice* is partly behind the left third costal cartilage's superior border, partly behind the sternum, represented by a horizontal line, 2.5 cm long; parallel lines from the ends of this, up to the left second costal cartilage, indicate the *pulmonary trunk*.

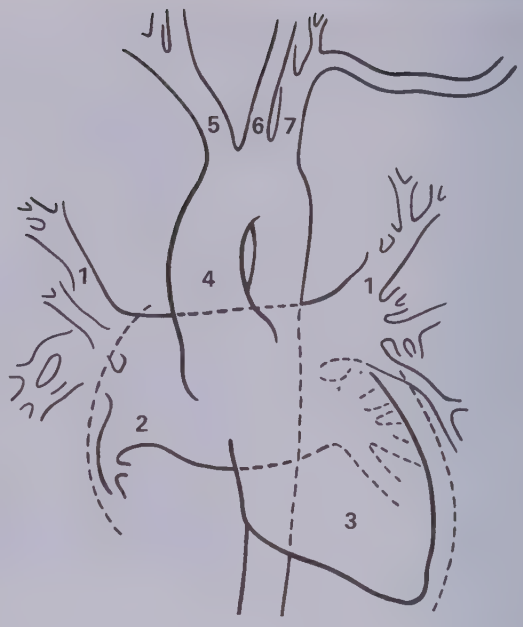
The *aortic orifice* is below and a little right of the pulmonary, marked by a line 2.5 cm long, from the medial end of the left third intercostal space downward to the right; two parallel lines from the ends of this line, slanting up to the right half of the sternal angle, outline the *ascending aorta*.

The *right atrioventricular orifice* is represented by a line, 4 cm long, commencing medially on the fourth right costal cartilage and passing down and slightly to the right; the centre of this should be midway in the right fourth space. The *left atrioventricular orifice* is behind the left half of the sternum opposite the fourth left costal cartilage, represented by a line, 3 cm long, descending to the right.



The *area of superficial cardiac dullness* is roughly triangular, as mapped out by light percussion, and corresponds to the cardiac area not covered by the lung (**8**.28A).

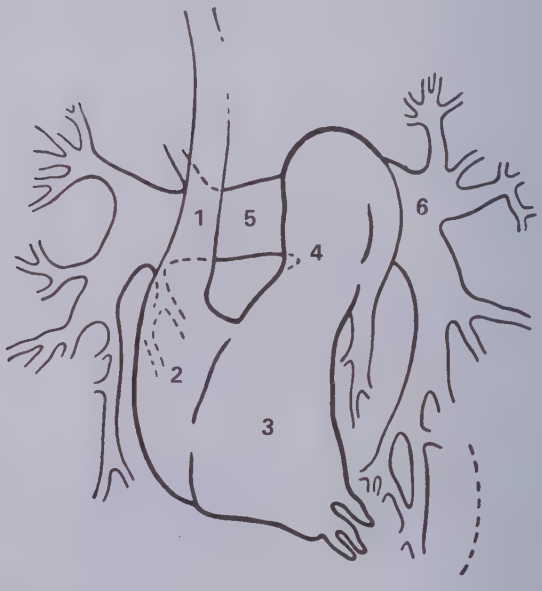
6.42 Diagram illustrating the relation of the sternocostal surface and valves of the heart to the thoracic cage. The right heart is blue, the arrow denoting the inflow and outflow channels of the right ventricle; the left heart is treated similarly in red. The positions, planes and relative sizes of the cardiac valves are shown. The position of the letters, A, P, T and M indicate the aortic, pulmonary, tricuspid and mitral *auscultation* areas of clinical practice.



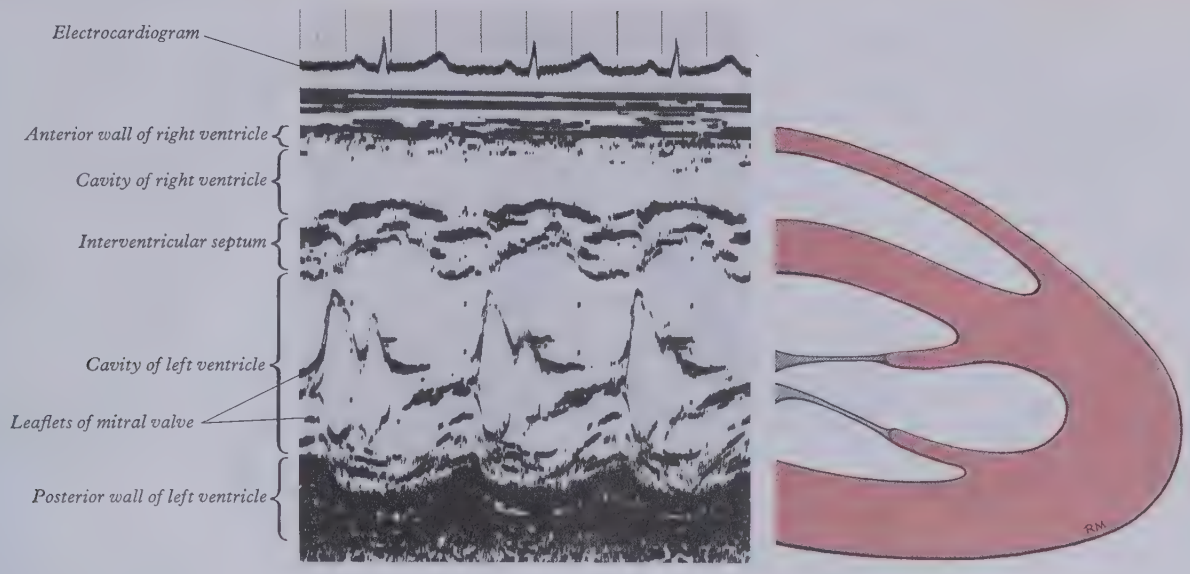
CARDIAC RADIOLOGICAL APPEARANCES (**6**.43,44,45)

The heart, being full of blood, casts a shadow, occupying the inferior mediastinum, in sharp contrast to areas occupied by air-filled lungs. Pulsation of this shadow is obvious. In full inspiration the apex is clear of the diaphragm, presenting a blurred outline in radiographs due to movement. The right border's shadow is continuous with those of the venae cavae. Due to the attachment of the pericardium to the diaphragm, the heart elongates during inspiration, shortening during expiration. The cardiac shape also varies with stature and attitude (p. 1335). In lateral radiographs the *retrocardiac space* is a translucent area between the heart and the vertebral column, occupied by the descending aorta and oesophagus (**8**. 105). For detailed study of the cavities and larger vessels angiocardiography is used (Robb & Steinberg 1939, Gardner 1949). A suitable intravenous contrast medium miscible with blood is followed in serial X-ray esposures, usually in anteroposterior or oblique views (**6**.44,45). Computerized radiography and echocardiography are routinely applied to the heart (e.g. **6**.46).

6.43 Radiograph of chest, postero-anterior view, of adult male. Note the difference in level of the right and left halves of the diaphragm. Supplied by Shaun Gallagher, Guy's Hospital.



6.44 Angiocardiogram (provided by Frances Gardner), showing the left side of the heart in a child of 11 years: anteroposterior view. 1. Upper pulmonary vein. 2. Left atrium. (Note that owing to the great obliquity of the atrial septum, the left atrium extends to the right behind the right atrium.) 3. Left ventricle. 4. Ascending aorta. 5. Brachiocephalic trunk. 6. Left common carotid artery. 7. Left subclavian artery. (The arms of the patient are raised above the head and as a result the distal end of the artery passes upwards.)



6.45 Angiocardiogram (provided by Frances Gardner), showing the right side of the heart in a child of 12 years; anteroposterior view. 1. Superior vena cava. 2. Right atrium. 3. Right ventricle. 4. Pulmonary trunk. 5. Right pulmonary artery. 6. Left pulmonary artery.

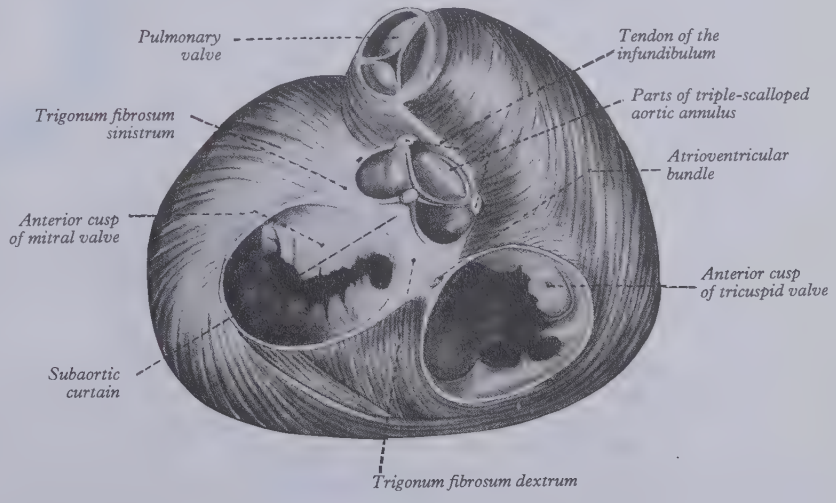
CARDIAC CONNECTIVE TISSUES AND FIBROUS SKELETON (6.47,48)

From epicardium to endocardium and from the orifices of the great veins to the roots of the arterial trunks, intercellular spaces between contractile and conducting elements are everywhere permeated by connective tissue, varying greatly in arrangement and texture in different locations.

Beneath the mesothelium of the serous visceral epicardium over much of the heart is a fine layer of areolar tissue; this accumulates adipose cells, *subepicardial fat*, variable in quantity but increasing with age, concentrated along the acute margin, coronary sulcus, interventricular grooves and their side channels. The coronary vessels and main branches are embedded in this. Endocardium also lies on a fine areolar tissue rich in elastic fibres. Fibrocellular components of these subepicardial and subendocardial layers blend on their mural aspects with the endomysial and perimysial connective tissue of the myocardium. Each cardiac myocyte is invested by delicate endomysium of fine reticulin, collagen and elastin fibres embedded in ground substance, absent only at desmosomal and gap junctional contacts of intercalated discs (p. 557). Similar arrangements apply to Purkinje myocytes and their extensive

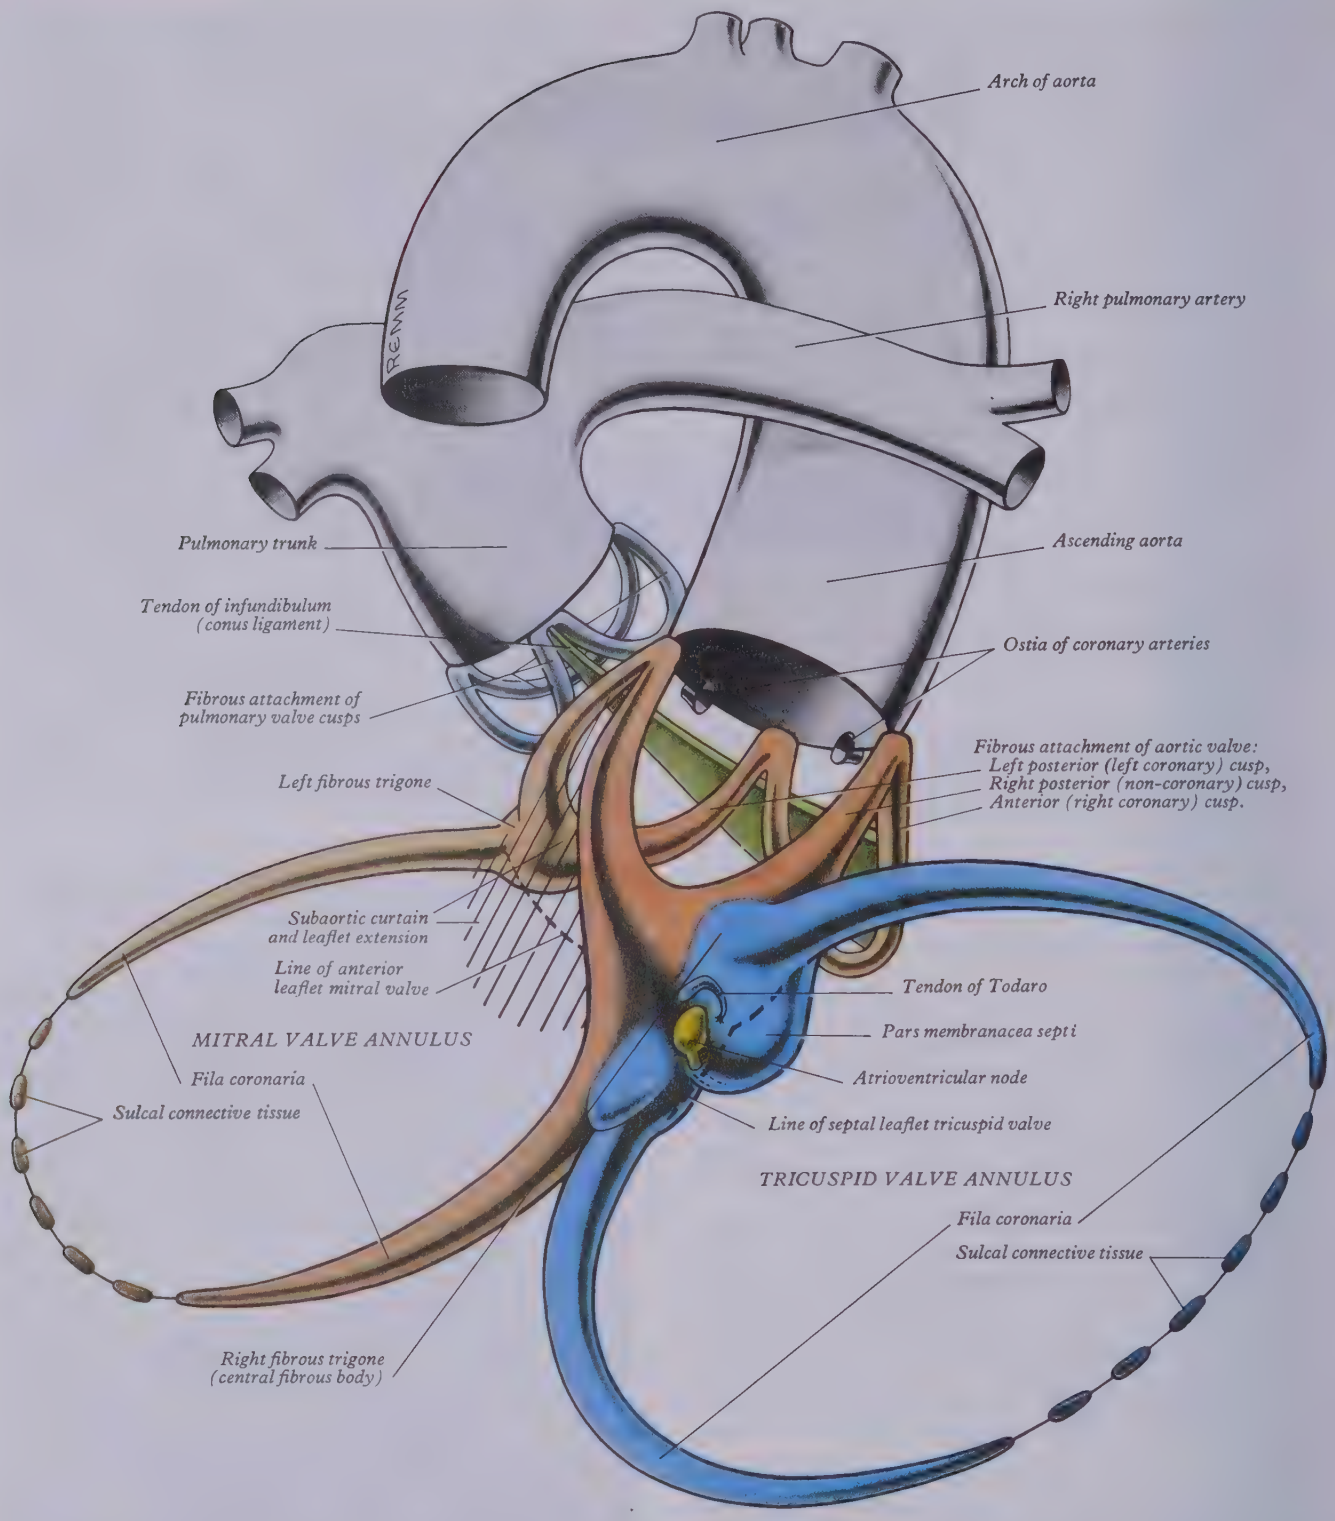
6.46 A standard echocardiogram of the heart recorded from the anterior aspect, as increasingly used in clinical practice. The outline diagram shows the corresponding reflecting surfaces. Note the biphasic closure of the mitral valve leaflets.

contacts. It is widely held that cardiac myocytes are structurally and functionally polarized, forming tracts interconnected laterally, and that substantial aggregations of these form bundles, strands or sheets of macroscopic proportions showing complex geometric patterning (p. 720). It has also been claimed that these larger myocardial bundles are 'surrounded' or 'separated' by, and perhaps attached to, stronger perimysial condensations. But more detailed research is needed for a comprehensive view of the three-dimensional array of such tracts and aggregations *and* disposition and properties of associated connective tissues.



Approximately coplanar with the coronary sulcus, i.e. at the 'ventricular base', and intimately related to atrioventricular inflow and arterial outflow orifices, is a complex framework of dense collagen with membranous, tendinous and fibro-areolar extensions, the whole sufficiently distinct to be termed the *cardiac fibrous skeleton*. (For early literature consult Wolff 1781, Henle 1876, Mall 1911, Walmsley 1929, Walmsley & Watson 1978, and detailed analyses by Zimmerman 1959, Zimmerman & Bailey 1962, and Zimmerman 1966.)

As already noted the four cardiac valves depart considerably from a single plane, the fibrous skeleton being a complex, deformable *continuum*. A single section near the ventricular base (**6**.47) provides incomplete data, leading some earlier observers to introduce simple two-dimensional terms such as 'trigones' and 'annuli', which are misleading but in such widespread use that they will be retained here; but wherever possible alternative and additional terms will be noted. Though it is difficult to illustrate this three-dimensional array, Figure **6**.48 may clarify its main features.



Mitral and tricuspid annuli are almost coplanar and inclined to face the cardiac apex. The aortic valve faces up, right and slightly forwards; it is anterosuperior to and right of the mitral orifice. Despite such differences these *three* valvar orifices are *intimately interconnected* through their basal collagenous frameworks. The pulmonary valve is remote from the others, anterosuperior and at right angles to the aortic, its only connection being the long, deformable tendon of the conus arteriosus (infundibulum).

Functions of the fibrous skeleton are: (1) to ensure electrophysiological discontinuity between the atrial and ventricular myocardium except via conducting tissue; (2) as a mechanical attachment for ventricular myocardium and more tenuously for atrial myocardium; (3) to maintain the cardiac position within the pericardium; (4) to establish a stable but deformable base for the attachments of the valvular fibrous cores.

The aortic annulus is central, interconnected with all surrounding fibrous structures; the aortic root always contains a high-pressure column of blood and is exposed to incessant impacts of the full ejection pressure of the left ventricle in each cardiac cycle which, as Mall said, without such strong intermediaries would tear the arterial trunk from the ventricle. The *aortic fibrous annulus* has already been briefly described (p. 711); it is the coaptation of three almost semicircular fibrous scallops (or crenations) like a three-pronged 'coronet'. Illustration **6**.48 shows that each scallop has two lateral 'high points' or zeniths and a central nadir, each with its own specialization. The *distal margin* of each scallop merges with the fibro-elastic wall of an aortic sinus; some myocardial strands may intermix with the fibro-elastic tissue; near the annulus collagen predominates but is distally replaced by increasing quantities of lamellated elastic tissue. The *luminal aspect* of each scallop blends with the lamina fibrosa of a cusp (or valvule). Adjacent *high points* meet and fuse, with some exchange of collagen fasciculi at the three *intercuspid commissures*. The latter do *not* reach the upper limit of the sinuses, which is marked by a circumferential thickening of the aortic wall, the *supravalvar ridge* (**6**.34). Between the commissures the walls of sinuses are quite elastic, allowing the commissures to retreat from each other, with

6.47 The base of the ventricles, after removal of the atria and the pericardium. Contrast the planes and positions of aortic and pulmonary valves. (From Walmsley 1929.) Contrast with **6**.48.

6.48 Principal elements of the fibrous skeleton of the heart: red = mitral and aortic 'annuli', blue = tricuspid and pulmonary 'annuli', green = tendon of the infundibulum. For clarity the view is from the *right posterosuperior aspect*. Note that due to perspective the pulmonary annulus *appears* smaller than the aortic annulus, whereas in fact the reverse obtains. Based in part on the work of Zimmerman & Bailey (1962) and Zimmerman (1966). Consult text for an extended discussion.

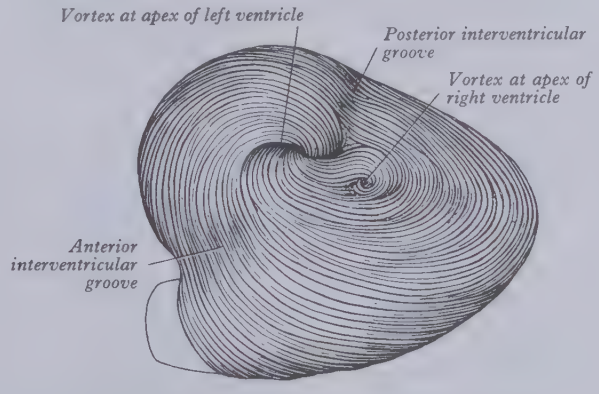
concomitant changes in cuspal shape and disposition in systolic valvar opening, and the converse in diastolic closure. The *nadirs* of the three scallops show collagenous thickenings to very different degrees. Least prominent is that of the anterior (right coronary) cusp, but its margins blend with the aortic end of the infundibular tendon (vide infra). The left posterior (left coronary) cusp's nadir is thickened to an intermediate extent; due its appearance in section in the plane of the atrioventricular valves, it is termed the *left fibrous trigone*. It is an attachment for part of the anterior mitral leaflet; posterolaterally and left it continues as one of the mitral, tapering, collagenous bundles (*fila coronaria* of Henle) which partially encircle the atrioventricular orifices. The nadir of the right posterior (non-coronary) scallop is the most massively developed; from its appearance in section earlier anatomists termed it the *right fibrous trigone*. In adult hearts it is a dense irregularly ellipsoidal mass of about 20 × 10 × 5 mm, which provides powerful structural and functional links between aortic, mitral and tricuspid orifices; in accord with its site and

multiple circumvalvar extensions, it is now often termed the heart's *central fibrous body*. It continues into the second mitral filum coronarium, providing a base for both tricuspid fila coronaria. Anteriorly the central body blends with the *pars membranacea septi* (vide infra); posterosuperiorly the *tendon of Todaro*, a palpable subendocardial bundle of collagen about 1 mm in diameter, extends into the right atrial wall, curving across the *torus aorticus* (p. 703) towards the medial end of the inferior caval valve, where its identity is lost. The tendon is one of the boundaries of the *triangle of Koch* (p. 703, **6**.34) and provides an important surgical guide to the atrio-ventricular node.

The *proximal* (ventricular) *aspect* of the triple scalloped fibrous condensation, constituting the aortic annulus, has three almost triangular areas, the *subaortic spans* (Zimmerman 1959, Zimmerman & Bailey 1962). The spans, originally termed *spatia intervalvularia* by Henle (1876), occupy intervals *between* adjacent aortic sinuses; their triangular apices correspond to intercuspid commissures; their walls variously consist of collagen or admixed muscle strands and fibro-elastic tissue; they surround the *subvalvular recesses* of the aortic vestibule. The interval between right (non-coronary) and left (left coronary) posterior sinuses is filled with the deformable *subaortic curtain (intervalvar septum)*, which continues into the base of the central part of the anterior mitral leaflet; down to the latter's base it has a thin covering of left atrial myocardium. Its critical functional role as an *aortic baffle*, between inflow and outflow tracts of the left ventricle, is noted on p. 709. The span between right posterior (non-coronary) and anterior (right coronary) sinuses is continuous with the anterior surface of the right fibrous trigone; it is a variably developed collagenous sheet, the *pars membranacea septi*. This is an oval area of about 1 cm from the aortic annulus to the muscular interventricular septum, about 1.2 cm anteroposteriorly and is normally about 1 mm in thickness. As far posteriorly as the angled attachment of the anteroseptal tricuspid commissure (p. 706), the pars membranacea separates the right and left *ventricles*, whereas posterior to the commissure it separates the left ventricle and right atrium (*atrioventricular septum*). After traversing the right fibrous trigone, the atrioventricular bundle of conducting tissue courses along the postero-inferior margin of the membranous septum to reach the muscular interventricular septum, where it divides into its initial bundles. This cardiac region has a complex developmental history related to the final stages of septation (p. 209) and is a very common site of congenital anomalies (p. 725). Since it lies at the heart's centre, interconnecting the aortic, mitral and tricuspid valves and the right and left ventricles and right atrium, and since it is so intimately related to the atrioventricular bundle and also frequently subject to maldevelopment, the membranous septum is of prime interest in cardiac investigation and surgery.

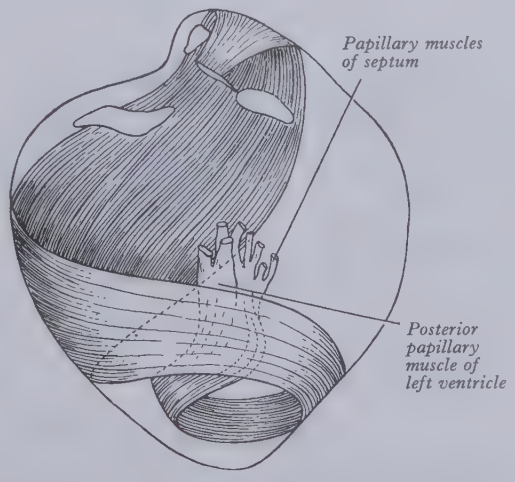
The third subaortic span, namely that between the anterior (right coronary) and left posterior (left coronary) aortic sinuses, is filled with fibro-elastic tissue blending along its anterior cuspal margin with the *infundibular tendon*; the rest of it is covered by the left ventricular myocardium.

The *pulmonary fibrous 'annulus'*, anterosuperior and almost at right angles to the aortic annulus, is similar in general construction; though of greater diameter, it is considerably less robust. It is triple-scalloped, with commissures at intercuspid apices and barely perceptible thickenings at the nadirs of scallops. The subvalvular spans are filled with fibro-elastic tissue, well-supported by interlacing myocardial extensions from the muscular infundibular wall. The *apex* of the subvalvular span nearest to the aorta becomes confluent with the pulmonary end of the infundibular tendon. Zimmerman & Bailey (1962) suggested that the tendon is a powerful bond between the two arterial trunks and that it 'permits a certain degree of torsional movement between them, while preventing them from being torn asunder by the differently directed ejaculatory forces of the ventricles'.



The *mitral* and *tricuspid annuli* have already been described (pp. 709, 705), but it is re-emphasized here that they are not simple, rigid, collagenous rings but dynamic, deformable lines of valvular attachment that vary greatly at different peripheral points and change considerably with each phase of the cardiac cycle and with increasing age.

MYOCARDIAL ARCHITECTURE



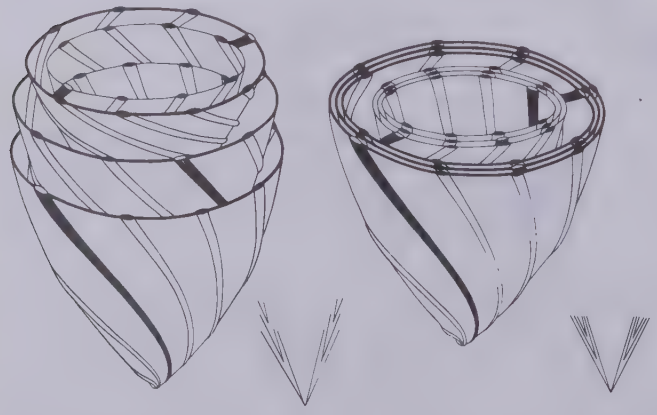
It has long been held that cardiac walls consist of 'fibres' transversely and longitudinally striated (p. 557) and intricately intermingled. They can be classed as (1) atrial, (2) ventricular, and (3) conducting fibres (p. 715). Atrial and ventricular muscle fibres are completely separated by the fibrous annuli, the only connection being via conducting fibres (p. 720). In modern terminology such fibres are presumed to consist of polarized rows, bundles or other aggregations of cardiac myocytes with their connective tissues (p. 557, and below.)

Atrial fibres form two layers: superficial, common to both atria, and deep, proper to each. *Superficial fibres* are most distinct anterior to the atria, crossing their bases transversely as a thin, incomplete layer; some pass into the atrial septum. *Deep fibres* are *looped* and *annular*, the former passing over each atrium to its corresponding atrioventricular annulus, in front and behind, while annular fibres surround their auricles and encircle the vena caval openings and fossa ovalis.

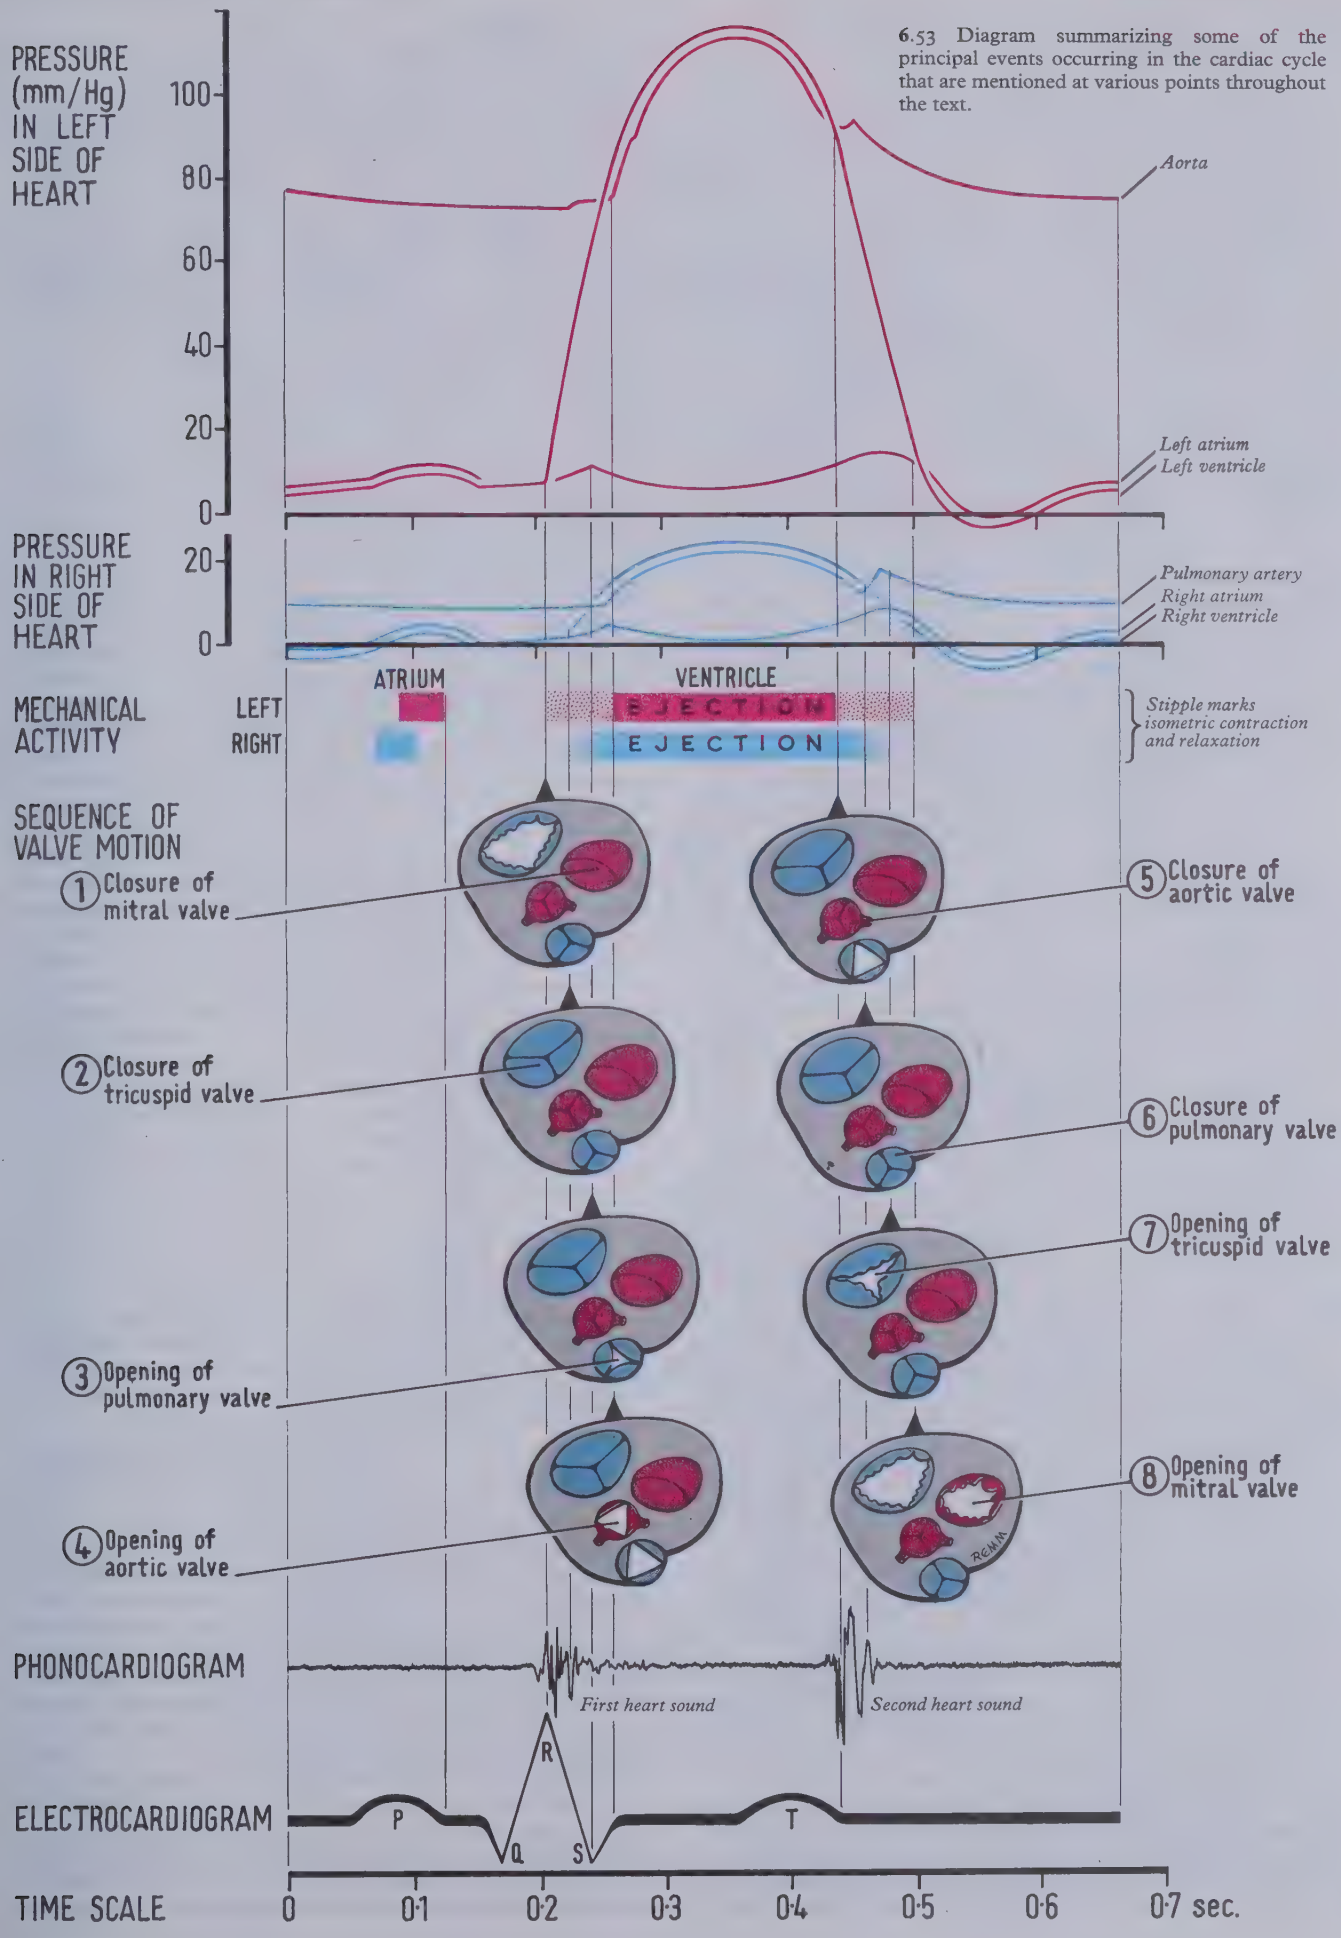
Ventricular fibres are complex and few descriptions since those of MacCallum (1897) and Mall (1911,1912) have been available until recently (vide infra). Superficial and deep layers exist, all but two bands of the latter entering papillary muscles. In the infundibulum superficial fibres are transverse to its long axis and deep fibres are axial; hence, vertical incisions may be preferable. *Superficial ventricular layers* include the following: (1) Fibres from the infundibular tendon (**6**.48,50) curve across the diaphragmatic surface, sweeping left across the anterior interventricular sulcus to form a vortex at the apex (**6**.49), finally ascending into the left ventricular papillary muscles. From the anterior half of the tendon fibres pass to both anterior and posterior papillary muscles, those from its posterior half only to the anterior muscle. (2) Fibres

6.49 The two vortices in the myocardium at the apex of the heart (after Mall).

6.50 The superficial muscular fibres of the ventricles of the heart originating in the tendon of the infundibulum (after MacCallum).



6.51 The arrangement of the deep layers of the muscular fibres of the ventricles, as seen in cross-section (after MacCallum).



from the *right* atrioventricular annulus, which cross the diaphragmatic surface of the right ventricle, reach its sternocostal surface, passing under the fibres just described across the *anterior* interventricular sulcus to wind round the apex, ending in the left ventricular posterior papillary muscle.

(3) Fibres from the *left* atrioventricular annulus cross the *posterior* interventricular sulcus to the right ventricle, ending in its papillary muscles. Three *deep ventricular* layers start in the papillary muscles of one ventricle and curve sinuously into the anterior interventricular groove to end in the papillary muscles of the other (6.51), the most superficial in the right ventricle is deepest in the left, and vice versa. The first layer almost encircles the right ventricle, crosses left in the septum, uniting with the superficial fibres from the right annulus to form the posterior papillary muscle; the second layer is less extensive in the right ventricle but greater in the left, joining the superficial fibres from the anterior half of the infundibular tendon to form the septal papillary muscles. The third layer almost encircles the left ventricle, joining the superficial fibres from the posterior half of the tendon to form the anterior papillary muscle. These deep layers are held to synchronize ventricular systole with atrioventricular closure. Two non-papillary bands are also described: one, from the *right* annulus crosses the septum (p. 703), encircles the deep left ventricular layers, to end in the *left* annulus; the second is confined to the left ventricle, passing from the *left* atrioventricular annulus to encircle the aortic orifice (Mall 1911, 1912). Fibres from both left ventricle and atrium also reach the aorta, close to its annulus and cusps. These are said to rotate the aortic base in the general twist of systole.

This account broadly agrees with views of most workers, MacCallum (1900) and Mall (1911) being most quoted. However, concepts of spiralling laminae, overlapping at differing angles in ventricular walls, the existence of apical ventricular vortices through which superficial fascicles spiral inwards—these and other details were all early described by Lower (1669), Borelli (1681), von Haller (1764), Gerdy (1823) and Pettigrew (1864). All these, like their successors, used blunt dissection of hearts which had been boiled (sometimes even roasted!), with varying concentrations of acetic or nitric acid. It is important to realize that, while such maceration of myocardial tissue is assumed to involve principally a change in endomysial connective tissue, the branching of cardiac myocytes entails that a multitude of minute tears of *muscle* occurs during such blunt dissection. Tears *across* tracts of myocytes may therefore be as likely as *along* them; but from Lower to the most recent exponent, Torrent Guasp (1970), all who have used the technique appear to be confident they could trace predominant orientation of a layer or fascicle throughout its supposed extent. MacCallum's *tour de force* was the 'unrolling' of ventricular muscle of a fetal pig's heart; his short study, accomplished in three weeks, included no human hearts; this aspect was extended by Mall after the former's premature demise. In his extensive investigation Mall (1911) emphasized the helical spread of superficial fibres after plunging deep into ventricular walls. In the porcine heart he described deep fibres which were illustrated like ropes encircling each ventricle; he thought these capable of twisting compression, producing a kind of *wringing* action, as suggested long before by Borelli (1681). Others have used the analogy of ropes in descriptions and particularly Torrent Guasp, whose extensive studies of human, bovine and other vertebrate hearts are somewhat inaccessible, being privately published monographs (1959, 1970). It is at this level of detail that many accounts become difficult to comprehend, as noted by Robb (1934) and Thomas (1957). Robb's brief survey emphasized the difficulty of equating alternative descriptions, except in most general statements. Even in major details there are difficult contradictions. Thomas (1957), who dissected canine and porcine hearts (in one of the few detailed studies of *atrial* musculature), states that all myocardial tracts begin and end by attachment to atrioventricular annuli, except those entering papillary muscles. This is the usual view but denied by Pettigrew (1864), who considered myocardial 'fibres' continuous, a view, with certain differences, also inherent in descriptions by Torrent Guasp (1970) of continuous arrangements of helical bands, which turn like 'figures of eight' in encircling both ventricles, an analogy used by Lower (1669). Pettigrew (1864) proposed a complex seven-layered structure, whereas most are content with a thin superficial layer, an irregular internal one concerned in formation of trabeculae and papillary muscles, and a thick intermediate layer, partly interventricular. Potential artificiality inherent in myocardial unravelling was admitted by Mall (1911), who stated that 'fasciculi and sheets are never fully separated from adjacent fasciculi and sheets'. Torrent Guasp (personal communication, 1978) also admits that the number of dissectable strata is indefinable. However, he has contributed perhaps the most complicated account of myocardial arrangement in mammals, including mankind. Details cannot be included here, but equation of such elaborate architecture with the mechanics of cardiac contraction and conducting pathways is of great interest. Unfortunately, comprehensible harmony between architecture and dynamics of cardiac activity has not been achieved, except in the crudest terms. However, a recent account of myocardial architectonics (Streeter 1979, 1980) confirms the work of Torrent Guasp in major details. Streeter's own approach is a mathematical analysis of the angular orientation between myocardial 'fibres' at different depths in the ventricular wall. He finds his results much in accord with Torrent Guasp's concept of 'nested' spiral laminae (6.52), perhaps foreshadowed by Krehl in 1891. The most up-to-date reviews are in a Symposium on the *Structure and Mechanics of the Heart* (1987) edited by Torrent Guasp and containing articles and bibliographies by eight contributors. Although all these efforts have not yet established the *total* arrangement of the myocardium, there is perhaps already enough to satisfy physiological concepts. The accepted existence of 'fibre-pathways' of obliquity, varying from circular to almost longitudinal, provides at least the powers to decrease ventricular cavities in all dimensions; passage of obliquely helical bands into papillary muscles also provides an integration between atrioventricular valves and cyclical changes in longitudinal ventricular dimensions. Some problems require further investigation, such as the 'attachment' of the ventricular myocardium to the misnamed atrioventricular annuli of the cardiac fibrous skeleton (p. 717).

6.52 Diagrammatic representation of one concept of the arrangement of ventricular myocardial 'fibre bundles', from the work of Torrent Guasp (1970).

6.53 Diagram summarizing some of the principal events occurring in the cardiac cycle that are mentioned at various points throughout the text.

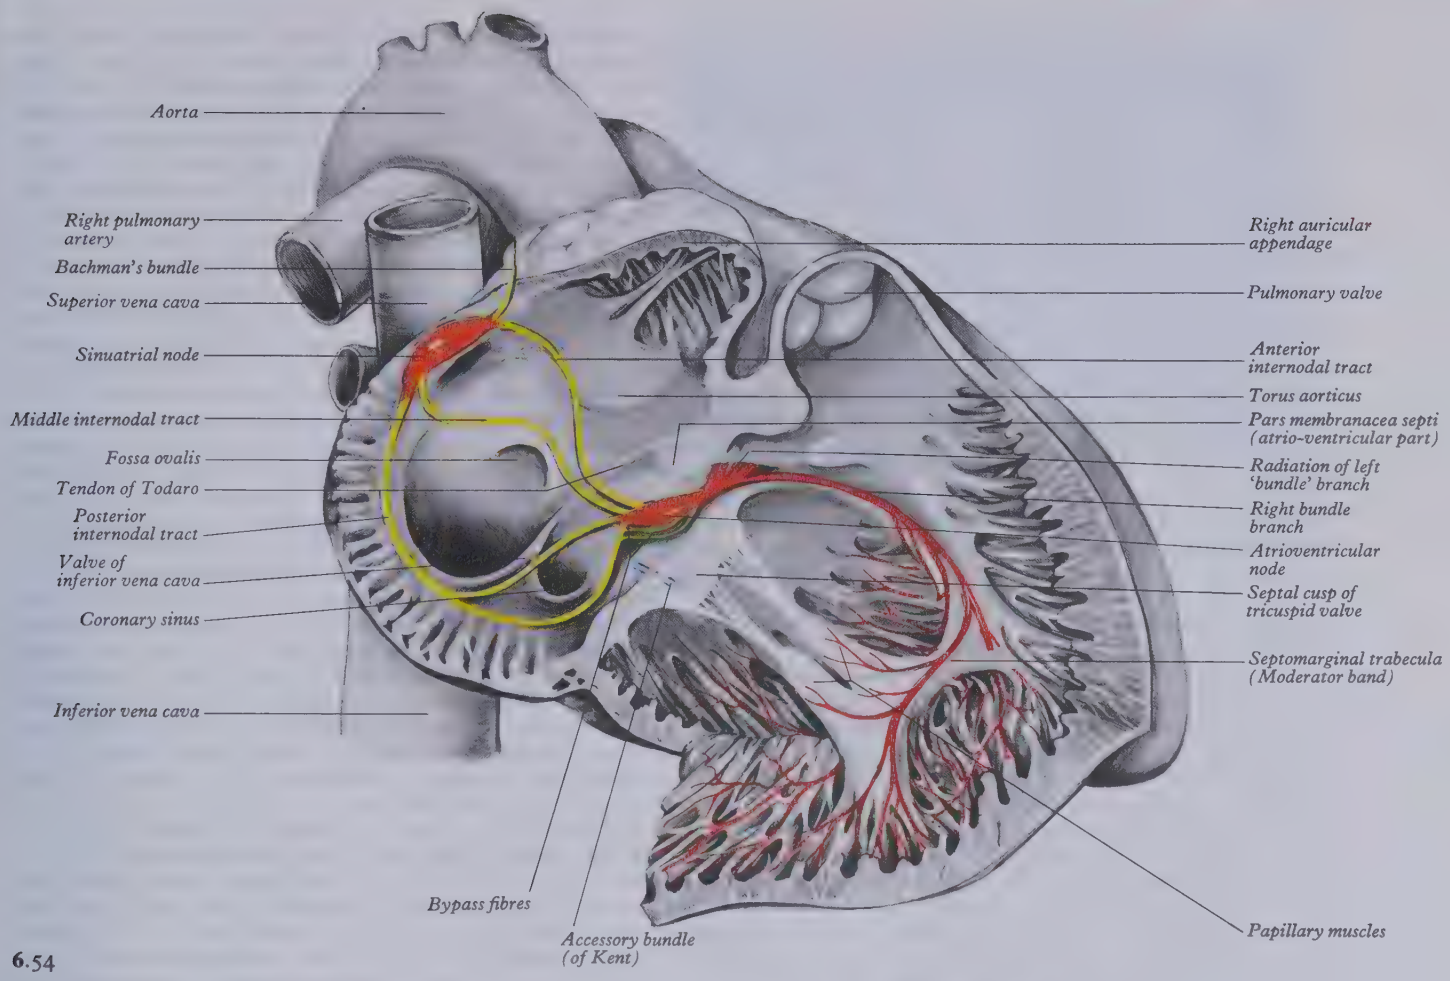
COORDINATION OF CARDIAC ACTIVITIES: THE CONDUCTING SYSTEM

The human heart beats ceaselessly at about 60–100 or more cycles every minute for many decades, maintaining perfusion of pulmonary and systemic tissues, the most critical being the cerebral tissues where even transient failure may lead to irreversible changes. The actual rate and 'stroke volume', of course, fluctuate in accord with prevailing physiological demands.

The contrasting roles of 'right' and 'left' hearts, the topography of cardiac chambers, construction and action of valves, the main elements of the fibrous skeleton and of general myocardial architecture have all been examined. The principal events in a cardiac cycle, including the electrocardiogram, mechanical sequences of diastole, atrial systole, isovolumetric contraction, ejection and isovolumetric relaxation in ventricular systole, the main elements of phonocardiogram, pressure profiles of right and left hearts and arterial trunks and the sequences of valvar events are summarized in Figure **6**.53; their study belongs elsewhere but a brief survey of structural elements involved in the cardiac cycle, with some indication of controversial features, must be added. Cardiac *efficiency* basically depends on precise timing of the operation in interdependent structures. Passive diastolic filling of the atria and ventricles is followed by atrial systole to complete ventricular filling. Excitation and contraction of the atria must be synchronous and complete before ventricular contraction; this is effected by an *atrioventricular conduction delay*. Further, ventricular contraction proceeds in a precise manner; structures exist to ensure that closure of atrioventricular valves is followed rapidly by waves of excitation and contraction spreading from the ventricular apices towards the outflow tracts and orifices, rapidly accelerating the blood during ejection.

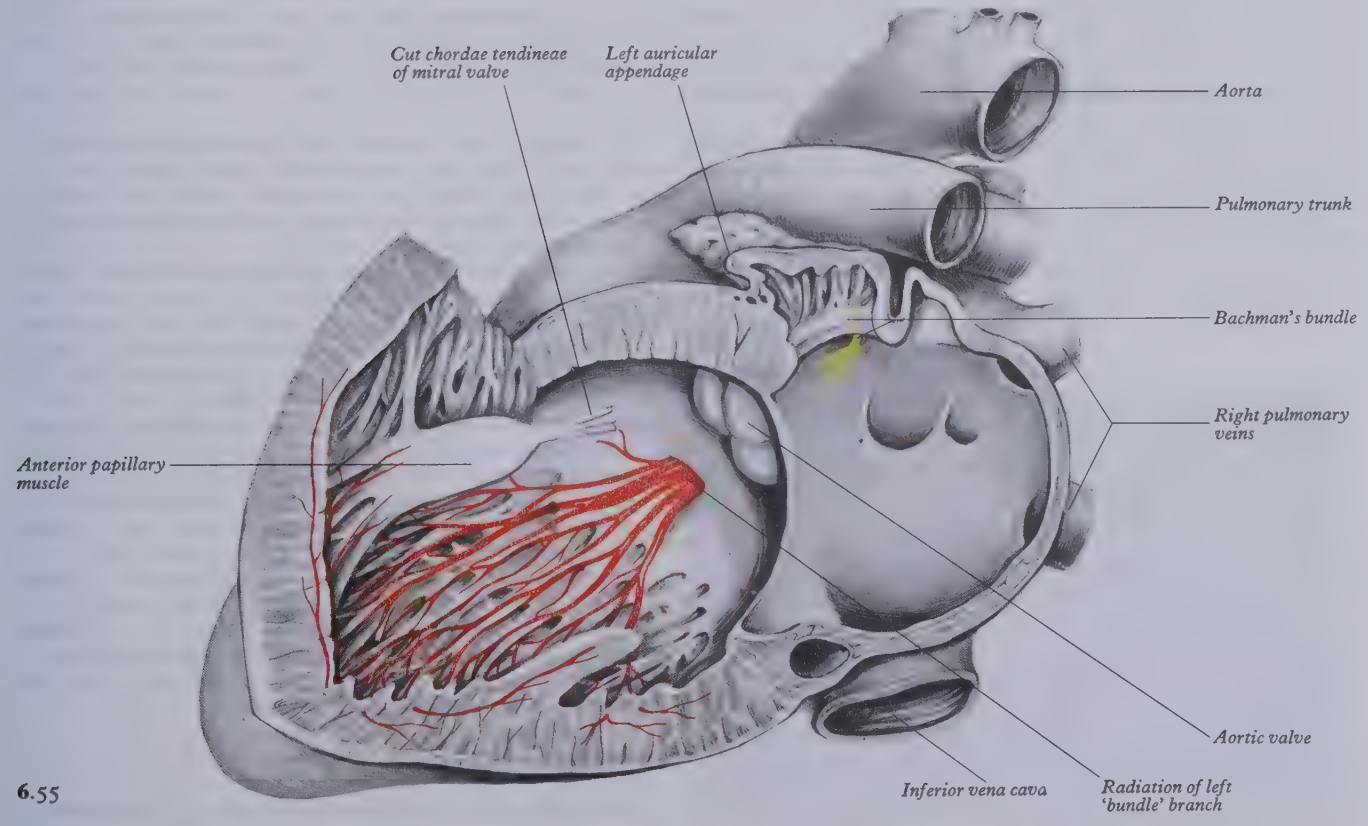
Vertebrate cardiac contraction is accepted as *myogenic*, originating in the myocytes, the neural influences merely adapting intrinsic rhythm to functional demands. *All* cardiac myocytes (p. 557) are excitable, with autonomous rhythmic depolarization and repolarization of cell membranes, conduction of waves of depolarization via gap junctions to adjacent myocytes and excitation-contraction coupling to their actomyosin complexes (p. 561). But these properties are developed to different degrees in different sites and in different types of myocyte. The *rate* of depolarization and repolarization is slowest in the ventricular myocardium, intermediate in the atrial, fastest in the sinuatrial nodal myocytes derived from the sinus venosus. The latter override those of slower rhythm and, in the normal heart, are the locus for the rhythmic initiation of cardiac cycles. Conversely, conduction *velocity* is slow in nodal and transitional myocytes, intermediate in general 'working' cardiac myocytes, and fastest in Purkinje myocytes.

The nodes, tracts and networks of these cell types (nodal, transitional and Purkinje myocytes) constitute the cardiac *conducting system* or *specialized conducting tissues*. While agreement on their main features is general, their cellular makeup and the existence of other elements remain debatable. Accepted parts are the sinuatrial node, atrioventricular node, common atrioventricular bundle, left and right bundle branches or *crura* and the subendocardial plexus of Purkinje 'fibres'. Advocated by some, rejected by others, are the interatrial and internodal tracts of conducting tissue, atrioventricular 'bypass' fibres and accessory atrioventricular bundles. These constituents are illustrated in Figures **6**.54,55. For reviews of the cardiac cycle consult Rushmer (1976) and Schlant (1978); comprehensive, sometimes controversial accounts of the cardiac conducting system are found in Hudson (1965), Anderson (1974, 1975, 1980), James (1978), James & Scherf (1978).



The sinuatrial node of Keith & Flack (1907), the cardiac 'pacemaker', is generally considered to initiate (in some of its cells) excitation of each cardiac cycle. It is at the junction between parts of the right atrium derived from embryonic sinus venosus and primitive atrium. Central histological features of the node are distinctive but at its periphery are less obvious, doubtless accounting for disagreements on its dimensions, shape and limits. Contrary to earlier views nodal tissue does not fill the full thickness of the right atrial wall from epicardium to endocardium but in most of its extent is about 1 mm from the epicardium and rather more from the endocardium. It is often covered by a plaque of subepicardial fat. It is elongated, extending on the right from the groove between the right atrial appendage and anterolateral aspect of the terminal superior vena cava, continuing postero-inferiorly into the upper part of the crista terminalis. Variously described as a flattened ellipsoid 'Indian war club', with a 'head, body and tail', it is generally considered to be about 10–20 mm in length and about 1 mm thick and 3 mm wide at its maximal lateral convexity.

In referring to structure of conducting tissues, the classification of cardiac cells proposed by James and co-workers (James 1978) will be followed (p. 557). This was based on abundant macroscopic and microscopic observations, but not all authorities recognize his full range of cardiac myocytes as present in all sites.



A main feature of the sinuatrial node is its central *artery of the sinuatrial node*; it has a surprisingly large calibre and is variable in origin (p. 730). Its tunica adventitia merges into a dense collagenous reticulum, firm to palpation, which permeates the node and surrounds its myocytes. Its small lateral branches supplying nodal tissue are few, the vessel continuing beyond the node to ramify in the atrial myocardium. Its enlarged adventitia serves a sensory function, responding to aortic pressure and pulsation, as part of a feedback stabilizing the appropriate sinus rhythm; pharmacological studies support this view. The nodal myocytes have long been described as 'primitive' cardiac cells, slender and fusiform or branched, typically pale-staining; most earlier observers considered them to make contacts *directly* with the atrial myocytes at nodal margins. James distinguishes the following in the nodal complex and its vicinity: (1) round, polygonal, fusiform or stellate *nodal myocytes* (pale-staining or P cells), (2) a heterogeneous and more complex group of short, slender *transitional myocytes*, (3) *Purkinje myocytes* and (4) atrial contractile *cardiac myocytes*.

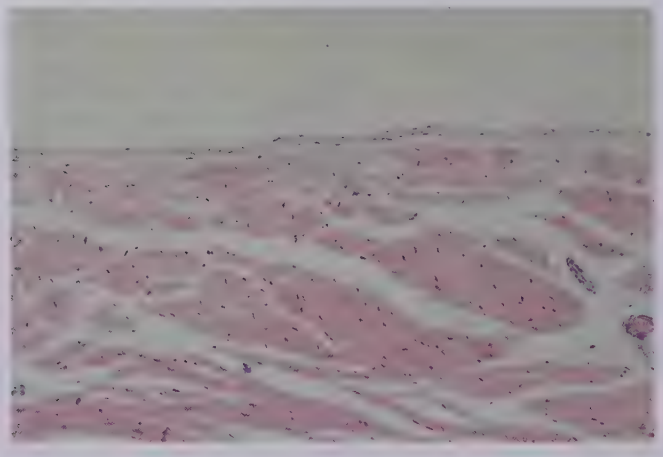
Nodal myocytes are confined to the nodal centre, circumferentially arranged around the nodal artery and more irregularly external to this. These cells are now considered 'pacemaker'; they make functional contacts with each other and adjacent transitional myocytes, which are much smaller than the general myocardial cells, their internal organization varying from a simple almost organelle-free type (as in the P cell) to one with a well-developed contractile system and complex sarcoplasmic reticulum; they are slow-conducting and interposed between P cells and either general myocardial or Purkinje myocytes. The latter, shorter and wider than general myocardial myocytes (p. 557), may have a rapid conduction velocity; in human and small mammalian hearts in general they are not markedly wider than general myocytes (contrasting with prominent Purkinje myocytes in larger ungulates). Therefore, some consider Purkinje myocytes absent from the atrial walls, reserving the term for more distal parts of the ventricular conducting system. James, however, considers Purkinje myocytes numerous around all nodal margins, extending also into the interatrial and internodal tracts (vide infra); according to him excitation of atrial myocardium follows this sequence: pacemaker activity of nodal myocytes, slow conduction along transitional myocytes, fast conduction along Purkinje myocytes, spreading excitation-contraction between general atrial myocytes.

The atrioventricular node (Tawara 1906) is oval or elliptical, its long (anteroposterior) axis about 7–8 mm, vertical 3mm, transverse 1 mm. It is under the right atrial septal endocardium in the triangle of Koch (p. 703), dorsal to the basal attachment of the tricuspid septal leaflet, 1 cm or less above the septal margin of the orifice of the coronary sinus and encircled by the subendocardial tendon of Todaro. Its atrial aspect is convex, its left concave, abutting on the base of the mitral annulus. Its dorsal end projects into the septum and narrows into the *nodal crest*; its antero-inferior end, close to the central fibrous body, becomes the common atrioventricular bundle. The node is pervaded by an irregular collagenous reticulum enmeshing myocytes, but this is less dense than in the sinuatrial node. Its arterial supply is noted on p. 730. *Nodal myocytes* are relatively few and confined to the deeper parts, particulary near the central fibrous body; the main population is of *transitional myocytes*, irregularly arranged in the dorsal part but increasingly arrayed in longitudinal tracts extending to the atrioventricular bundle. All nodal surfaces are said to be covered by Purkinje myocytes, which (1) receive fine terminals of internodal

6.54

6.55

6.54, 55 Diagram of the conducting tissues of the heart as seen from the right (**6.54**) and left (**6.55**) aspects. Generally accepted elements are shown in red; accessory atrioventricular paths and 'bypass' bundles in blue. The internodal and interatrial pathways shown in yellow are subject to some controversy. Consult text for further discussion. Note the conducting tissue accompanying fine trabeculae carneae and false chordeae; cf. ventricular bands p. 710 and **6.37B–D**.



conduction paths and 'bypass' fibres (vide infra) and (2) continue as one cellular component of the atrioventricular bundle.

The large population of slow-conducting transitional myocytes in the atrioventricular node is probably responsible for the *atrioventricular conduction delay*.

The atrioventricular bundle (His 1893) is formed by tracts of myocytes converging at the antero-inferior pole of the atrioventricular node. Narrowing rapidly, ensheathed in delicate vascular connective tissue, it becomes transversely oval, quadrangular or triangular as it enters a channel in the central fibrous body (right fibrous trigone, p. 717). Traversing this, it reaches the dorsal edge of the pars membranacea septi, coursing along its postero-inferior margin to the muscular interventricular septal crest. It is commonly described as dividing into *right* and *left branches (crura)*, implying simple bifurcation: but this is misleading. The *right branch (crus dextrum)* continues as a narrow, discrete round group of fascicles at first in myocardium and then subendocardially towards the right ventricular apex, entering the septomarginal trabecula to reach the anterior papillary muscle. In its septal course it has few branches to the ventricular walls, but in the papillary muscle it divides profusely into fine subendocardial fascicles, which diverge and first embrace the right ventricular papillary muscles, then return towards the ventricular base to reach all parts of the ventricular parieties. Fascicles of conducting tissue are also carried by trabeculae carneae and *right ventricular bands* (p. 703). The *left branch (crus sinistrum)* is misnamed, because numerous fine fascicles, separately ensheathed, leave the left margin of the parent bundle through much of its course along the membranous septum; these fascicles form a *flattened sheet* arching over the crest of the muscular interventricular septum. The sheet diverges apically and sub-endocardially across the left aspect of the ventricular septum and soon separates into anterior and posterior sheets to the corresponding papillary muscles. Fine branches leave the sheets, forming subendocardial networks, which first encompass the papillary muscles and then curve back subendocardially to all parts of the ventricle. Mention has already been made (p. 710) of structures that have a free course across the ventricular cavity, connecting terminally with papillary muscles and/or points on the ventricular walls. Named *left ventricular bands*, and sometimes confused with false chordae tendineae, they occur in about 50% of human hearts. Many if not all such bands of fibromuscular tissue contain Purkinje myocytes. Their role in the overall pattern of conduction has yet to be determined (see **6**.37B,C,D.)

The atrioventricular bundle, at its start, contains extensions of *transitional myocytes* from the node, but distally and in its branches and terminal parts, cells increase in diameter, assuming the features of polarized tracts of *Purkinje myocytes* (**6**.56), intermingled are tracts of cells with the ultrastructure of general cardiac myocytes, whose conduction properties are unknown.

Principal branches of the bundle are insulated from the surrounding myocardium by sheaths of connective tissue, the functional contacts between Purkinje myocytes and ventricular myocardium becoming numerous only in the subendocardial terminal reticula. Hence papillary muscles contract first, followed by a wave of excitation and contraction travelling *from* ventricular *apex* to basal outflow tract and orifice; and, because the Purkinje network is subendocardial, ventricular excitation proceeds from the endocardial to the epicardial aspect. Little is known concerning the deployment of Purkinje myocytes in ventricular walls; even their degree of penetration is uncertain.

6.56 Section of conducting, Purkinje fibres in the left ventricular wall. Note the paler, enlarged cells among normal myocytes. Haematoxylin and eosin. Magnification × 500.

Interatrial and internodal conduction paths. It has long been standard teaching in physiological texts that sinuatrial activity *directly* excites general atrial myocytes, with radial spread via the intercellular nexuses to both atria, excitation eventually reaching the atrioventricular node; a further assumption is that the pathways followed merely reflect the complex topography of the atrial walls, in particular the positions of orifices. Indeed, some current texts dismiss any specialized interatrial and internodal conduction pathways (Anderson et al 1974, 1975, Anderson 1975, Rushmer 1976) or consider that such could have no demonstrable physiological role (Marriot & Myerberg 1978).

However, others have postulated such specialized routes (e.g. Wenckeback 1908, Thorel 1909, 1910, Bachmann 1916). Interest re-awakened when it was shown that impulses from the sinuatrial node arrive at the atrioventricular more rapidly than they could have travelled through ordinary myocardium (Hoffman & Cranefield 1960). James (1978), a strong supporter of interatrial and internodal pathways, claims to have shown them by dissection and subsequent microscopy. The following pathways, each an admixture of Purkinje myocytes and ordinary cardiac myocytes, have been described.

The *anterior internodal tract* (including the *interatrial bundle of Bachmann*) leaves the anterior end of the sinu-atrial node, skirts the anterior aspect of the superior caval opening and passes posteromedially to the anterior margin of the interatrial septum. Here it divides, some fibres *penetrating* the septum to diverge in *left* atrial walls (Bachmann's bundle), the others descending across the right side of the septum behind the torus aorticus to divide into terminal fascicles approaching the atrioventricular node (vide infra).

The *middle internodal tract* (of Wenckebach) emerges posterosuperiorly, curving posterior to the superior caval orifice to the interatrial septum and crossing it to splay out near the atrioventricular node.

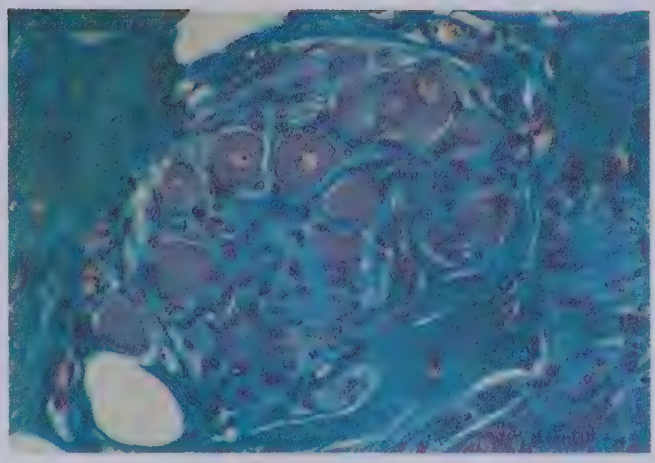
The *posterior internodal tract* (of Thorel) leaves the postero-inferior part of the node, continues through the crista terminalis and valve of the inferior vena cava and proceeds to the posterior margin of the atrioventricular node; its relation to the ostium of the coronary sinus varies.

Fine terminal branches of these internodal tracts are said to enter the atrioventricular node to make functional contact with transitional myocytes at many levels, including its crest, its convex right atrial surface and even the atrioventricular bundle beyond the node. Such radicles could be '*bypass fibres*' circumventing much or all of the node, a possible anatomical basis for a *dual form* of atrioventricular transmission first proposed by Moe et al (1956). It is to be emphasized, however, that mere existence and all details of interatrial and internodal conducting tracts remain controversial.

The existence of **accessory atrioventricular bundles** is often invoked to explain various cardiac arrhythmias. It is a general belief that these may exist near the atrioventricular bundle, or at any point on the circumference of either the mitral or tricuspid 'annuli'. They are generally described as slender, irregular in occurrence and of no functional significance in *normal* cardiac cycles. Their structure is unknown, but current research is directed towards their anatomico-physiological analysis and assessment of applied surgical relevance.

THE CARDIAC NERVE SUPPLY

Initiation of the cardiac cycle may be myogenic or neurogenic in invertebrates; but in vertebrates it is myogenic. In vertebrate hearts, with increasing specialization, initiating foci and conducting tracts have progressively elaborated to integrate the cycle. This *conducting system* has been described (p. 720). The cardiac



cycle is harmonized in rate, force and output by an extrinsic nerve supply, operating on cardiac nodal tissue and its prolongations, on coronary vessels and perhaps cardiac muscle. This supply is autonomic, efferent and afferent. Parasympathetic fibres reach the heart through vagal branches (p. 1116), the sympathetic by rami of the sympathetic trunk (p. 1162). Vagal preganglionic fibres proceed from brainstem origins, particularly the medulla, including the nucleus ambiguus (p. 956), the reticular nuclei (p. 989) and possibly the dorsal vagal nucleus (p. 956). Vagal preganglionic axons leave in the cardiac branches to reach the cardiac plexuses without interruption (see, however, p. 1155). Sympathetic preganglionic neurons are in the lateral grey column of the thoracic spinal cord, in its upper five or six segments (Kuntz 1953). Preganglionic fibres from these sources end in cervical and third and fourth thoracic sympathetic ganglia (Mitchell 1953), from all of which bilateral cardiac nerves of postganglionic fibres proceed to the heart (pp. 1116, 1164). (See also general comments and modern reservations concerning the simplification implicit in the terms pre- and postganglionic, p. 1154.)

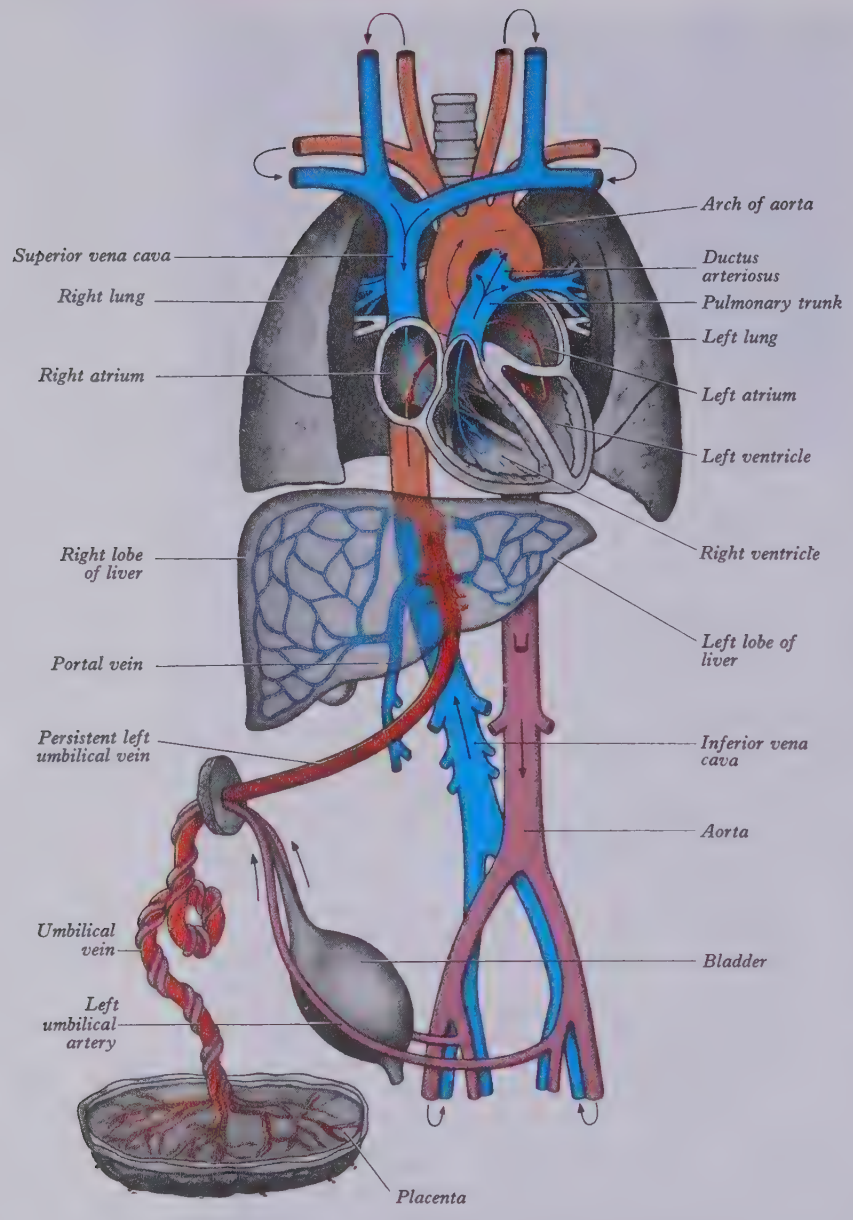
The central connections of cardiac preganglionic neurons, parasympathetic and sympathetic, are described elsewhere (*Reticular System, Hypothalamus*, and *Cerebral Cortex*). The existence and behaviour of these integrating influences is deducible in terms of function, but precise locations of connecting pathways in the spinal cord, brainstem, and cranial to this, are uncertain, perhaps because they do not form aggregated tracts. Also, many pathways are probably polysynaptic.

Nearing the heart these autonomic nerves form a mixed *cardiac plexus* (p. 1164), usually considered divisible into a ventral (superficial) part, inferior to the aortic arch and ventral to the pulmonary artery, and a dorsal (deep) part between the aortic arch and tracheal bifurcation. These plexuses contain ganglia, which also occur in the heart (**6**.57) along the distribution of branches of the plexus, their neurons considered largely, if not exclusively, postganglionic parasympathetic in nature. With the advent of reliable staining techniques for cholinergic and adrenergic nerve cells, axons and axon terminals, the distribution of cardiac autonomic elements has been subjected to detailed examination, though methylene blue clarified many details prior to this. Even a brief review is impossible here; Kuntz (1953), Mitchell (1956), and Pick (1970) have all summarized the earlier work; more recent observations cited here are merely representative of the large literature.

Cholinergic and adrenergic fibres, arising in or passing through the cardiac plexus, are distributed to nodal tissue (sinuatrial and atrioventricular), to the atrial and ventricular myocardium and to coronary arteries and cardiac veins, in rodents and dogs, according to many observers (Glabella 1976). Whole mounts of the right atrial wall, in pigs, demonstrate a rich supply of cholinergic nerve fibres (Bojsen-Møller & Tranum-Jensen 1971); the same technique shows extensions of the cardiac plexus to nodes and the atrioventricular bundle. These cholinergic fibres presumably originate in small ganglia frequently described in the cardiac plexus and its prolongations. In man a single ganglion in its 'superficial' part has alone been described; but in other mammals numerous small ganglia occur in the atrial walls, especially near both nodes and along the coronary arteries. Adrenergic neurons have not yet been identified in such ganglia but they contain chromaffin cells of the small, intensely-fluorescent type (SIF-cells, see p. 1466), according to Nielsen & Owman (1968). Adrenergic fibres occur in all cardiac chambers; both cholinergic and adrenergic axons appear more abundant in the atria and near nodal tissue than elsewhere; but in cats adrenergic fibres appear more densely distributed in the ventricles. According to Chiba & Yamauchi (1970) cholinergic fibres are more numerous in human atrial myocardium and adrenergic axons in the ventricular wall.

In most reports nerve fibres are described as close to nodal tissue or myocardium; but Thaemart (1969) has reported neuromuscular junctions, with a gap of 78–100 nm, in the atria, ventricles and septa of murine hearts. Such ultrastructural studies have been reviewed by Yamauchi (1973). To summarize, adrenergic and cholinergic terminals occur in nodes, atrial and ventricular myocardium, the atrioventricular bundle and coronary vessels of a wide variety of laboratory mammals. The functions of such supplies are not difficult to postulate but are not yet confirmed. Confirmation of such innervations in human hearts is uncertain, though it seems probable that similar arrangements exist.

6.57 Postsynaptic parasympathetic (vagal) ganglion in the wall of the left atrium (monkey), showing large ganglion cells surrounded by smaller satellite cells and myocardial tissue. Masson's trichrome stain. Magnification × 600.



Afferent cardiac nerves have attracted less anatomical interest, though their existence is physiologically certain. Some fibres accompanying coronary arteries have long been considered visceral afferents; afferents from the atria, including sinuatrial and atrioventricular nodes, from the terminations of caval and pulmonary veins and from the root, ascending trunk and arch of the aorta are generally accepted. The precise routes of such visceral afferents are not established (p. 1155) but the cardiac branches of vagi and middle and inferior cervical sympathetic ganglia probably provide major pathways. Most research has concerned the 'terminations' of cardiac visceral afferents. Ultrastructural identification of these largely depends on the mitochondrial accumulations, which are characteristic. By such criteria Kisch (1958) reported subendothelial afferent terminals in the atria and ventricles of mammals, including man; he considered them to mediate the pain phenomena of *angina pectoris*. (*Anginal pain* is almost invariably substernal but in a considerable proportion there is further radiation of pain, most commonly to the *left* side of the neck and medial border of the *left* arm. On occasion *both* arms are involved; exceptionally, the substernal pain is accompanied by radiation exclusively to the *right* arm. This re-emphasizes our poor understanding of the three-dimensional distribution of afferent cardiac innervation.) Similar nerve endings have been demonstrated in the pulmonary valve (Chiba & Yamauchi 1970).

Vessels of the Heart

Arteries of cardiac supply, the aortic coronary branches, are described on pp. 720–731, cardiac veins and the coronary sinus on pp. 792–793 and lymphatic drainage on p. 857.

The Fetal Circulation

Fetal blood reaches the placenta via *two umbilical arteries* and it returns in early fetal life by *two umbilical veins*; later the right one disappears (p. 202). The persisting *left umbilical vein* enters the abdomen at the umbilicus and traverses the falciform ligament's edge to the hepatic visceral surface, where it sends two or three branches into the left lobe, including the quadrate lobe (see discussion on hepatic lobation, p. 1385). At the porta hepatis it then joins the left branch of the portal vein; opposite the junction a large vessel arises and ascends posterior to the liver to join the left hepatic vein near its termination in the inferior vena cava; this is the *ductus venosus*. (For a detailed developmental account, with illustrations, of the circumhepatic veins see p. 221.) The fetal portal vein is small compared with the umbilical and parts of its left branch, proximal

6.58 Plan of the fetal circulation. The arrows indicate the direction of blood flow. The placenta is drawn to a greatly reduced scale.

and distal to their junctions function as branches of the latter, carrying oxygenated blood to the right and left parts of the liver (**6.58**). Hence, blood in the left umbilical vein reaches the inferior vena cava by three routes: some enters the liver directly and reaches the inferior vena cava via the hepatic veins; a considerable quantity circulates through the liver with portal venous blood before also entering the inferior vena cava by the hepatic veins; the remainder is bypassed into the inferior vena cava by the ductus venosus (with its complex developmental history).

In the inferior vena cava, blood from the ductus venosus and hepatic veins mixes with blood from the lower limbs and abdominal wall. It enters the right atrium and, guided by the inferior vena cava's valve, passes mostly through the *foramen ovale* into the left atrium, where it mingles with limited venous return from the pulmonary veins. However, some blood returning via the inferior vena cava, instead of traversing the foramen ovale, joins blood from the superior vena cava passing through the right atrium into the right ventricle. From the left atrium blood enters the left ventricle and thence the aorta, by which it is probably distributed almost entirely to the heart, head (brain and special sense organs) and upper limbs, little reaching the descending aorta. Blood from the head and upper limbs returns via the superior vena cava to the right atrium, all traversing the right atrioventricular orifice, with the small amount returned via the inferior vena cava (as already mentioned). From the right ventricle this blood enters the pulmonary trunk. Fetal lungs being inactive, only a little traverses the right and left pulmonary arteries and this returns by the pulmonary veins to the left atrium; the greater part of the pulmonary trunk outflow is bypassed via the *ductus arteriosus* to the aorta, where it mixes with the small quantity of blood passed from the left ventricle into this part of the aorta. The mixture descends the aorta and is partly distributed to the lower limbs and viscera of the abdomen and pelvis, but most is returned via the umbilical arteries to the placenta.

This fetal circulation has been confirmed by radiographic observation of radio-opaque substances, and by timing the appearance of tracer material in different parts after injection of isotopically labelled serum albumin into the bloodstream of fetal sheep (Barclay et al 1944, Dawes 1961). The following points, supported by evidence of blood-gas analysis, can be inferred: (1) The placenta serves nutrition and excretion, receiving deoxygenated fetal blood and returning it with oxygen and nutriment. (2) Some blood in the left umbilical vein traverses the liver before entering the inferior vena cava, a fact linked with the relatively large size of the fetal liver, especially in earlier months. (3) Only the pulmonary veins open directly into the left atrium, blood entering it from them being small in volume. Much more enters the right atrium, within which pressure is much higher than in the left atrium; hence the flap-like septum primum (p. 210) is thrust to the left (**2.83**), allowing blood to pass from the right to left atrium. The inferior vena cava's valve is so placed as to direct nearly all blood from the vein to the foramen ovale and left atrium, whereas superior vena caval blood enters the right ventricle directly through the right atrioventricular orifice. (4) Refreshed placental blood, mixed with blood from the portal vein and inferior vena cava, passes almost directly to the aorta for distribution to the head and upper limbs. (5) Blood in the descending aorta, chiefly after circulation through the head and upper limbs, with a small amount from the left ventricle, is distributed to the abdomen, lower limbs but *principally* to the placenta.

Changes in the Vascular System at Birth

At birth, as pulmonary respiration begins, increased amounts of blood from the pulmonary trunk traverse the pulmonary arteries to the lungs and return by the pulmonary veins to the left atrium; consequently its pressure rises. A fall in pressure also occurs in inferior vena cava due to reduction of venous return by occlusion of the umbilical vein. Atrial pressures become equal and the valvular foramen ovale is closed by apposition and later the fusion of septum primum to septum secundum (p. 212). Contraction of the atrial septal muscle, synchronized with that in the superior vena cava, may assist this closure (which occurs after *functional* closure of the ductus arteriosus (vide infra, and Barclay & Franklin 1938). Sometimes fusion is incomplete, a potential atrial communication persisting throughout life; this, unless large, has no functional effect, since the inequality of atrial pressures and the valve-like arrangement of the opening do not favour passage of blood.

When the umbilical cord is ligated, arresting placental circulation, the umbilical vein thromboses (see p. 817), gradually becoming the *ligamentum teres*. Umbilical vessels are muscular but devoid of a nerve supply in their extra-abdominal course. They constrict in response to handling, stretching, cooling and altered oxygen and carbon dioxide tensions. The ductus venosus shuts down by an unknown mechanism; it is absent or already closed in about 30% of newborn infants (Rudolph et al 1961). Its fibrous remnant is the *'ligamentum' venosum*. After ligation of the umbilical cord, the umbilical (hypogastric) arteries also thrombose from the origin of their last branches (superior vesical arteries) to the umbilicus, subsequently becoming fibrous cords (medial umbilical ligaments) in the extra-peritoneal fat of the abdominal wall, which raise the peritoneal *medial umbilical folds*.

Obliteration of the ductus arteriosus is essential; it contracts rapidly at first. Blood probably flows intermittently through it for a week or so after birth but flow is reversed, due to a rise in systemic vascular resistance resulting from exclusion of the placental circulation and a fall in pulmonary resistance with the

expansion of the lungs. When blood flows through a narrowed ductus arteriosus loud cardiac murmurs may be heard on auscultation (Burnard 1959). Closure is due to proliferation of its lining endothelium but takes some months to complete. Initial constriction at birth has been attributed to raised oxygen tension. A nervous factor may also be involved; the muscular wall has afferent and efferent nerve endings and responds to adrenalin and noradrenalin (Barcroft 1941, Franklin 1939, Barclay et al 1942). Before birth the ductus is directly continuous with the pulmonary trunk and of similar calibre. It becomes an impervious *ligamentum arteriosum* connecting the left pulmonary artery (near its origin) with the aortic arch. (For morphological and biomechanical studies of the ligamentum arteriosum consult Dohr et al 1986.) For a general review of perinatal vascular changes see Dawes (1969).

Cardiac Abnormalities

Cardiac malformations are relatively common, amounting to about one-quarter of all developmental abnormalities, with an incidence estimated at 6 per 1000 live births and 2% of stillbirths. Owing to early death, incidence in older children is about a half of this. Some cardiac anomalies can be attributed to genetic or environmental factors; the majority are believed to be multifactorial, genetic factors being effective only in certain environmental conditions (Abbot 1936, Brown 1950, Taussig 1961, Hudson & Wendell-Smith 1966).

Complete absence, *acardia*, is rare; surveys account for 155 cases (Napolitani & Schreiber 1960, Severn & Holyoke 1973), with an incidence of 1 in 34 600 births (Gillian & Hendricks 1957). Afflicted individuals are almost always monochorionic twins, depending for development on the other's heart.

1. Abnormalities of Position

(*a*) The heart may be completely reversed, with an apex directed right instead of left, associated with transposition of great vessels. It may be part of a general transposition of viscera (*situs inversus*) or involve only the heart (*dextrocardia*).

(*b*) In *ectopia cordis* the heart projects on the surface through the lower thoracic wall, associated with breakdown of the thin body wall and anterior part of the pericardium at a very early stage of development.

2. Abnormalities Due to Failure of Normal Development

This group includes most anomalies, the commonest being complete or partial failure of the division of common cardiac chambers. In the complete form there is a common atrium or common ventricle, or both persist (*cor triloculare* and *cor biloculare*). When incomplete, defects involve the interatrial septum, interventricular septum or both, or failure of division of the bulbus cordis and truncus arteriosus.

(*a*) **Atrial septal defects**

(i) *Defects of ostium secundum.* A persistent communication between right and left atria is common, resulting from failure of fusion of the septum primum and secundum. Though rarely of functional importance, the communication may be large if the septum primum cannot occlude the foramen ovale.

(ii) *Persistence of ostium primum.* Normal occlusion of the ostium primum by union of the free edge of the septum primum with the fused atrioventricular cushions fails, often associated with malformation of the tricuspid septal leaflet or mitral posterior leaflet, sometimes with underdevelopment of the septum secundum.

(iii) *Other atrial septal defects.* Rare defects occur dorsal to the fossa ovalis, sometimes associated with drainage of pulmonary veins into the right atrium. They are difficult to explain in terms of development.

(*b*) **Ventricular septal defects**

(i) *Defects of membranous septum.* The commonest defect is in the right wall of the aortic vestibule, below the commissure between the right and anterior aortic cusps. The defect is beneath the tricuspid septal leaflet and below the *supraventricular crest* (p. 703). It results from failed development of the membranous interventricular septum, being usually associated with overriding of the muscular interventricular septum by the aortic orifice, pulmonary stenosis or atresia and hypertrophy of the right ventricle (*Fallot's tetralogy*); rarely the pulmonary trunk is normal or even dilated (*Eisenmenger's complex*). This defect may also be associated with transposition of the great vessels (vide infra), in which the *pulmonary* trunk overrides the muscular interventricular septum (*Taussig–Bing syndrome*). In such septal defects the atrioventricular bundle and its right and left crura are usually along the postero-inferior margin of the defect; occasionally they are on its anterior margin (Campbell 1965).

(ii) *Defects of proximal bulbar septum.* Less commonly part of the interventricular septum formed from the bulbar ridges may be deficient below the commissure between the left and posterior pulmonary cusps and between the anterior and right aortic cusps. It connects the outflow channels of both ventricles.

(iii) *Defects of the muscular septum.* A defect in the muscular part of the interventricular septum is rare (*Maladie de Roget*).

(*c*) **Combined atrial and ventricular septum defects.** These are usually linked with a persistent common atrioventricular orifice and defects in the adjacent septa. The defect is bounded inferoposteriorly by a free margin of the muscular interventricular septum. Atrioventricular valves are abnormal; frequently a superior and an inferior leaflet common to both sides is draped across the free border of the muscular interventricular septum.

(*d*) **Persistent truncus arteriosus** (Truex & Bishof 1958). A large undivided channel is above and astride the free margin of the muscular interventricular septum connecting the ventricles. Right and left pulmonary arteries arise independently from it as it continues as the ascending aorta. A persistent truncus usually has a valve with four cusps. The defect is due to a failure of development of the bulbar ridges and the aorticopulmonary septum.

3. Abnormalities Resulting from Defective Progress in some Developmental Process (Truex & Bishof 1958)

(*a*) **Abnormal bulbar and truncal septation**

(i) *Complete transposition*, in which the aorta arises from the right ventricle and the pulmonary trunk from the left. This may be linked with an incomplete interventricular septum or a defective septum of the type described above (*Taussig–Bing syndrome*).

(ii) *Varying degrees of partial transposition of the great arteries*, usually associated with the defective interventricular septum of type described in (2.*b*.i). The pulmonary trunk usually arises from the right ventricle, but aortic position varies from a wholly right ventricular origin to varying degrees of overriding of the ventricular septum.

(*b*) **Anomalous entry of the great veins**

(i) *A persistent left superior vena cava* may drain into the coronary sinus or superior aspect of the left atrium.

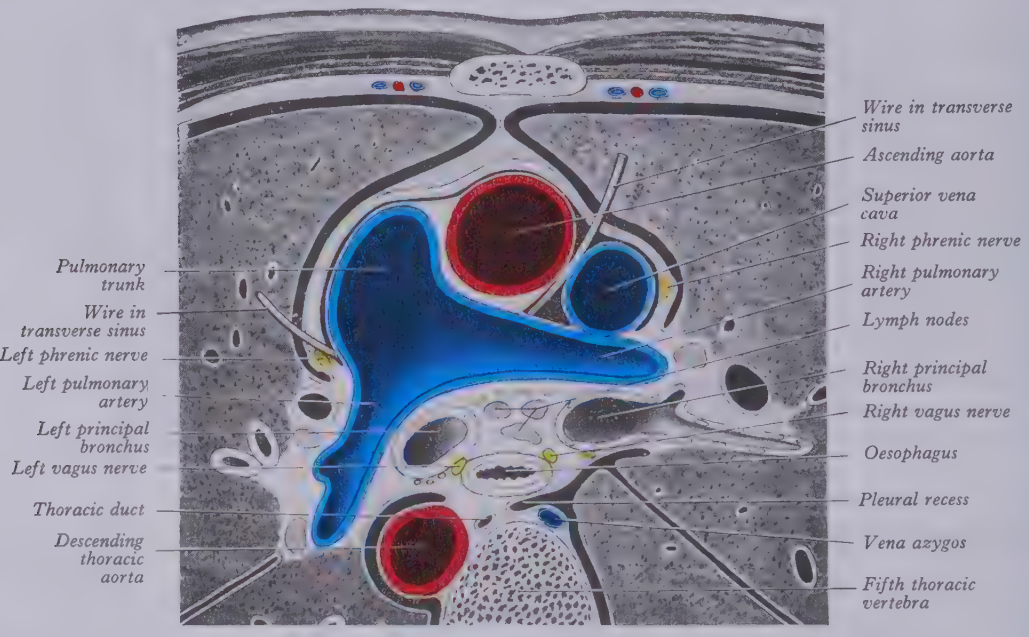
(ii) *The inferior vena cava* may be duplicated.

(iii) *The right pulmonary veins*, or less frequently all four, may drain into the right atrium. Any one may drain into some part of the thoracic systemic venous system or, less frequently, into the abdomen.

4. Abnormalities of visceral arches

(*a*) Right aortic arch (p. 214).

(*b*) Patent ductus arteriosus (p. 724).



(*c*) Coarctation of the aorta (p. 766).

Congenital cardiac malformations are often multiple and probably occur more frequently in sibs and children of consanguineous marriages, but there is a low correlation among monozygotic twins. About 20% are ventricular septal defects; persistent ductus arteriosus, atrial septal defects, aortic coarctation, pulmonary stenosis, Fallot's tetralogy and transposition of the great vessels each account for about 10%, aortic stenosis for about 5% of all cases.

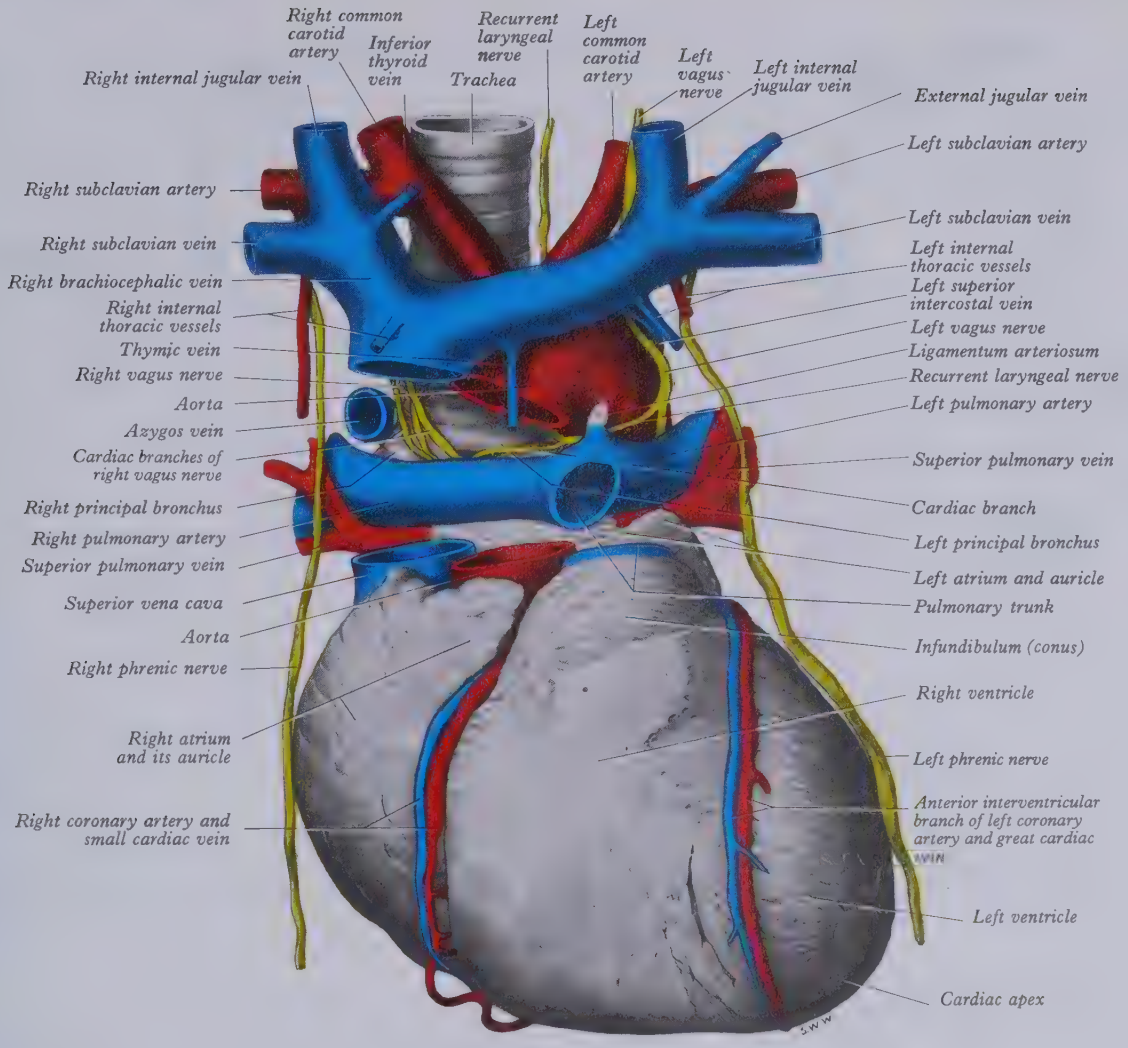
THE ARTERIAL SYSTEM

The Pulmonary Trunk

The pulmonary trunk (**6**. 59,60,64) conveys deoxygenated blood from the right ventricle to the lungs (Fishman & Hecht 1969). About 5 cm in length and 3 cm in diameter, it arises from the right ventricle's base (from the complex pulmonary annulus surmounting the conus arteriosus) above and left of the supraventricular crest. It slopes up and back, at first in front of the ascending aorta, then to its left. Below the aortic arch it divides, level with the fifth thoracic vertebra and to the left of the midline, into the right and left pulmonary arteries of almost equal size. Thus the pulmonary trunk bifurcation is *antero-inferior* and *left* of the tracheal bifurcation, with its associated inferior tracheobronchial lymph nodes and deep cardiac plexus of nerves.

6.59 Transverse section through the mediastinum at the level of the upper border of the fifth thoracic vertebra: superior aspect. Note nerve fibres of the deep cardiac and posterior pulmonary plexuses, inferior tracheobronchial and hilar lymph nodes.

Relations. It is entirely within the pericardium, enclosed with the ascending aorta in a common tube of visceral pericardium; fibrous pericardium gradually peters out in the adventitia of the pulmonary arteries. *Anteriorly* it is separated from the sternal end of the left second intercostal space by the pleura, left lung and pericardium. *Posterior* are at first the ascending aorta and left coronary artery, then the left atrium. The ascending aorta is finally on its right. An auricle and coronary artery are on each side of its origin. The superficial cardiac plexus is between the pulmonary bifurcation and the aortic arch; above, behind and right are the tracheal bifurcation, lymph nodes and nerves (vide supra).



The right pulmonary artery, slightly longer and larger, runs horizontally to the right, behind the ascending aorta, superior vena cava and upper right pulmonary vein, then in front and below the tracheal bifurcation (vide supra) and thence in front of the oesophagus and right main bronchus to the right pulmonary hilum where it bifurcates. Its lower, larger branch is distributed to the middle and lower lobes, the upper accompanies the right upper lobar bronchus. (Because the right pulmonary artery commences left of the midline and its relation to the tracheal bifurcation, it is related—at an oblique depth— to the roots of both left and right principal bronchi.)

The left pulmonary artery, shorter and smaller than the right, runs horizontally in front of the descending aorta and the left principal bronchus to the left hilum, dividing into upper and lower lobar branches. It is connected to the concavity of the aortic arch by the ligamentum arteriosum, to the left of which is the left recurrent laryngeal nerve and on the right the superficial cardiac plexus. The pericardial fold of the left vena cava (p. 696) passes from its lower border to the upper left pulmonary vein.

Branching of right and left pulmonary arteries shows little variation (except in dextrocardia, where the pulmonary lobation may also be reversed). Cory & Valentine (1959) found the usual pattern in all 34 right and all 80 left of 114 pulmonary arteries observed at operation (p. 1284). Treatment of congenital pulmonary stenosis, with and without associated 'right to left intracardiac shunt', has advanced rapidly from indirect 'systemic/ pulmonary vessel anastomosis' (Blalock 1947) to a direct blind approach to the narrow pulmonary orifice and right ventricular outflow tract (Brock 1949), and finally via open dry heart techniques employing hypothermia or suitable pump/oxygenator circulatory replacement machines.

THE AORTA

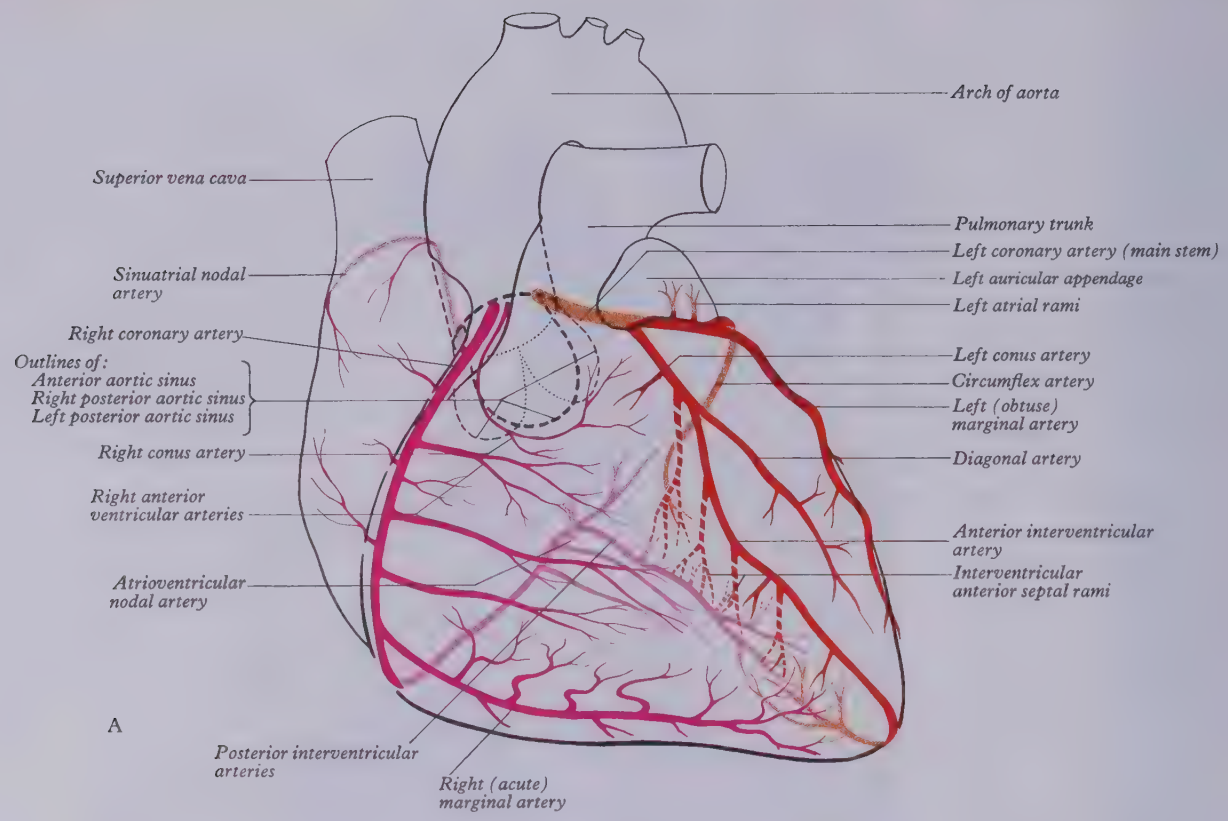
The aorta, the trunk of the arterial tree conveying oxygenated blood to the body, begins at the aortic annulus (pp. 711, 715), part of the base of the left ventricle, where it is about 3 cm in diameter. Passing up and right for about 5 cm, it arches upwards, backwards and to the left over the left pulmonary hilum and then descends in the thorax at first left of the vertebral column, then gradually inclining towards the midline, to enter the abdomen via the diaphragm's aortic hiatus. Diminished in size to about 1.75 cm, it ends a little left of the midline, level with lower border of the fourth lumbar vertebra, dividing into the right and left common iliac arteries. For convenience it is described as arbitrarily divided into *ascending*, *arch* and *descending thoracic* and *abdominal* parts.

6.60 The relations of the pulmonary arteries and primary bronchi seen from the front. Parts of the ascending aorta, pulmonary trunk and superior vena cava have been removed in the dissection. The right vagal trunk is uncoloured to avoid confusion.

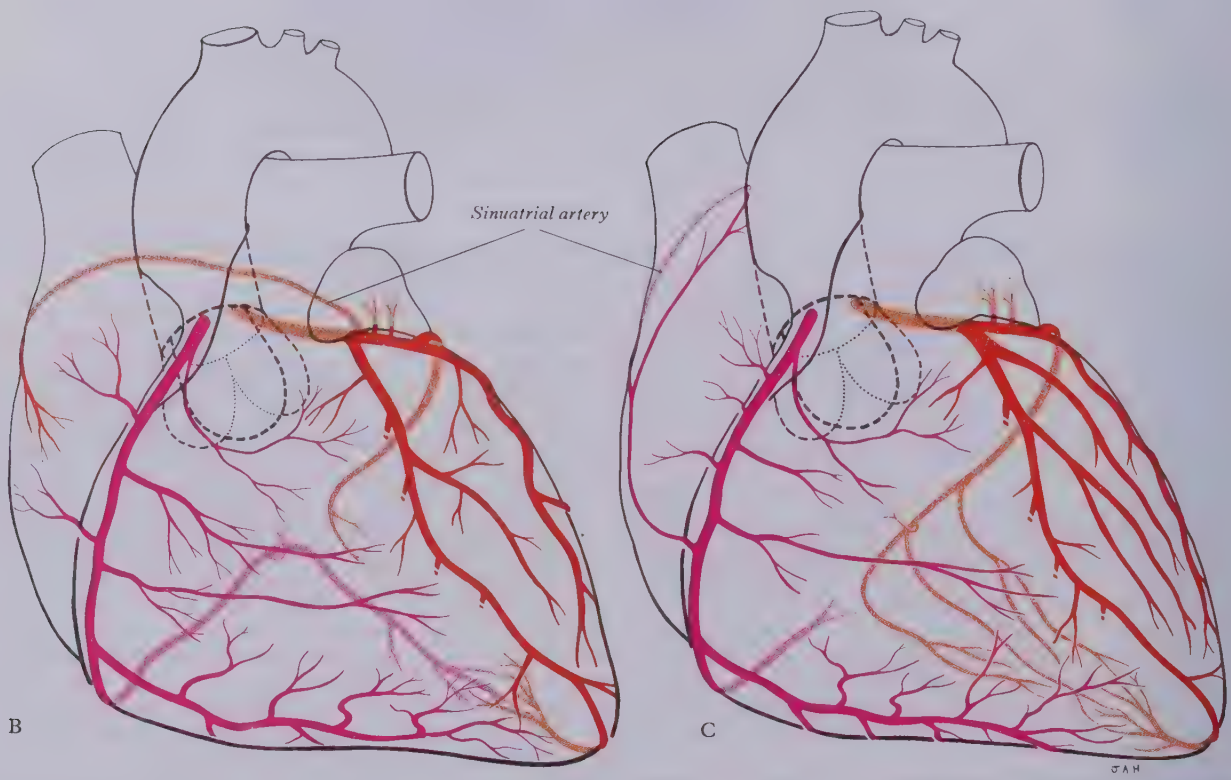
The Ascending Aorta

The ascending aorta (**6**.28,59,60,63), about 5 cm long, begins at the base of the left ventricle, level with the third left costal cartilage's lower border; it ascends obliquely, curving forwards and right, behind the left half of the sternum to the level of the second left costal cartilage's upper border. At its origin, distal to the aortic annulus, are three *aortic sinuses* (p. 711), beyond which the vessel's calibre is slightly increased by a bulging of its right wall; this *aortic bulb* gives the vessel an oval section.

Relations. The ascending aorta is within the fibrous pericardium, enclosed in a tube of serous pericardium with the pulmonary trunk (**6**.26). *Anterior* to its lower part are the infundibulum (p. 703), the commencement of the pulmonary trunk, and right auricle; *superiorly*, it is separated from the sternum by the pericardium, right pleura, the anterior margin of the right lung, loose areolar tissue and thymic remains; *posterior* are the left atrium, right pulmonary artery and principal bronchus; *right lateral* are the superior vena cava and right atrium, the former partly posterior; *left lateral* are the left atrium and, at a higher level, the pulmonary trunk.



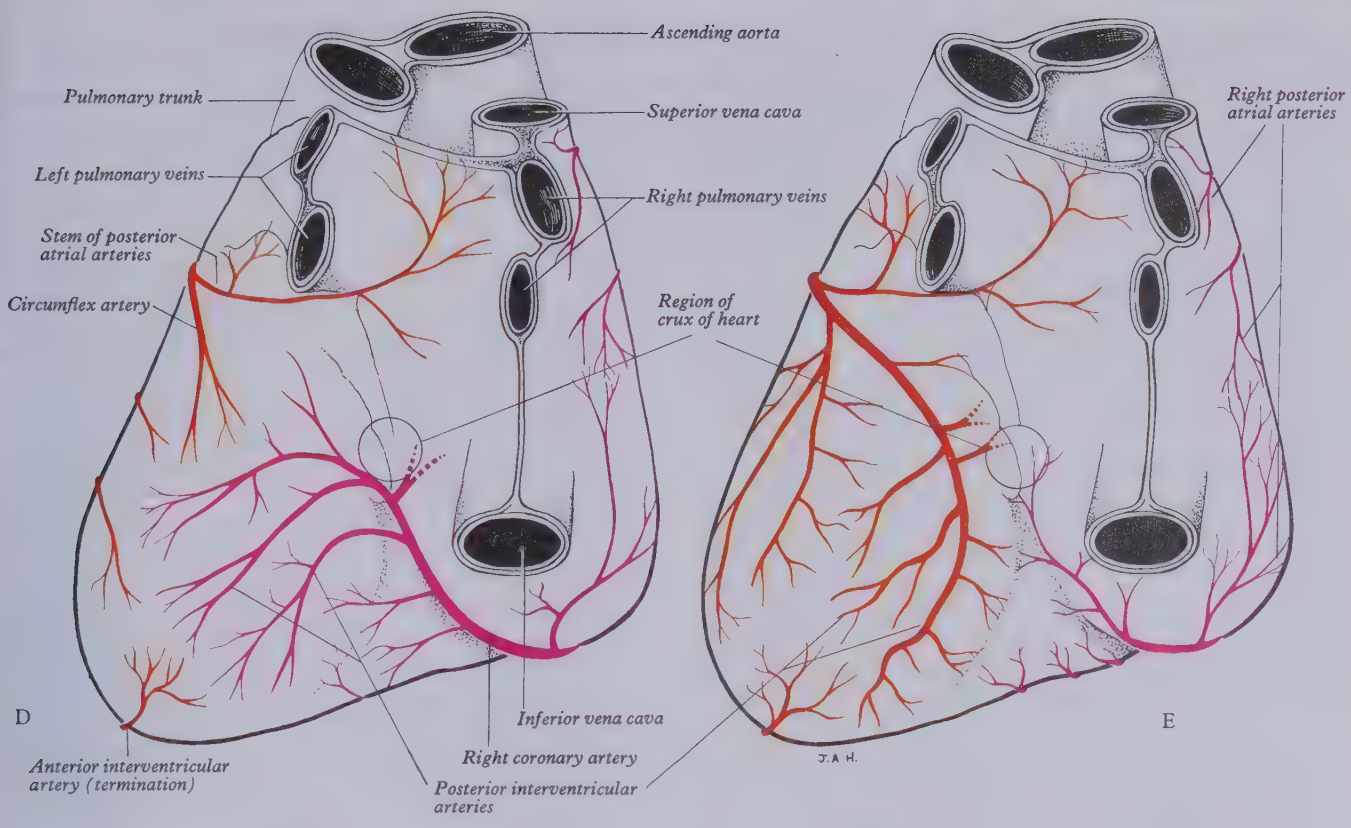
At least two structures (reminiscent of the carotid arterial chemoreceptors and baroreceptors, p. 1472) lie between the ascending aorta and the pulmonary trunk. The *inferior aorticopulmonary body* is near the heart and anterior to the aorta; the *middle aorticopulmonary body* is near the right side of the ascending aorta (Boyd 1961).



Branches are the right and left coronary arteries (**6**.61A–E,62), supplying the heart itself.

THE CORONARY ARTERIES (**6**.61A–E,62)

The right and left coronary arteries open from the ascending aorta in its anterior and left posterior sinuses. (Some clinicians call these right and left coronary sinuses, the right posterior being inelegantly termed 'non-coronary'.) Variations are rare but the two may start, separately or in common, from the same sinus; three or even four coronary arteries have been observed; the most common variation concerns a right coronary branch, *arteria coni arteriosi* or 'conus artery', which is usually (64%) its first branch but often arises separately in the anterior sinus (36%), as a third coronary artery. The left coronary opening may be double, leading into major initial branches, usually the circumflex and anterior interventricular; one may lead into a stem common to one such branch and a diagonal ventricular ramus. The levels of coronary orifices are variable; Thebesius (1708) appears to have started a view that aortic cusps obstruct them when fully spread in systole; but the coronary orifices are at a higher level, at or above cuspal margins, though below in about 10% (right coronary) and 15% (left). (Further, as detailed on p. 710 et seq, it is now established that, even at the height of systole, the cusps do not 'flatten' against i.e. co-apt to, the walls of their sinuses.)



The two arteries, as indicated by their name, form an oblique inverted *crown*, with an anastomotic *circle* in the atrioventricular

6.61A–C Anterior views of the coronary arterial system, with the principal variations. A. The commonest arrangement. B. A common variation in the origin of the sinuatrial nodal artery. C. An example of *left* 'dominance' by the left coronary artery, showing also an uncommon origin of the sinuatrial artery.

Note that in **6.61A–E** the right coronary arterial tree is shown in magenta, the left in full red. In both cases posterior distribution is shown in a paler shade.

6.61D,E Postero-inferior views of the coronary arterial system. D. An example of the more normal distribution in *right* 'dominance'. E. A less common form of *left* 'dominance'.
N.B. In these 'posterior' views the diaphragmatic (inferior) surface of the ventricular part of the heart has been artificially displaced and foreshortening ignored to clarify the details of the so-called posterior (inferior) distribution of the coronary arteries.

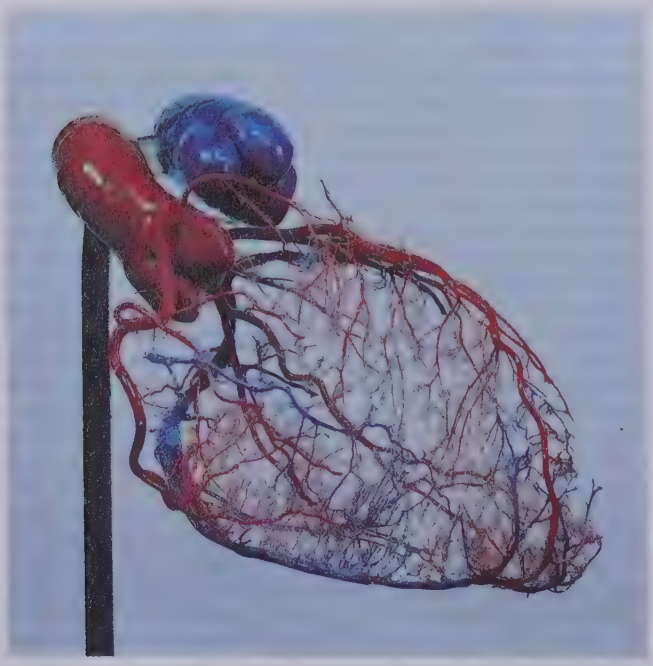
sulcus connected by marginal and interventricular *loops* intersecting at the cardiac apex (**6.61**). This is, of course, only an approximation; the degree of anastomosis is most variable and usually insignificant (vide infra). The main arteries and major rami are usually sub-epicardial but those in the atrioventricular and interventricular sulci are often deeply sited, occasionally hidden by overlapping myocardium or embedded in it. Myocardial strands may also cross atrial or ventricular branches; Polacek (1961) found them in more than 80% of ventricles; Bloor & Lowman (1963) have emphasized their importance in interpretation of coronary arteriograms.

The diameters of coronary arteries, both main stems and larger branches, have often been recorded; such figures are of limited value, since technique is not always stated, physiological state often ignored and measurement of external or internal diameters not clearly distinguished. Calibre is usually the basis, most measurements being made on arterial casts or angiograms. The maximum ranges recorded in major studies are 1.5–5.5 mm for coronary arteries at their origins. Baroldi & Scomazzoni (1967) give means of 4.0 and 3.2 mm. The left exceeds the right in about 60% of hearts, the right being larger in 17%, the vessels approximately equal in 23%. Vogelberg (1957) considered that coronary diameters increase up to the thirtieth year.

The Right Coronary Artery

Arising from the anterior ('right coronary') aortic sinus, the artery passes at first anteriorly and slightly to the right between the right auricular appendage and pulmonary trunk, where the sinus usually bulges. Reaching the atrioventricular (coronary) sulcus it descends in this almost vertically to the right (acute) cardiac border, curving around it into the posterior part of the sulcus, where it approaches its junction with both interatrial and interventricular grooves, a region appropriately termed the *crux of the heart*. In about 60% the artery reaches the crux and ends a little left of it by variable anastomosis with circumflex branch of the left coronary. In a minority (*c.* 10%) the right coronary artery ends near the right cardiac border or between this and the crux (*c.* 10%); more often (*c.* 20%) it may reach the left border, replacing part of the circumflex artery.

Branches of the right coronary supply both right atrium and ventricle and, variably, parts of the *left* chambers and atrioventricular septum. The first branch (arising separately from the anterior aortic sinus in 36%) is the *conus artery* (sometimes a 'third coronary'); since a similar vessel comes from the left coronary, this is more correctly named the *right conus artery*. It ramifies anteriorly on the lowest part of the pulmonary conus and upper part of right ventricle; it commonly anastomoses with a similar left coronary branch to form the '*annulus of Vieussens*', a tenuous anastomotic 'circle' around the pulmonary trunk. Descriptions of the conus artery vary (Baroldi & Scomazzoni 1967), some regarding the right conus artery of significance in coronary arterial disease; some consider it to be the right coronary's first ventricular branch, supplying a variable region from the conus to the apex.



Anterior atrial and ventricular rami diverge from the so-called *first segment of the right coronary*, extending from its origin to the right margin of the heart. Both groups diverge widely, approaching a right angle in the case of ventricular arteries, in contrast to the more acute origins of the left coronary ventricular rami. The **right anterior ventricular rami**, usually two or three, ramify towards the cardiac apex, which they rarely reach unless the **right marginal branch** is included, as it is by some; this is then the largest right anterior ventricular ramus, greater in calibre and long enough to reach the apex in most hearts (93%, Baroldi & Scomazzoni 1967). When the right marginal artery is very large, the remaining anterior ventricular rami may be reduced to one, or is completely absent. From the *second segment of the right coronary artery* (between the right border and crux) one to three small **right posterior ventricular rami**, commonly two, supply the diaphragmatic aspect of the right ventricle. Their size is reciprocal to that of the right marginal artery, as in the anterior right ventricular supply, the right marginal usually extending to the cardiac diaphragmatic surface. Posterior right ventricular rami may be absent.

As the right coronary approaches the crux, it produces one to three posterior interventricular rami but only one in the interventricular sulcus; this **posterior interventricular artery**, single in about 70%, is otherwise accompanied by parallel *right* coronary branches, to the right or left or on both sides of the sulcus. When these flanking vessels exist, branches of the posterior (descending) interventricular artery are small and sparse; when it exists alone it gives off a few branches, particularly to the right ventricle but also to the left. It is replaced in about 10% by a left coronary branch.

The **atrial rami** of the right coronary artery are sometimes described as anterior, lateral (right or marginal) and posterior *groups* but are most frequently single, small vessels averaging 1 mm in diameter. The right anterior and lateral are occasionally double, very rarely triple and supply chiefly the right atrium. The posterior ramus is usually single, distributed to the right and left atria; but in 40% or more a left posterior atrial branch of the right coronary exists. The **artery of the sinuatrial node** is an atrial branch, distributed largely to the myocardium of both atria, mainly the right. Its origin is variable: from the *left* coronary in about 35% (Hutchinson 1978), arising from its circumflex branch (vide infra); when it is a branch of the right coronary, it usually comes from its anterior stem, less often from its right lateral part, least of all from its posterior atrioventricular part. This 'nodal' artery thus usually passes back in the sulcus between the right auricular appendage and aorta. Whatever its origin the artery usually branches around the superior vena cava's base, commonly as an *arterial loop* from which small rami supply the right atrium. A large '*ramus cristae terminalis*' (Spalteholz 1924) traverses the sinuatrial node (**6**.61), perhaps instead this ramus should be termed 'nodal artery', since most of the currently named vessel actually supplies the atria and is more appropriately named the '*main atrial branch*' (Baroldi & Scomazzoni 1967).

Right coronary **septal rami** are relatively short, leaving its posterior interventricular ramus to supply the posterior interventricular septum. They are numerous but do not usually reach the apical septal parts (supplied by terminal septal branches of the anterior interventricular). The largest posterior septal artery, usually the first, is commonly from the *inverted loop* said to characterize the right coronary artery at the crux, where its posterior interventricular branch arises; this **large posterior septal artery** usually supplies the **atrioventricular node**—in 80% of hearts, according to Hutchinson (1978).

DiDio (1967) described the *atrioventricular rami* of the right coronary artery as consisting of small recurrent branches from each ventricular artery crossing the atrioventricular sulcus to supply the adjoining atrial myocardium, or ventricular twigs from the atrial arteries.

6.62 A composite coloured resin cast: red = the aortic root, aortic sinuses and coronary arteries; blue = the pulmonary trunk, sinuses and the coronary sinus and its tributaries. Note reduplication of the right coronary artery; the smaller of these vessels is known as the artery of the conus. Note particularly the septal arterial and venous rami. See text for detailed account. Photography by Kevin Fitzpatrick, Guy's Hospital Medical School.

The Left Coronary Artery

The left coronary artery is the larger in calibre, supplying a greater *volume* of myocardium, including almost all the left ventricle and atrium, except in so-called 'right dominance' where the right coronary partly supplies a posterior region of the left ventricle. The left coronary usually supplies most of the interventricular septum. Its *initial stem*, between its ostium in the left posterior ('left coronary') aortic sinus and its first branches, varies in length from a few millimetres to a few centimetres. It lies between the pulmonary trunk and the left auricular appendage, emerging into the atrioventricular sulcus, in which it turns left; this part is loosely embedded in subepicardial fat and usually has no branches; but a small atrial ramus may occur and, rarely, the *sinuatrial nodal artery* may arise from the left coronary artery (James 1961); but when it is a ramus of the left coronary it almost always comes from the circumflex branch. Reaching the atrioventricular or coronary sulcus, the left coronary divides into two or three main rami, its **anterior interventricular (descending) ramus** being commonly described as its continuation; this descends obliquely forward and left in the interventricular sulcus, sometimes deeply embedded or crossed by bridges of myocardial tissue and by the great cardiac vein and its tributaries. It reaches the apex almost always, terminating there in one-third of specimens, but more often turning round the apex into the posterior interventricular sulcus, in which it traverses a third to a half of its length, to meet the terminal twigs of the corresponding right coronary ramus.

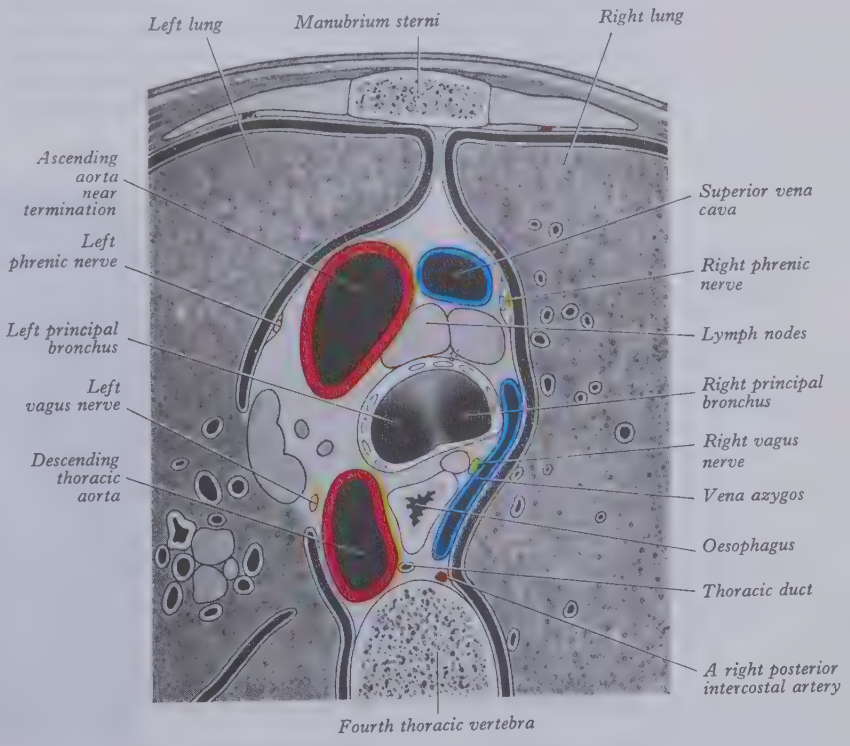
The **anterior interventricular artery** produces right and left anterior ventricular, anterior septal and variable, corresponding posterior rami. *Right anterior ventricular rami* are small and rarely number more than one or two, the right ventricle being supplied almost wholly by the right coronary artery.

From two to nine large **left anterior ventricular arteries** branch at acute angles from the anterior interventricular to cross *diagonally* the left ventricle's anterior aspect, larger terminals reaching the rounded (obtuse) left border. One is often large and may arise separately from the left coronary *trunk* (which then ends by trifurcation); this **left diagonal artery**, reported in 33–50% or more cases, is occasionally duplicated (20%). A small *left conus artery* frequently leaves the anterior interventricular near its start, anastomosing on the conus with that of the right coronary and with the vasa vasorum of the pulmonary artery and aorta. The **anterior septal rami** leave the anterior interventricular almost perpendicularly, passing back and down in the septum, of which they usually supply about the ventral two-thirds. Small *posterior septal rami* from the same source supply the posterior septal third for a variable distance from the cardiac apex.

The **circumflex artery**, in calibre comparable to the anterior interventricular, curves left in the atrioventricular sulcus, continuing round the left cardiac border into the posterior part of the sulcus and ending left of the crux in most hearts, but sometimes continuing as a posterior interventricular artery. Proximally the left auricular appendage usually overlaps it. In about 90% a large ventricular branch, the **left marginal artery**, arises perpendicularly from it to ramify over the rounded 'obtuse' margin, supplying much of the adjacent left ventricle, usually to the apex. Smaller anterior and posterior rami of the circumflex artery also supply the left ventricle. **Anterior ventricular branches** (1–5, commonly 2 or 3) course parallel to the diagonal artery, when present, replacing it when absent. **Posterior ventricular branches** are smaller and fewer, the left ventricle being partly supplied by the posterior interventricular artery; when this is small or absent, it is accompanied or replaced by an interventricular continuation of the circumflex. Such a **left posterior interventricular artery** is frequently double or triple. **Atrial**

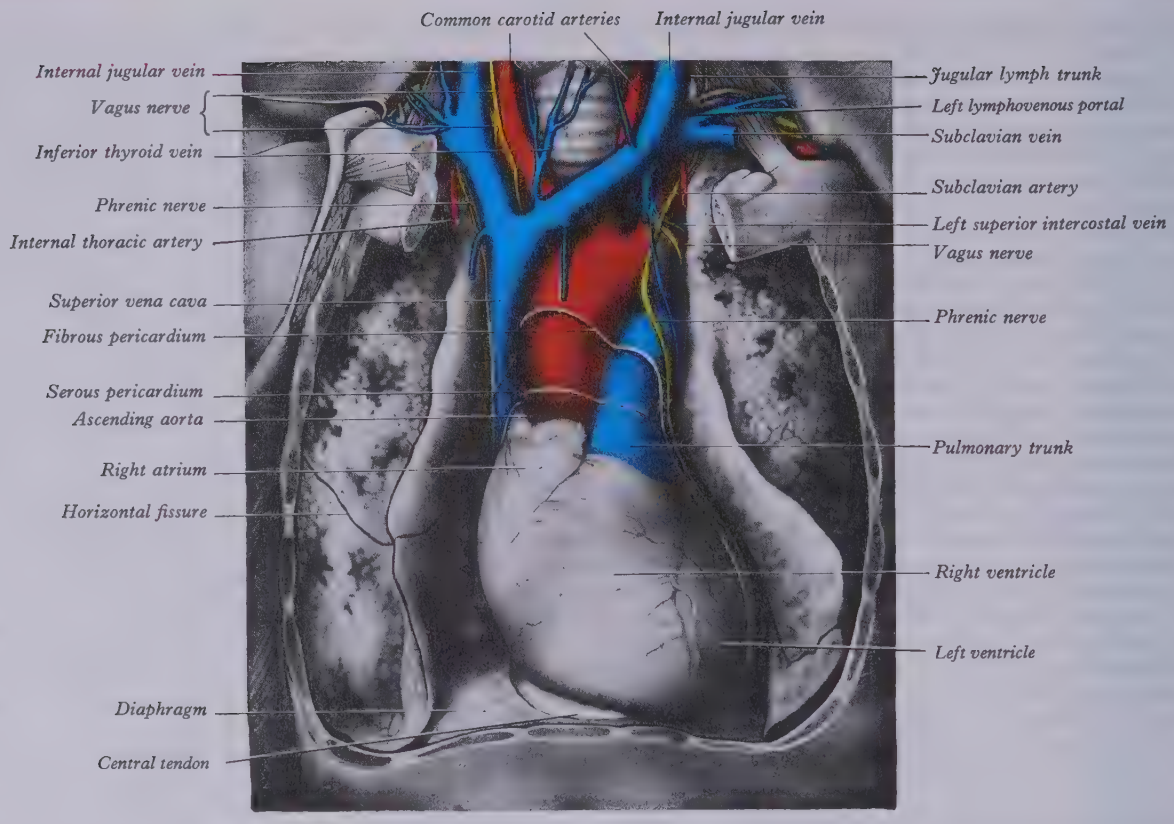
rami, anterior, lateral and posterior, from the circumflex, supply the left atrium.

Inconstant branches of the circumflex artery require mention. The **artery to the sinuatrial node** is a branch in about 35% (Hutchinson 1978), usually from the anterior circumflex segment, less often the circummarginal. It passes over and supplies the left atrium, encircling the superior vena cava like a right coronary nodal ramus. It sends a large branch to (and through) the node but is predominantly atrial in distribution. The **artery to the atrioventricular node**, the terminal ramus in 20%, arises near the crux and then the circumflex usually supplies a posterior interventricular ramus, an example of so-called 'left dominance' (vide infra). *Kugel's anastomotic artery*, '*arteria anastomotica auricularis magna*' was described by Kugel (1927) as a constant circumflex branch, usually from its anterior part, traversing the interatrial septum (near its ventricular border) to establish direct or indirect anastomosis with the right coronary. This anastomosis is controversial, apparently accepted by James (1974) but denied by Baroldi & Scomazzoni (1967). James considered it an auxiliary supply to the atrioventricular node.



Details of coronary distribution require integration into a concept of total cardiac supply. Most commonly the *right coronary* supplies all the *right* ventricle (except a small region right of the anterior interventricular sulcus), a variable part of the *left* ventricular diaphragmatic aspect, the postero-inferior third of the intraventricular septum, the right atrium and part of the left, and the conducting system as far as the proximal parts of the right and left crura. *Left coronary* distribution is, of course, reciprocal, including most of the *left* ventricle (vide supra), a narrow strip of *right* ventricle (vide supra), the anterior two-thirds of the interventricular septum and most of the left atrium. As noted, variations (**6**.61A–E) chiefly affect the diaphragmatic aspect of ventricles residing in relative '*dominance*' of supply by the left or right coronary artery. The term is misleading, since the left artery almost always supplies a greater *volume* of tissue. In '*right dominance*' the posterior interventricular artery is from the right coronary, in '*left dominance*' from the left. In the so-called '*balanced*' pattern, branches of both run in or near the sulcus. Less is known of variation in atrial supply; the small vessels involved are not easily preserved in corrosion casts. From Hutchinson's results (1978) it is apparent that in over 50% the right atrium is supplied only by the right coronary, the rest receiving a dual supply. More than 62% of left atria are largely supplied by the left and about 27% by the right coronary; but in each group a small accessory supply from the other coronary exists, 11% being supplied almost equally by both. Sinuatrial and atrioventricular supplies also vary. According to James (1961) right and left coronary arteries supply the sinuatrial node respectively in 55% and 45%, corresponding values from Baroldi & Scomazzoni's study (1967) being 51% and 41% (8% receiving bilateral supply), and from Hutchinson (1978) 65% and 35%. For the atrioventricular node James's values are 90% (right coronary) and 10% (left coronary), Hutchinson's 80% and 20% respectively; Baroldi & Scomazzoni merely note that right coronary supply is common and left supply rare.

Coronary Anastomosis

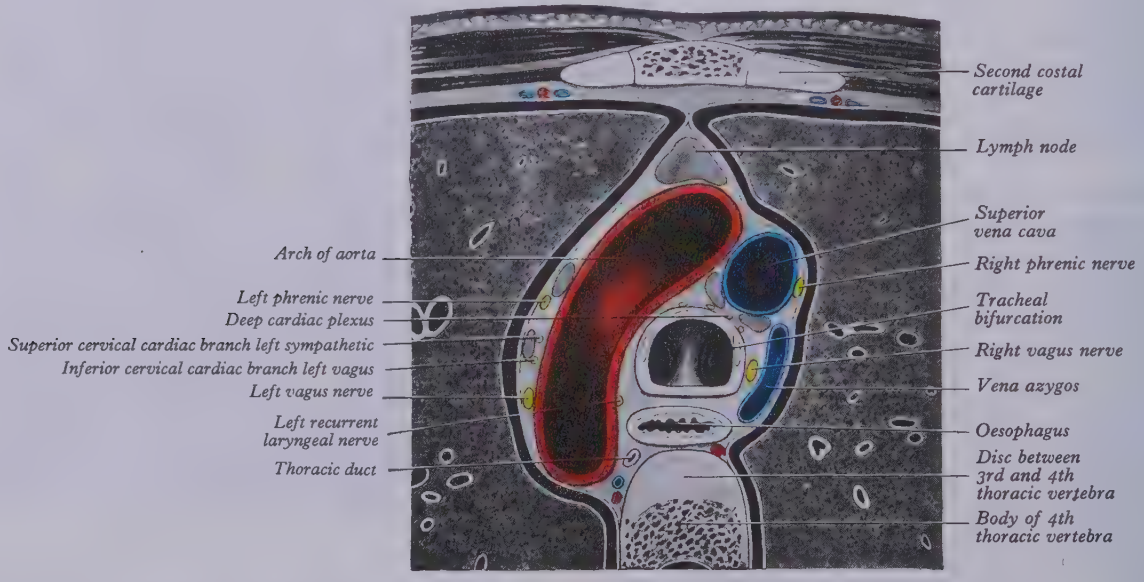


Anastomoses between branches of coronary arteries, subepicardial or myocardial, and between these arteries and extracardiac vessels are of prime medical import. Clinical experience suggests that anastomoses cannot rapidly provide collateral routes sufficient to circumvent sudden coronary obstruction. It is hence traditional to regard coronary circulation as end-arterial. Nevertheless, anastomosis has long been established particularly between the finer subepicardial rami. According to Gross (1921) such anstomoses may improve during individual life. Those who have *investigated* coronary arteries by radio-opaque perfusants (Vastesueger et al 1957 in post-mortem hearts, Laurie & Woods 1958 by in vivo coronary radiography), by perfusion with calibrated spherules (Prinzmetal et al 1947) or by subsequent corrosion casts of plastic resins (Baroldi et al 1956, James 1961) have almost all described anastomoses, and in vessels up to 100–200 μm in calibre. Baroldi & Scomazzoni (1967) have tabulated all results reported since 1880; no study denying anastomoses has been recorded since 1957. Some describe anastomoses only between branches of individual coronary arteries but the majority record *intercoronary* anastomoses. James (1974) considers evidence conclusive for anastomoses at all levels: subepicardial, myocardial, and subendocardial; the most frequent sites of extramural anastomoses are the apex, the anterior aspect of the right ventricle, posterior aspect of the left ventricle, crux, interatrial and inter-ventricular sulci and between the sinuatrial nodal and other atrial vessels. The functional value of such anastomoses must vary but they appear to become more effective in *slowly* progressive pathological conditions. Their structure is uncertain; most observations depend on corrosion casts, which suggest that anastomotic vessels are relatively straight in normal hearts, but much coiled in hearts subject to coronary occlusion. Little has been recorded of their microscopic structure; they appear little more than endothelial tubes, without muscle or elastic tissue.

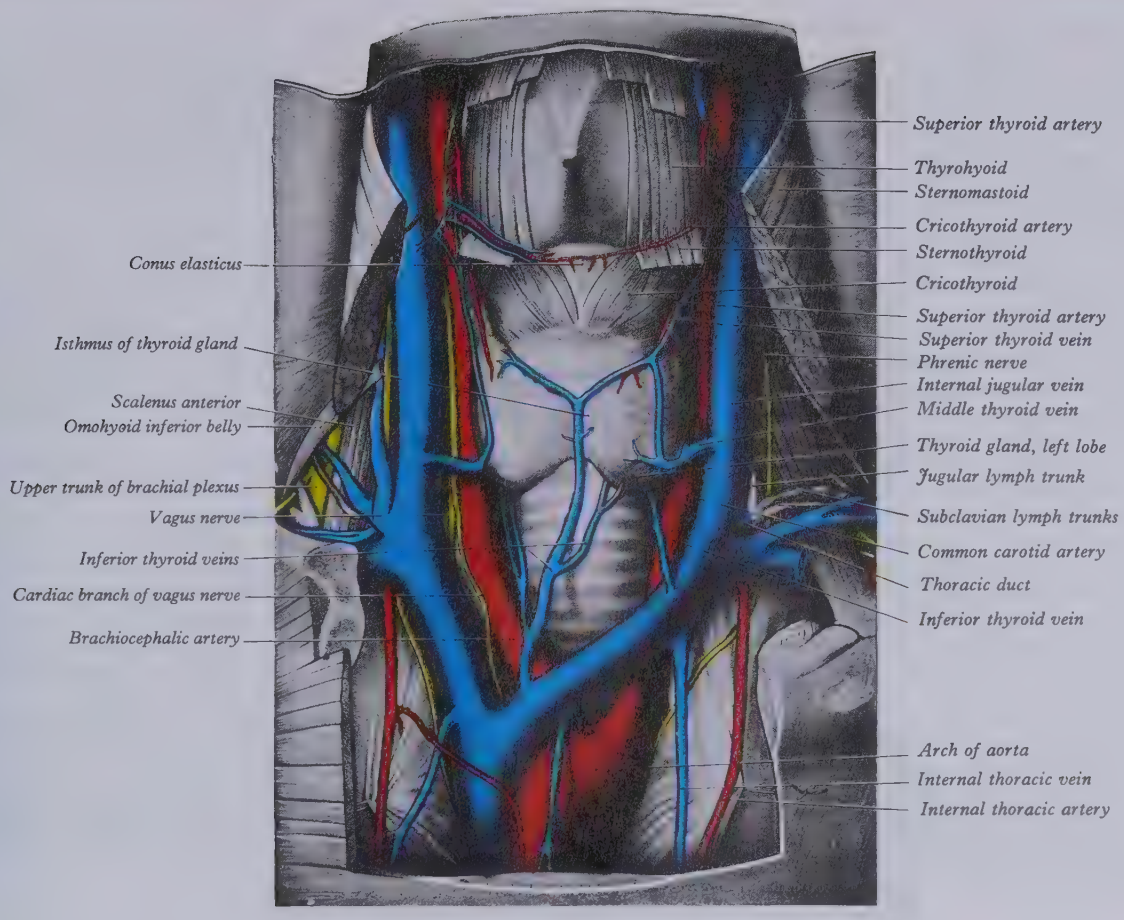
Extracardiac anastomoses may connect various coronary branches with other thoracic vessels via the pericardial arteries and arterial vasa vasorum of vessels linking the heart with systemic and pulmonary circulations. The classic study of Hudson et al (1932) showed that coronary injections of India ink could reach the diaphragm through the aortic vasa vasorum. Similar connections along pulmonary trunks reach the mediastinal and bronchial arteries and also exist along pulmonary veins and venae cavae. These results have been confirmed (Baroldi & Scomazzoni 1967) but the effectiveness of such connections as collateral routes in coronary occlusion is unpredictable.

Coronary arteriovenous anastomoses were reported by Nussbaum (1912). His evidence was indirect but Hirsch (1960) described glomeral structures with typical sphincteric appearances (p. 693) in cardiac sulci; these must be regarded as at present unproven. Various other forms of 'arteriovenous' connections have been described; Wearn et al (1933) recorded numerous connections through the very thin-walled 'arterial' vessels between the coronary circulation and cardiac cavities, naming them '*myocardial sinusoids*' and '*arterio-luminal*' vessels. They have been confirmed (Watanabe 1960) and indirect evidence of them, from perfusion experiments, dates back to Vieussens (1706). Their value in coronary disease is uncertain.

6.63 Transverse section through the mediastinum at the level of the lower part of the body of the fourth thoracic vertebra, viewed from above. The deep cardiac plexus of nerves is omitted.



6.64 Dissection to display the heart, great vessels and lungs in situ. The sternum and the sternal ends of the costal cartilages, together with the parietal pleura on each side, have been excised and the mediastinal pleura and parietal layer of the pericardium over the sternocostal surface of the heart have been removed. The lungs have been displaced to expose the heart and the epicardium dissected off the heart and the great vessels.

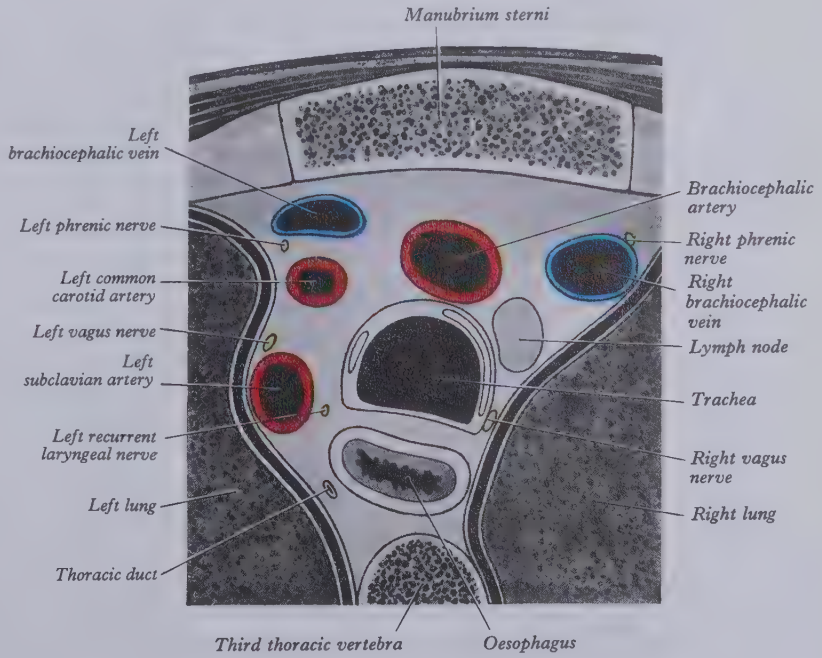


The Arch of the Aorta

The aortic arch (**6**.59–65) begins behind approximately the *right* half of the manubrium sterni, level with the upper border of the second *right* sternocostal articulation. It first ascends diagonally back and to the left over the anterior surface of the trachea, then back across its left side and finally descends left of the fourth thoracic vertebral body, continuing at its lower border as the descending thoracic aorta. Its end corresponds, in level, with the sternal end of the second, *left* costal cartilage (**6**.42). Thus, the aortic arch lies wholly in the superior mediastinum. It has two curvatures: one convex upwards, the other convex forwards and to the left. Its upper limit is usually at about *mid-level* of the manubrium sterni.

Relations. *Anteriorly and to the left* is the left mediastinal pleura, deep to which it is crossed by four nerves: the left phrenic, left lower cervical vagal cardiac branch, left superior cervical sympathetic cardiac branch and left vagus, in anteroposterior

6.65 Transverse section through the mediastinum at the level of the upper part of the body of the fourth thoracic vertebra, viewed from above.



6.66 Dissection of the lower part of the front of the neck and of the superior mediastinum. The manubrium sterni and the sternal ends of the clavicles and the first costal cartilages have been removed and the pleural sac and lung have been retracted on each side. In this specimen each superior thyroid artery arose from the common carotid artery.

order. As the left vagus crosses the arch its recurrent laryngeal branch hooks below the vessel left and behind (developmentally caudal to) the ligamentum arteriosum and then ascends on the arch's right. The left superior intercostal vein ascends obliquely forwards on the arch, superficial to left vagus, deep to the left phrenic nerve (**6**.64). Left lung and pleura separate all these from the thoracic wall. *Posteriorly to the right*, are the trachea and deep cardiac plexus, the left recurrent laryngeal nerve, oesophagus, thoracic duct and vertebral column. *Above*, the brachiocephalic, left common carotid and left subclavian arteries arise from its convexity, crossed anteriorly near their origins by the left brachiocephalic vein. *Below* are the pulmonary bifurcation, left principal bronchus, ligamentum arteriosum (p. 725), superficial cardiac plexus and left recurrent laryngeal nerve. (Best viewed from the left, the concavity of the aortic arch is the upper curved limit through which structures gain access or exit through the hilum of the left lung.)

The fetal aortic lumen narrows between the origin of the left subclavian artery and the attachment of the ductus arteriosus, as the *aortic isthmus*; beyond the ductus arteriosus the vessel presents a fusiform *aortic spindle*, the junction of the two parts being marked inferiorly by an indentation; these features persist variably in adults.

Variations. The summit of the arch is usually about 2.5 cm below the superior sternal border but may diverge from this. Sometimes the aorta curves over the *right* pulmonary hilum (as a right aortic arch) descending right of the vertebral column, a condition normal in birds; there is usually transposition of thoracic and abdominal viscera. Less often, after arching over the right hilum, it passes behind the oesophagus to its usual position; this is not accompanied by visceral transposition. The aorta may divide, as in some quadrupeds, into ascending and descending

6.67 Transverse section through the superior mediastinum at the level of the body of the third thoracic vertebra, viewed from above.

trunks, the former dividing into three branches to supply the head and upper limbs. Sometimes it divides near its origin, the two branches soon reuniting; the oesophagus and trachea usually pass through the interval between them; this is the normal condition in reptilia and is due to the persistence of a part of the right dorsal aorta which usually disappears (p. 214).

Radiological appearances. The shadow of the arch is easily identified in anteroposterior radiographs (**6**.45) and its left profile is sometimes called the 'aortic knuckle'. The arch may also be visible in left anterior oblique views enclosing a pale space, 'the aortic window', in which shadows of the pulmonary trunk and its left branch may be visible.

Branches (**6**.64,67). Three branches spring from the vessel's convex aspect: the brachiocephalic trunk, left common carotid and left subclavian arteries. They may branch from the beginning of the arch or the upper part of the ascending aorta; the distance between these origins varies, the most frequent being approximation of the left common carotid artery to the brachiocephalic trunk (Wright 1969). Primary branches may be reduced to one, more commonly two, the left common carotid arising from the brachiocephalic trunk (7%), or (more rarely) the left common carotid and subclavian arteries arising from a left brachiocephalic or right common carotid and subclavian arising separately, in which case the latter more often branches from the left end of the arch and passes behind the oesophagus (p. 214). The left vertebral artery may arise between the left common carotid and the subclavian. Very rarely, external and internal carotid arteries arise separately, the common carotid being absent on one or both sides; or both carotids and one or both vertebrals may be separate branches. When a 'right aorta' occurs, the arrangement of its three branches is reversed. The common carotids may have a single trunk, the subclavians separate, the right arising from the left end of the arch. Other arteries may branch from it, most commonly one or both bronchial arteries and the arteria thyroidea ima.

An analysis of variation in branches from 1000 aortic arches (Anson 1963) showed in 65% the usual pattern; in 27% a left common carotid shared the brachiocephalic trunk (contrast percentage quoted above); in 2.5% the four large arteries branched separately. The remaining 5% showed a great variety of patterns, the commonest (1.2%) being symmetrical right and left brachiocephalic trunks.

The Brachiocephalic Artery

The brachiocephalic (innominate) artery, the largest branch of the aortic arch, is from 4–5 cm in length (**6**.60,66,67), arising from the arch's convexity posterior to the centre of the manubrium sterni; it ascends posterolaterally to the right, at first anterior to trachea, then on its right. Level with the right sternoclavicular joint's upper border it forks into the right common carotid and subclavian arteries.

Relations. *Anterior* are sternohyoid and sternothyroid, the remains of the thymus, left brachiocephalic and right inferior thyroid veins, crossing its root and sometimes the right vagal cardiac branches, all separating it from the manubrium. *Posterior* are the trachea below, right pleura above, where the right vagus is posterolateral before passing lateral to the trachea; *right lateral* are the right brachiocephalic vein, the upper part of the superior vena cava and pleura; *left lateral* are the thymic remains, the origin of the left common carotid artery, the inferior thyroid veins and the trachea at a higher level.

Branches. The brachiocephalic artery usually has only terminal branches but occasionally an *arteria thyroidea ima* arises from it, sometimes a *thymic* or *bronchial branch*.

Arteria thyroidea ima, small and inconstant, ascends on the trachea to the thyroid isthmus, in which it ends. It may arise from the aorta, right common carotid, subclavian or internal thoracic arteries.

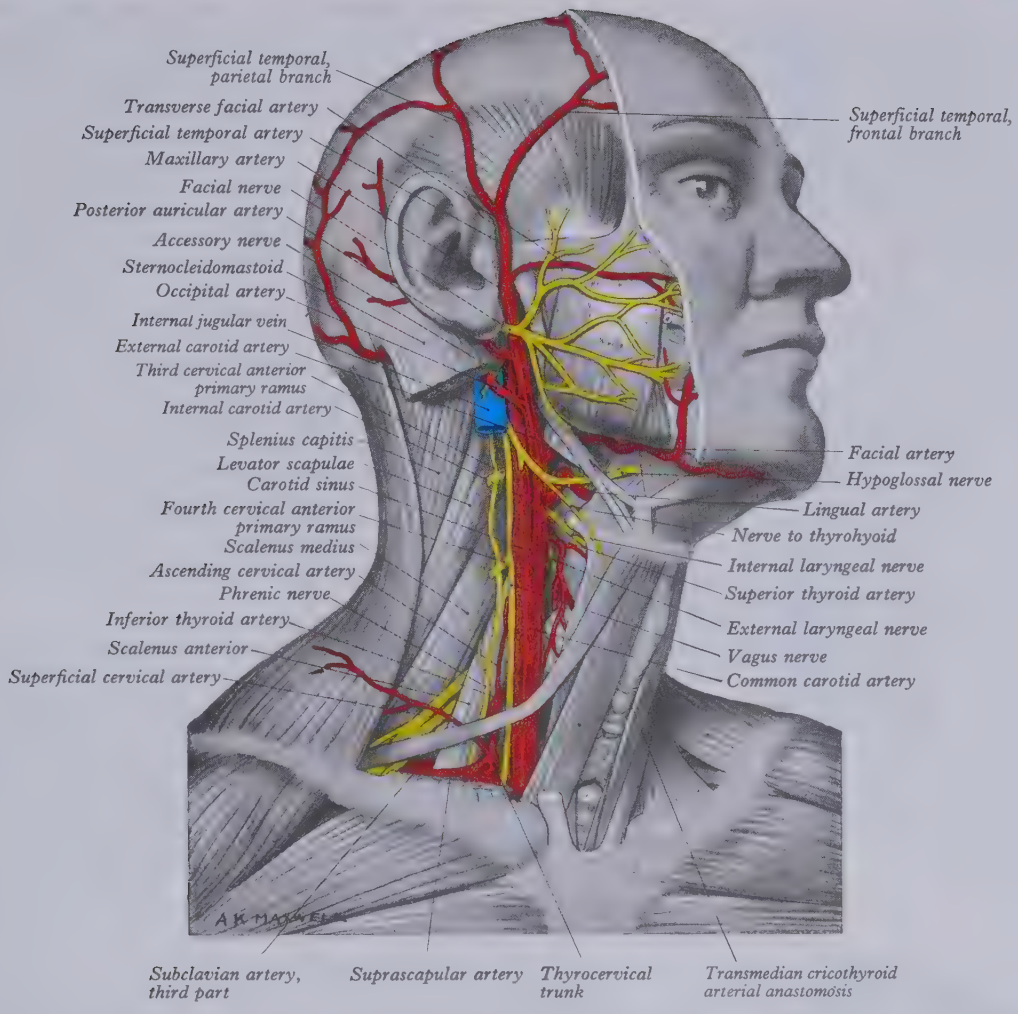
THE CAROTID SYSTEM OF ARTERIES

The common carotid arteries are the main supply to the head and neck; they ascend to the level of the thyroid cartilage's upper border, where each divides into: an external carotid, supplying the exterior of the head, face and most of the neck; and an internal carotid, supplying the cranial and orbital contents.

The common and internal carotid arteries, with veins and nerves accompanying them, lie in a cleft bounded posteriorly by cervical transverse processes and attached muscles, medially by the trachea, oesophagus, thyroid gland, larynx and pharyngeal constrictors, anterolaterally by the sternocleidomastoid with, at different levels, omohyoid, sternohyoid, sternothyroid, digastric and stylohyoid muscles. (Other styloid structures have a varying relationship depending on the length of the styloid process.)

Common Carotid Arteries

These differ in length and origin, the *right*, exclusively cervical, begining at the brachiocephalic bifurcation behind the right sterno-clavicular joint, the *left* at the highest part of the aortic arch immediately posterolateral to the brachiocephalic trunk and therefore having both thoracic and cervical parts.



The **thoracic part of the left common carotid artery** (**6**.66,67) ascends until level with the left sternoclavicular joint, where it enters the neck. It lies at first in front of the trachea, then later inclines to its left side.

Relations. *Anterior* are the sternohyoid and sternothyroid, the anterior parts of the left pleura and lung, the left brachiocephalic vein and the thymic remnants, separating it from the manubrium; *posterior* are the trachea, left subclavian artery, left edge of the oesophagus, left recurrent laryngeal nerve and thoracic duct. *Right lateral* are (below) the brachiocephalic trunk and (above) the trachea, inferior thyroid veins and thymic remains; *left lateral* are the left vagus and phrenic nerves, left pleura and lung.

Cervical parts of both common carotid arteries have similar courses (**6**.66,67,69). Each ascends, diverging laterally from behind the sternoclavicular joint to the thyroid cartilage's upper border, where it divides into external and internal carotid arteries (**6**.68, 70). At its division the vessel has a dilatation, the *carotid sinus*, usually involving or restricted to the beginning of the *internal* carotid; the tunica media is thinner here and the tunica adventitia, relatively thick, contains many receptor endings of the glossopharyngeal nerve (p. 1113); these show some degeneration and regeneration, suggesting continuous turnover, which may accelerate in the elderly (Rusager & Weddell 1962). The sinus is responsive to changes in arterial blood pressure, leading to reflex haemodynamic modification. Its situation on the brain's main artery is appropriate to its role as a baroreceptor in control of intracranial pressure. The *carotid body*, behind the common carotid bifurcation, a small, reddish-brown structure, is a 'chemoreceptor'. (See Adams 1958 for a comparative account and p. 1473 for modern views on its ultrastructure and modus operandi.)

In the lower neck the common carotids are separated by a narrow gap into which projects the trachea; above this the thyroid gland, larynx and pharynx project between them. Each is contained in a carotid sheath (p. 582), continuous with the deep cervical fascia and of loose texture, though that actually around the artery is denser. This sheath encloses also the internal jugular vein and vagus nerve, the vein lateral to the artery, the nerve between them and posterior to both. The superior root of the ansa cervicalis is embedded in its anterior wall.

Relations. The artery is crossed *anterolaterally*, level with the cricoid cartilage, by the intermediate tendon (sometimes the

6.68 Dissection of the right side of the neck, showing the carotid and subclavian arteries and their branches. The parotid and submandibular glands have been removed together with the lower part of the internal jugular vein, most of the sternocleidomastoid and the upper parts of the stylohyoid and posterior belly of the digastric.

superior belly) of omohyoid. Below this muscle it is sited deeply, covered by skin, superficial fascia, platysma, deep cervical fascia, the sternocleidomastoid, sternohyoid and sternothyroid. Above the omohyoid it is more superficial, covered merely by skin, superficial fascia, platysma, deep cervical fascia and the medial margin of sternocleidomastoid and is crossed obliquely from its medial to lateral side by the sternocleidomastoid branch of the superior thyroid artery. In front of, or embedded in, the carotid sheath is the superior root of the ansa cervicalis, joined by its inferior root from the second and third cervical spinal nerves and crossing the vessel obliquely. The superior thyroid vein usually crosses near the artery's end, the middle thyroid vein a little below cricoid level; the anterior jugular vein crosses it above the clavicle, separated by sternohyoid and sternothyroid. *Posterior* are the fourth to sixth cervical transverse processes, and attached to them the longus colli and longus capitis and tendinous slips of scalenus anterior; the sympathetic trunk and ascending cervical artery are between the common carotid artery and the muscles. Below the level of the sixth cervical vertebra the artery is in an angle between the scalenus anterior and longus colli, anterior to the vertebral vessels, inferior thyroid and subclavian arteries, sympathetic trunk and, on the left, thoracic duct. *Medial* are the oesophagus, trachea, inferior thyroid artery and recurrent laryngeal nerve and, at a higher level, the larynx and pharynx; the thyroid gland overlaps it anteromedially. *Lateral* is the internal jugular vein; *posterolaterally* in the angle between artery and vein is the vagus nerve.

On the right, low in the neck, the recurrent laryngeal nerve crosses obliquely behind the artery; the right internal jugular vein diverges from it below but the left vein approaches and often overlaps its artery.

Variations. In about 12% the *right* common carotid artery arises above the level of the sternoclavicular joint or it may be a separate branch from the aorta; again it may arise with its fellow. The *left* common carotid artery varies in origin more than the right; it may arise with the brachiocephalic (see also p. 734). Division of the common carotid may occur higher, near the level of the hyoid bone, more rarely at a lower level alongside the larynx. Very rarely it ascends without division, either the external or internal carotid being absent. Rarely, also, it is replaced by separate external and internal carotid arteries arising directly from the aorta, on one side or bilaterally.

The common carotid artery usually has no branches but the vertebral, superior thyroid (**6**.66) or its laryngeal branch, ascending pharyngeal, inferior thyroid or occipital may be branches of it.

The External Carotid Artery

This artery (**6**.45,53) begins lateral to the thyroid cartilage's upper border, level with the disc between the third and fourth cervical vertebrae. A little curved, and with a gentle spiral, it first ascends slightly forwards and then inclines backwards and a little laterally, to pass midway between the mastoid tip and mandibular angle where, in the substance of the parotid gland behind the mandible's neck, it divides into the superficial temporal and maxillary arteries. It diminishes rapidly in calibre due to its many

large branches. In children it is smaller than the internal carotid but in adults the two are of almost equal size. At its origin, it is in the carotid triangle and lies anteromedial to the internal carotid but becomes anterior, and then lateral to this as it ascends. At mandibular levels the styloid process and its attached structures intervene between the vessels, the internal carotid being deep and the external carotid superficial to the styloid. The carotid triangle may be *seen* as a triangular depression in the living neck; a finger tip placed here perceives *powerful arterial pulsation*. Beneath the finger lie the termination of the common carotid, the origins of external and internal carotids and the stems of the external carotid's initial branches.

Relations. *Superficial* to the artery *in the carotid triangle* are: the skin, superficial fascia, the loop between the facial nerve's cervical branch and the transverse cutaneous nerve of the neck, deep fascia and the anterior margin of sternocleidomastoid; it is *crossed* by the hypoglossal nerve and its vena comitans and by the lingual (common), facial and sometimes the superior thyroid veins. Leaving the triangle it is crossed by the posterior belly of the digastric and stylohyoid and ascends between this muscle and the posteromedial surface of the parotid gland, which it enters, lying medial to the facial nerve and the junction of the superficial temporal and maxillary veins. *Medial* to the artery are at first the pharyngeal wall, superior laryngeal nerve and ascending pharyngeal artery; at a higher level the internal carotid artery is separated from the external by the styloid process, styloglossus and stylopharyngeus, glossopharyngeal nerve, pharyngeal branch of vagus nerve and part of the parotid gland (**6**.69). The relation of the artery to the parotid gland is controversial, many clinicians asserting that it is often *medial* to it rather than *in* it. A recent study (Guffarth & Graumann 1975), a short series of dissections, indicated that both relations occur at about equal frequency.

Branches of the external carotid artery (**6**.68,72) are:

1. Superior thyroid
2. Ascending pharyngeal
3. Lingual
4. Facial
5. Occipital
6. Posterior auricular
7. Superficial temporal
8. Maxillary

1. The Superior Thyroid Artery (6.68)

This arises from the front of the external carotid artery just below the level of the greater cornu of the hyoid, dividing into terminal branches at the apex of the thyroid lobe, but it may issue from the common carotid (**6**.66).

Relations. From an origin under the sternocleidomastoid it descends forwards in the carotid triangle along the lateral border of the thyrohyoid, covered by skin, platysma and fasciae and then deep to the omohyoid, sternohyoid and sternothyroid. *Medial* are the constrictor pharyngis inferior and external laryngeal nerve; the nerve is often posteromedial.

Branches. It supplies the adjacent muscles and thyroid gland; it anastomoses with its fellow and the inferior thyroid arteries. Glandular rami are *anterior*, along the medial side of the upper pole of the lateral lobe, supplying mainly the anterior surface, a branch crossing above the isthmus to anastomose with its fellow; and *posterior* descending on the posterior border, supplying the medial and lateral surfaces and anastomosing with the inferior thyroid artery. Sometimes a lateral branch supplies the lateral surface. The artery also has named branches: infrahyoid, superior laryngeal, sternocleidomastoid and cricothyroid.

The infrahyoid artery is small, runs along the lower border of the hyoid deep to thyrohyoid and anastomoses with its fellow.

The sternocleidomastoid artery, frequently arising from the *external* carotid, descends laterally across the carotid sheath.

The superior laryngeal artery accompanies the internal laryngeal nerve deep to the thyrohyoid, pierces the lower part of the thyrohyoid membrane, supplies the larynx and anastomoses with its fellow and the inferior laryngeal branch of the inferior thyroid.

The cricothyroid artery is small and crosses high on the cricothyroid ligament, communicating with its fellow.

2. The Ascending Pharyngeal Artery (6.79)

This, the smallest branch of the external carotid, is a long, slender vessel, arising near the external carotid's origin and ascending between the internal carotid artery and pharynx to the cranial base; it is crossed by the styloglossus and stylopharyngeus with longus capitis posterior to it; it anastomoses with the facial artery's ascending palatine branch. Its named branches are: pharyngeal, inferior tympanic and meningeal.

Three or four **pharyngeal arteries** supply the constrictors and stylopharyngeus. A variable ramus supplies the palate and may replace the facial's ascending palatine branch; it descends forwards between the superior border of the superior constrictor and the levator veli palatini, accompanying the latter to the soft palate; it gives minute branches to the tonsil and one to the auditory tube.

The inferior tympanic artery, a small branch, traverses the temporal canaliculus for the tympanic branch of the glossopharyngeal nerve to supply the tympanic cavity's medial wall.

The meningeal branches are small vessels to the nerves, dura mater and adjacent bone, entering the cranium through the foramen lacerum, jugular foramen and hypoglossal canal. They supply the nerves in these passages and their surrounding tissues.

Numerous small rami supply the longi capitis et colli, the sympathetic trunk, hypoglossal, glossopharyngeal and vagus nerves and cervical lymph nodes, anastomosing with rami of the ascending cervical and vertebral arteries.

3. The Lingual Artery (6.68)

This vessel, bringing the chief supply to the tongue and buccal floor, arises anteromedially from the external carotid opposite the tip of the hyoid's greater cornu, between the superior thyroid and facial arteries. Ascending medially at first, it loops down and forwards to the greater cornu, passes medial to the posterior border of the hyoglossus and horizontally forwards deep to it and, ascending again almost vertically, courses sinuously forwards on the tongue's inferior surface as far as its tip (**6**.71). Its relation to the hyoglossus naturally divides the vessel into descriptive 'thirds'.

Relations. In its *first part* the lingual artery is in the carotid triangle; superficial to it are the skin, fascia and platysma; the middle pharyngeal constrictor is medial. It ascends a little medially, then descends to the level of the hyoid bone, its loop crossed externally by the hypoglossal nerve. Its *second part* passes along the hyoid's upper border, deep to the hyoglossus, the tendon of digastric, stylohyoid, the lower part of the submandibular gland and posterior part of the mylohyoid; the hyoglossus separates it from the hypoglossal nerve and its vena comitans; here its medial aspect adjoins the middle constrictor and crosses the stylohyoid ligament; it is accompanied by lingual veins (p. 797). The *third part* is the *arteria profunda linguae*, which turns upward near the anterior border of the hyoglossus, passing forwards close to the inferior lingual surface near the frenulum, accompanied by the lingual nerve. Medial to it is the genioglossus, lateral to it the longitudinalis linguae inferior, below it the lingual mucous membrane. Near the lingual tip it anastomoses with its fellow.

Branches of the lingual artery:

The suprahyoid artery is very small, it runs along the hyoid's upper border to anastomose with the contralateral artery.

The dorsal lingual arteries, usually two or three small vessels, arise medial to the hyoglossus, ascending to the posterior part of the lingual dorsum to supply its mucous membrane, palatoglossal arch, tonsil, soft palate and epiglottis; they anastomose with the opposite vessels.

The sublingual artery arises at the anterior margin of hyoglossus and goes forward between the genioglossus and mylohyoid to the sublingual gland, supplying this, the mylohyoid and the buccal and gingival mucous membranes. One ramus courses through the mandibular gingiva to anastomose with its fellow; another pierces the mylohyoid and joins the submental branches of the facial artery.

The lingual artery often arises with the facial or, less often, with the superior thyroid artery. It may be replaced by a ramus of the maxillary artery.

4. The Facial Artery (6.72,79)

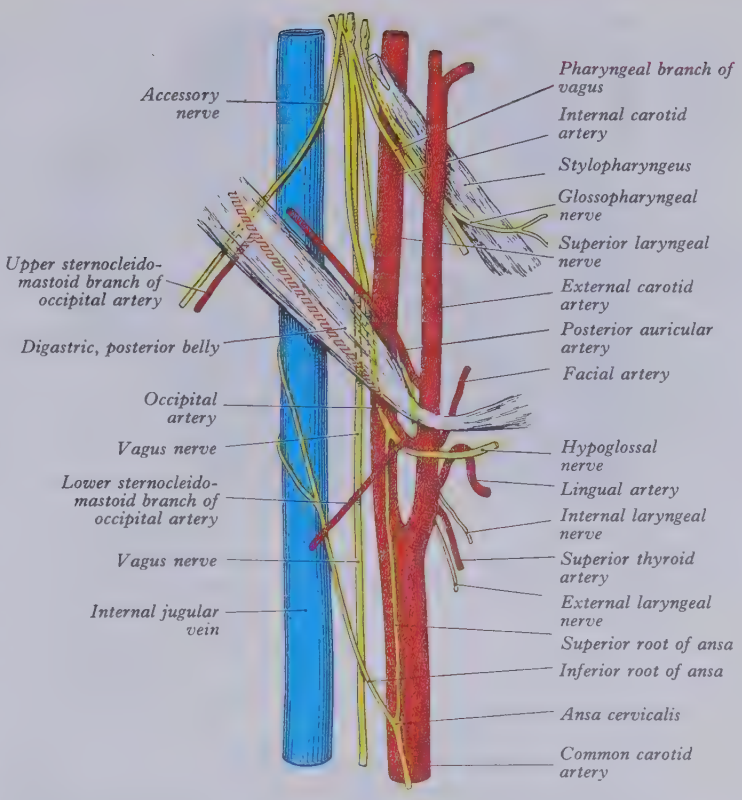
This arises anteriorly from the external carotid in the carotid triangle above the lingual artery and immediately above the

greater cornu of the hyoid bone. Medial to the mandibular ramus it arches upwards and grooves the submandibular gland's posterior aspect; it then turns down again between the gland and the medial pterygoid. Reaching the surface of the mandible it curves round its inferior border anterior to the masseter to enter the face. Here it ascends forwards across the mandible and buccinator to traverse a cleft in the modiolus (p. 574) near the buccal angle. It then ascends the side of the nose and ends at the medial palpebral commissure, supplying the lacrimal sac and joining the dorsal nasal branch of the ophthalmic artery. The artery is very sinuous throughout: in the neck perhaps to adapt to the movements of the pharynx during deglutition and on the face to movements of the mandible, lips and cheeks. Distal to its superior branch (**6**.72) it is termed the *angular artery*. Facial artery pulsation is most palpable where it crosses the mandibular base and between thumb and finger, near the buccal angle.

Relations. In the neck, at its origin, the artery is superficial, covered by the skin, platysma and fasciae and often crossed by the hypoglossal nerve. It runs up and forwards, deep to the digastric and the stylohyoid and posterior part of the submandibular gland. At first on the middle pharyngeal constrictor, it may reach the lateral surface of the styloglossus, separated there from the tonsil only by this muscle and the lingual fibres of the superior constrictor. Thence it descends to the lower border of the mandible in a lateral groove on the submandibular gland. *In the face*, where, as noted, its pulse can be felt as it crosses the mandible, it is superficial and at first just beneath the platysma. It is covered by skin, the fat of the cheek and near the buccal angle by superficial modiolar muscles (p. 574). Deep to it are the buccinator and levator anguli oris; it may pass over or through the levator labii superioris. Terminally it is embedded in the levator labii superioris alaeque nasi. The facial vein is posterior, in a more direct course across the face; at the anterior border of the masseter the two are in contact; in the neck the vein is superficial. Branches of the facial nerve cross forwards over the artery, which supplies the muscles and tissues of the face, submandibular gland, tonsil and soft palate. Its branches are cervical and facial.

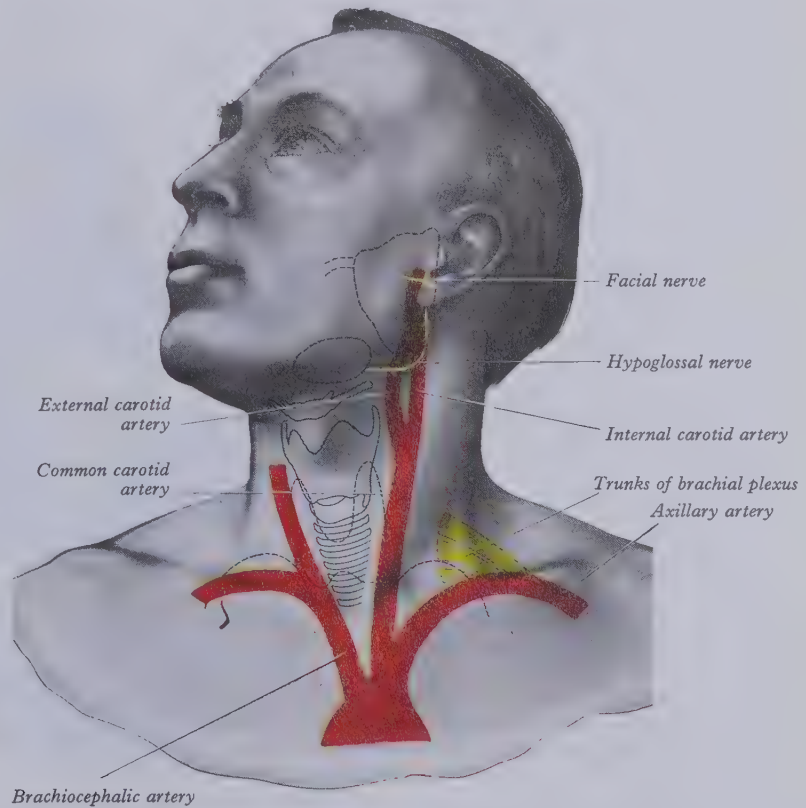
Cervical Branches of the Facial Artery

The ascending palatine artery (**6**.79), starting near the facial's origin, ascends between the styloglossus and stylo-pharyngeus to the side of the pharynx, along which it ascends between the superior constrictor and the medial pterygoid towards the cranial base. Near the levator veli palatini it bifurcates: one branch follows this muscle, winds over the upper border of the superior constrictor, supplies the soft palate and anastomoses with its fellow and the greater palatine branch of the maxillary artery; the other branch pierces the superior constrictor to supply the tonsil and pharyngotympanic tube, joining with tonsillar and ascending pharyngeal arteries.



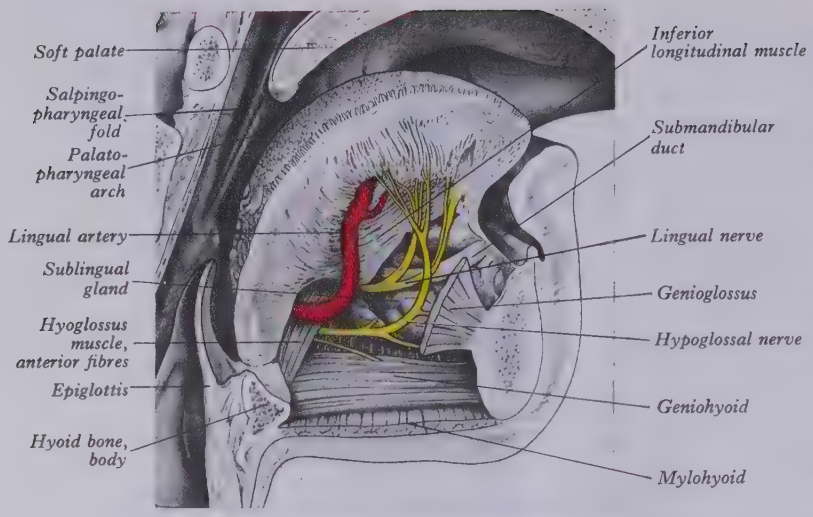
The tonsillar artery, the main supply to the tonsil, sometimes arises from the ascending palatine, though usually separate; it ascends between the medial pterygoid and styloglossus and at the latter's upper border it perforates the superior constrictor and ramifies in the tonsil and posterior lingual musculature.

The glandular branches, three or four large vessels, supply the submandibular salivary gland and lymph nodes, adjacent muscles and skin.



The submental artery, the largest cervical branch, arises as the facial quits the submandibular gland, turning forwards on the mylohyoid (**6**.72) below the mandible. It supplies the surrounding muscles and anastomoses with a sublingual branch of the lingual and mylohyoid branch of the inferior alveolar arteries; at the chin it ascends the mandible, dividing into superficial and deep branches which anastomose with the inferior labial and mental arteries, supplying the chin and lower lip.

Facial Branches of the Facial Artery



The inferior labial artery (**6**.72), arising near the buccal angle, passes up and forwards under the depressor anguli oris, penetrates the orbicularis oris and runs sinuously near the lower lip's margin between the muscle and the mucous membrane. It supplies the inferior labial glands, mucous membrane and

6.69 The structures crossing the internal jugular vein and carotid arteries and those intervening between the external and internal carotid arteries.

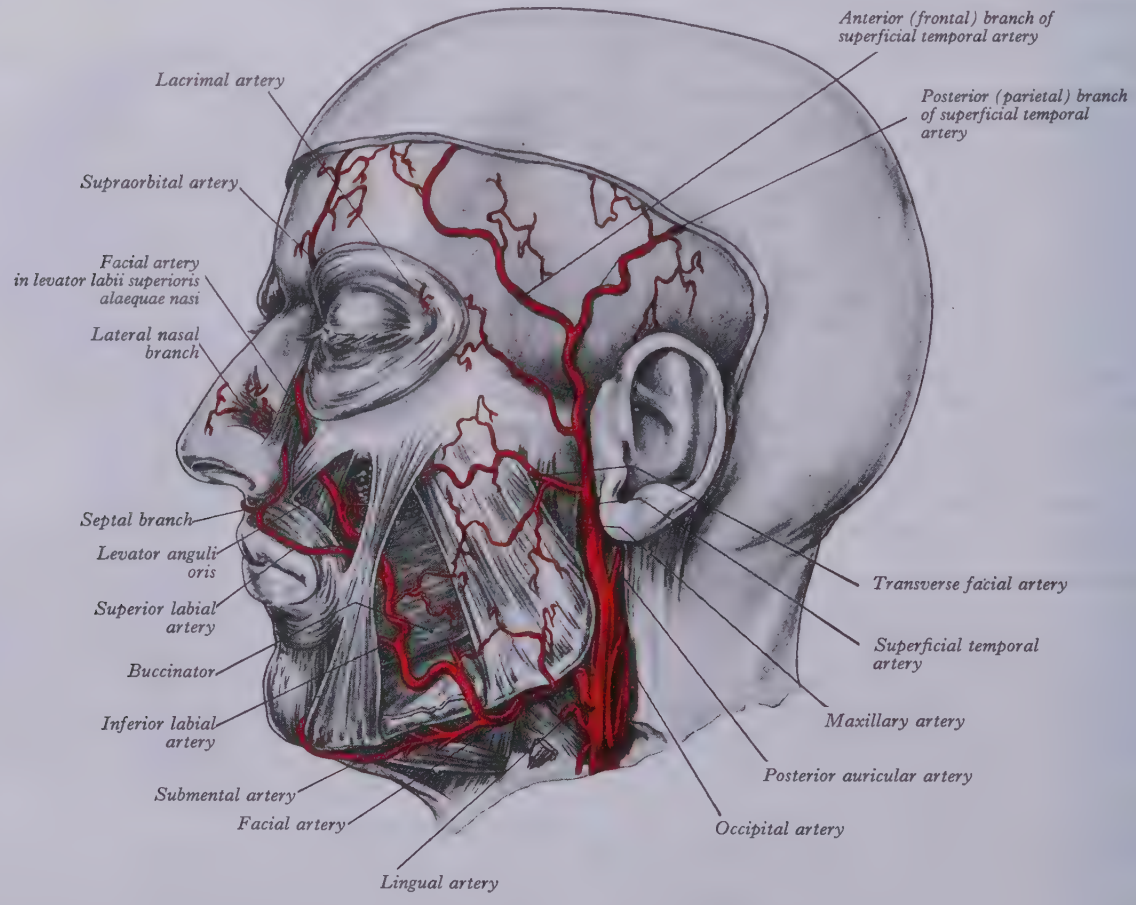
6.70 The surface projection of some of the larger structures in the face and neck. Note that the parotid gland and duct, the submandibular and thyroid glands and the apices of the lungs are shown as interrupted outlines; the hyoid bone and the thyroid, cricoid and tracheal cartilages are indicated by continuous outlines.

6.71 Dissection of the left half of the tongue from the medial side, exposing the end of the second part and the beginning of the third part of the left lingual artery and adjoining structures, in an edentulous subject.

muscles, anastomosing with its fellow and the mental branch of the inferior alveolar artery.

The superior labial artery (6.72), larger and more tortuous than the inferior, has a similar course along the superior labial margin between the mucous membrane and the orbicularis oris; it anastomoses with its fellow, supplying the upper lip, a *septal branch*, which ramifies antero-inferiorly in the nasal septum, and an *alar branch*.

The lateral nasal artery (6.72), branching from the facial as it ascends the side of the nose, supplies the nasal ala and dorsum, anastomosing with its fellow, the septal and alar branches of the superior labial, dorsal nasal ramus of the ophthalmic and infra-orbital branch of the maxillary artery. It may be replaced by several small rami or arise from the superior labial, diverging from its septal branch (as in 6.72).



Facial anastomoses are numerous not only with corresponding contralateral rami but also: *in the neck*, with the sublingual branch of the lingual, ascending pharyngeal and palatine branch of the maxillary; *on the face*, with the mental branch of the inferior alveolar, transverse facial branch of the superficial temporal, infra-orbital branch of the maxillary and dorsal nasal branch of the ophthalmic. The anastomoses in the lips are by main trunks, an important fact in labial injuries.

Variations. The facial artery may arise with the lingual, as a *linguo-facial trunk*. It varies in size and supply to the face: it may end as the submental artery and often extends only to the buccal angle. The deficiency is then filled by rami of neighbouring arteries. In 110 human fetuses a common linguo-facial trunk occurred in 43%; in 42% the facial did not reach the medial orbital angle, ending as a superior (20%) or inferior (22%) labial artery (Kozielec & Jozwa 1977).

5. The Occipital Artery (6.73)

This artery arises from the back of the external carotid, opposite the facial; at first medial to the posterior belly of the digastric, it ends posteriorly in the scalp.

Course and relations. At its origin, the artery is crossed superficially by the hypoglossal nerve, winding round it from behind. It goes back, up and deep to the posterior digastric belly, crossing the internal carotid, internal jugular vein, hypoglossal, vagal and accessory nerves (6.73). Between the transverse process of the atlas and temporal mastoid process it reaches the lateral border of

6.72 The arteries of the left side of the face and their main branches. Many of the post-modiolar muscles and part of the modiolus (through which the facial artery passes) have been resected. Note the less usual origin of the lateral nasal branch in this specimen.

the rectus capitis lateralis. It then runs in the temporal bone's occipital groove, medial to the mastoid process and attachments of the sternocleidomastoid, splenius capitis, longissimus capitis and digastric, lying successively on the rectus capitis lateralis, obliquus superior and semispinalis capitis. Finally, it turns up to pierce the fascia connecting the cranial attachments of the trapezius and sternocleidomastoid, ascends tortuously in the dense superficial fascia of the scalp and divides into many branches. Its terminal part is accompanied by the greater occipital nerve and its branches are as follows.

Two sternocleidomastoid branches are usual, *the lower* arising near the origin of the occipital but sometimes directly from the external carotid. It descends backwards over the hypoglossal nerve and internal jugular vein, enters the sternocleidomastoid, and anastomoses with the sternocleidomastoid branch of the superior thyroid. The *upper branch* arises as the occipital crosses the accessory nerve, running down and backwards superficial to the internal jugular vein. It enters the deep surface of the sternocleidomastoid with the accessory nerve.

The mastoid artery, small in size and sometimes absent, enters the cranial cavity via the mastoid foramen, supplying the mastoid air cells and dura mater.

The stylomastoid artery branches from the occipital in two-thirds of subjects (p. 740).

An auricular branch supplies the medial aspect of the auricle, anastomosing with the posterior auricular artery.

Muscular branches supply the digastric, stylohyoid, splenius, longissimus capitis and neighbouring muscles.

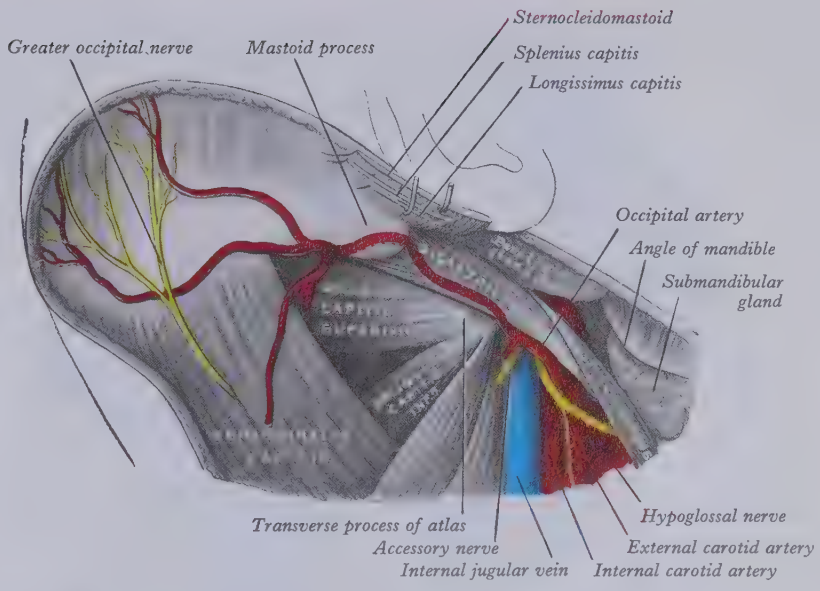
A descending branch (**6**.73) arises where the occipital adjoins the obliquus superior, dividing into superficial and deep rami. The *superficial ramus* passes deep to the splenius, anastomosing with the superficial branch of the transverse cervical artery; the *deep ramus* descends between the semispinales capitis et cervicis, anastomosing with both the vertebral and the deep cervical artery (from the costocervical trunk) (**6**.79).

Meningeal branches enter the cranium via the jugular foramen and condylar canal to supply the dura mater and bone of the posterior cranial fossa and the caudal four cranial nerves.

Occipital branches, tortuous terminal rami distributed to the scalp as far as the vertex, run between the skin and the occipital belly of the occipitofrontalis, anastomosing with the opposite occipital, posterior auricular and temporal arteries and supplying the occipital belly of the occipitofrontalis, skin and pericranium. One may have a meningeal ramus, traversing the parietal foramen.

6. The Posterior Auricular Artery (**6**.72)

This small vessel branches posteriorly from the external carotid just above the digastric and stylohoid. It ascends between the parotid gland and the styloid process to the groove between the auricular cartilage and the mastoid process, dividing into auricular and occipital branches. As well as supplying the digastric, stylohyoid, sternocleidomastoid, and parotid gland, the posterior auricular artery has three named branches:



The stylomastoid artery, an indirect branch of the posterior auricular in about a third of subjects (Blunt 1954), enters the stylomastoid foramen to supply the facial nerve, tympanic cavity, mastoid antrum and air cells, and semicircular canals. In the young its posterior tympanic ramus forms a circular anastomosis with the anterior tympanic artery (p. 740).

The auricular branch, ascending deep to auricularis posterior, ramifies on the cranial aspect of the auricle; some branches pierce this, others curve round it to supply its lateral aspect.

The occipital branch passes laterally across the mastoid process, turning back over the sternocleidomastoid to supply the occipital belly of the occipitofrontalis and scalp above and behind the ear; it anastomoses with the occipital artery.

7. The Superficial Temporal Artery (**6**.68)

This, the smaller terminal branch of the external carotid, begins in the parotid gland behind the mandible's neck, crosses the posterior root of the zygomatic process of the temporal bone and about 5 cm above this divides into anterior and posterior branches.

6.73 Dissection to show the course of the occipital artery. The upper and lower sternocleidomastoid branches of the artery have been transected and are not labelled.

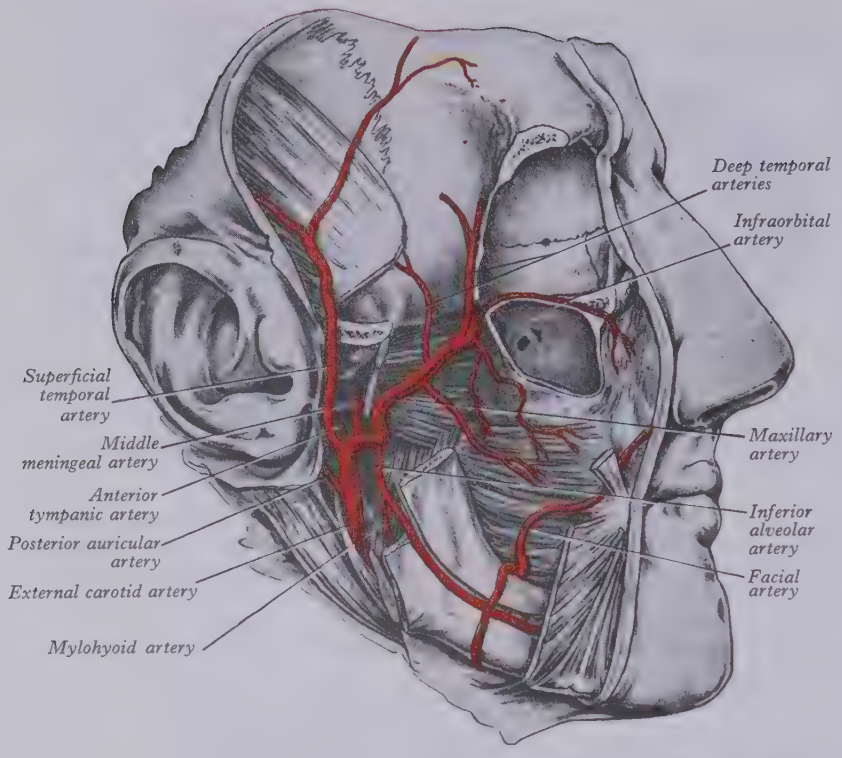
Relations. As it crosses the zygoma it is covered by the auricularis anterior; in the parotid gland temporal and zygomatic branches of the facial nerve cross it; in the scalp it is accompanied by corresponding veins, and just posterior to it lies the auriculotemporal nerve.

Branches. The superficial temporal supplies the parotid gland, temporomandibular joint and masseter and it also has several named branches:

The transverse facial artery (**6**.72) arises before the superficial temporal emerges from the parotid gland; it traverses the gland, crosses the masseter between the parotid duct and the zygomatic arch, accompanied by one or two facial nerve branches, and divides into numerous rami supplying the parotid gland and duct, masseter and skin, anastomosing with the facial, masseteric, buccal, lacrimal and infraorbital arteries.

The anterior auricular branches are distributed to the lobule and anterior part of the auricle and the external acoustic meatus.

The zygomatico-orbital artery, sometimes from the middle temporal, skirts the upper border of the zygomatic arch between two layers of temporal fascia to the lateral orbital angle; supplying the orbicularis oculi, it anastomoses with the lacrimal and palpebral rami of the ophthalmic artery.



The middle temporal artery branches just above the zygomatic arch, perforates the temporal fascia, supplies the temporalis and anastomoses with the deep temporal branches of the maxillary.

The frontal (anterior) branch meanders towards the frontal tuberosity, supplying muscles, skin and pericranium in this region; it anastomoses with its fellow and the supraorbital and supratrochlear arteries.

The parietal (posterior) branch, larger than the frontal, curves up and back superficial to the temporal fascia, anastomosing with its fellow and the posterior auricular and occipital arteries.

Variation in the superficial temporal artery is largely in the relative sizes of the frontal, parietal and transverse facial branches; the first two may be absent, the transverse facial may replace a shortened facial artery. Variations in fetal material have been described by Kozielec & Jozwa (1976).

Applied Anatomy. Crossing the zygomatic process the artery is palpable through skin and fascia and is easily compressed here to control temporal haemorrhage. This vessel and other arteries supplying the scalp from below are well protected by dense tissue. Rarely are all implicated in a scalping injury and its branches

6.74 The right maxillary artery. An extensive dissection has been carried out, involving the removal of the parotid gland, the zygomatic arch, part of the ramus of the mandible, the lateral walls of the orbit and maxillary sinus and the orbital contents.

anastomose so freely that a partially detached scalp may be replaced with reasonable hope of success as long as one vessel is intact. In craniotomy, incisions should be convex upwards to include the superficial temporal artery in the flap. In carotid angiograms branches of the superficial temporal and middle meningeal arteries are superimposed, but are distinguishable by the straighter course, lack of anastomoses and narrower calibre in the meningeal rami (Domnić-Stošić & Jeličić 1974).

8. The Maxillary (Internal Maxillary) Artery (**6**.74)

This, the larger terminal branch of the external carotid, arises behind the mandibular neck, at first embedded in the parotid gland; it then passes medial to the mandibular neck and superficial or deep to the lower head of the lateral pterygoid to reach the pterygopalatine fossa, usually passing between the two heads of the lateral pterygoid. It has mandibular, pterygoid and pterygopalatine segments, related sequentially to bone, muscle and bone, a useful indication of its branches.

The *first, mandibular part* is horizontal and passes between the mandible's neck and the sphenomandibular ligament, parallel with and slightly below the auriculotemporal nerve; it crosses the inferior alveolar nerve and skirts the lower border of the lateral pterygoid.

The *second, pterygoid part* ascends obliquely forwards medial to the temporalis and superficial to the lower head of the lateral pterygoid; it is often deep to the latter, lying between it and branches of the mandibular nerve and it may then project as a lateral loop between the two parts of the lateral pterygoid.

The *third, pterygopalatine part* passes between the heads of the lateral pterygoid and through the pterygomaxillary fissure into the pterygopalatine fossa, where it is situated anterior to the pterygopalatine ganglion.

Branches. The artery is distributed to the mandible, maxilla, teeth, muscles of mastication, palate, nose and cranial dura mater. Its branches form three groups, corresponding with its parts.

Branches of the First Part (**6**.74). **The deep auricular artery**, often arising with the anterior tympanic, ascends in the parotid gland behind the temporomandibular joint, pierces the cartilaginous or osseous wall of the external acoustic meatus and supplies its cuticular lining, the exterior of the tympanic membrane and the joint.

The anterior tympanic artery ascends behind the temporomandibular joint, enters the tympanic cavity through the petrotympanic fissure and ramifies on the interior of the tympanic membrane, forming a vascular circle around it with the posterior tympanic branch of the stylomastoid; it anastomoses with twigs of the artery of the pterygoid canal and caroticotympanic branches of the internal carotid artery in the mucosa of the tympanic cavity.

The middle meningeal artery, largest of the meningeal arteries, ascends between the sphenomandibular ligament and lateral pterygoid, passes between the roots of the auriculotemporal nerve and may lie lateral to the tensor veli palatini before entering the cranial cavity through the foramen spinosum. It then runs in an anterolateral groove on the squamous part of the temporal bone, dividing into frontal and parietal branches. The *frontal (anterior) branch*, the larger, crosses the greater wing of the sphenoid, reaches a groove or canal in the parietal's sphenoidal angle and divides into branches between the dura mater and cranium, some ascending to the vertex, others to the occipital region. One ascending branch grooves the parietal bone about 1.5 cm behind the coronal suture, corresponding approximately to the precentral sulcus. The *parietal (posterior) branch* curves back on the squamous temporal bone, reaching the lower border of the parietal anterior to its mastoid angle and dividing to supply the posterior parts of the dura mater and cranium. These branches anastomose with their fellows and with the anterior and posterior meningeal arteries.

In the cranial cavity the artery has the following branches: (1) Numerous *ganglionic branches* supply the trigeminal ganglion and roots. (2) A *petrosal branch* enters the hiatus for the greater petrosal nerve and supplies the facial nerve, ganglion and tympanic cavity, anastomosing with the stylomastoid artery (pp. 739, 740). (3) A *superior tympanic artery* runs in the canal for the tensor tympani, supplying both muscle and the canal's lining membrane. (4) *Temporal branches* traverse minute foramina in the sphenoid's greater wing and anastomose with deep temporal arteries. (5) An *anastomotic branch* (p. 746) enters the orbit lateral in the superior orbital fissure, anastomosing with a recurrent branch of the lacrimal artery; enlargement of this anastomosis explains an occasional origin of the lacrimal from the middle meningeal artery. Apart from these and a supply to the dura mater, the middle meningeal artery is predominantly periosteal, supplying bone and red bone marrow.

Surface Anatomy (**6**.119). The *middle meningeal artery* enters the skull medial to the zygoma's midpoint (**6**.119), dividing 2 cm above this. From here the frontal branch runs first up and forwards to the pterion and then up and back towards a point midway between the inion and nasion. The parietal branch runs up and back towards the lambda.

Applied Anatomy. The middle meningeal artery may be torn in temporal fractures or by injuries separating the dura mater from the bone, followed by haemorrhage between them. Trephining may be necessary to reduce cerebral compression.

The accessory meningeal artery may arise from the maxillary or the middle meningeal. It enters the cranial cavity through the foramen ovale, supplying the trigeminal ganglion, dura mater and bone, but its main distribution is *extracranial* (Baumel & Beard 1961), principally the medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, sphenoid bone (greater wing and pterygoid processes), mandibular nerve and otic ganglion. It is sometimes replaced by separate small arteries.

The inferior alveolar (dental) artery descends posterior to the inferior alveolar nerve, to the mandibular foramen. Here it is between bone laterally and the sphenomandibular ligament medially. Before entering the foramen it has a *mylohyoid branch*, which pierces the sphenomandibular ligament to descend with the mylohyoid nerve in its groove on the mandibular ramus; it ramifies superficially on the muscle and anastomoses with the facial's submental branch. The inferior alveolar artery then traverses the mandibular canal with the inferior alveolar nerve and divides into the incisor and mental branches near the first

premolar. The *incisor* branch continues below the incisor teeth to the midline, where it anastomoses with its fellow. In the canal the arteries supply the mandible, tooth sockets and teeth by rami entering minute holes at apices of their roots to supply the pulp. The *mental branch* leaves the mental foramen, supplies the chin and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery has a *lingual* branch, which descends with the lingual nerve to supply the buccal mucous membrane.

Branches of the Second Part (6.74). **Deep temporal branches**, anterior and posterior, ascend between the temporalis and bone, supplying mainly the former. They anastomose with the middle temporal artery. The anterior connects with the lacrimal by small rami perforating the zygomatic bone and greater wing of the sphenoid.

Pterygoid branches, irregular in number and origin, supply the pterygoid muscles.

The masseteric artery is small and with the masseteric nerve passes behind the tendon of temporalis through the mandibular incisure (notch) to the deep surface of masseter, in which it anastomoses with the masseteric branches of the facial and transverse facial arteries.

The buccal artery runs obliquely forwards with the buccal nerve between the medial pterygoid and the attachment of the temporalis to supply the external surface of the buccinator (and through it the mucosa), anastomosing with rami of the facial and infraorbital arteries.

Branches of the Third Part. **The posterior superior alveolar (dental) artery** leaves the maxillary artery as it enters the pterygopalatine fossa. Descending on the maxilla's infratemporal surface, it divides, some branches entering the alveolar canals to supply molar and premolar teeth and the maxillary sinus, others continuing over the alveolar process to supply the gingivae.

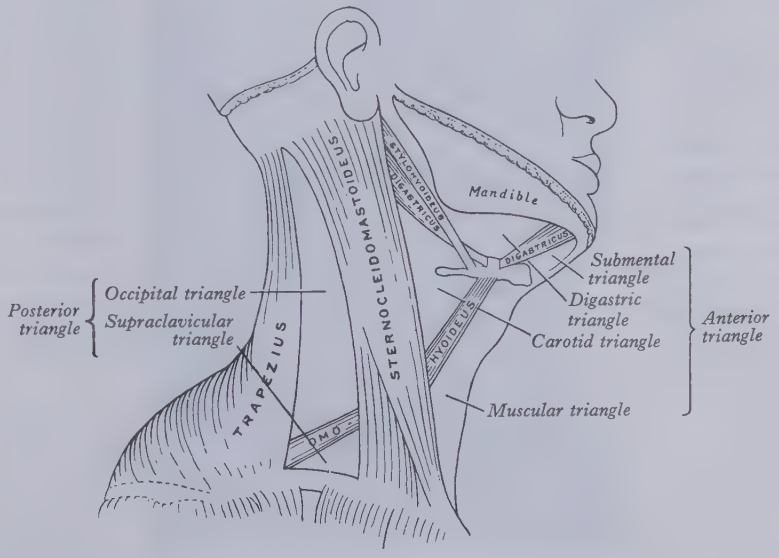
The infraorbital artery often arises with the posterior superior alveolar, entering the orbit posteriorly through the inferior orbital fissure, to run in the infraorbital groove and canal with the infraorbital nerve, both emerging on the face via the infraorbital foramen, deep to the levator labii superioris. In the canal it has (1) *orbital branches*, which supply the rectus inferior, obliquus inferior and lacrimal sac, and (2) *anterior superior alveolar (dental) branches*, which descend via the anterior alveolar canals to supply the upper incisor and canine teeth and mucous membrane in the maxillary sinus. On the face some branches ascend to the medial canthus and lacrimal sac, anastomosing with the terminal rami of the facial; others anastomose with a dorsal nasal branch of the ophthalmic artery and some descend between the levator labii superioris and levator anguli oris, anastomosing with the facial, transverse facial and buccal arteries.

The remaining branches arise in the pterygopalatine fossa. **The greater palatine artery** and nerve descend in their palatine canal; the artery gives off two or three *lesser palatine arteries*, transmitted through lesser palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine. The main vessel emerges on the palate's oral surface by the greater palatine foramen and runs in a curved groove near the alveolar border of the hard palate to the incisive canal; it ascends this canal and anastomoses with a branch of the sphenopalatine artery. It distributes rami to the gingivae, palatine glands and mucous membrane.

The pharyngeal artery, very small, runs back through the pharyngeal (palatovaginal) canal with the pharyngeal branch of the pterygopalatine ganglion; it supplies mucosa of the nasal roof, the nasopharynx, sphenoidal air sinus and auditory tube.

The artery of the pterygoid canal, frequently from the greater palatine, passes back in the pterygoid canal with the corresponding nerve, supplying its walls and contents and the mucous membrane of the upper pharynx, pharyngotympanic tube and tympanic cavity.

The pharyngeal artery is medial, that of the pterygoid canal lateral and the trunk of the maxillary artery passes anterior to the pterygopalatine ganglion.



The sphenopalatine artery, the termination of the maxillary, traverses the sphenopalatine foramen into the walls of the nasal cavity posterior in the superior meatus. Here its *posterior lateral nasal branches* ramify over the conchae and meatuses, anastomosing with the ethmoidal arteries and nasal branches of the greater palatine, supplying the frontal, maxillary, ethmoidal and sphenoidal sinuses. Crossing anteriorly on the inferior sphenoid surface, the artery ends on the nasal septum as the *posterior septal branches*, which anastomose with the ethmoidal arteries; one ramus descends on the vomer to the incisive canal to join the end of the greater palatine artery and septal branch of the superior labial.

Collateral circulation, after interruption of one common carotid, is often established by the connections across the midline between the carotids, intra-and extracranial, and by enlargement of the subclavian branches. Chief extracranial connections are between superior and inferior thyroid arteries, the deep cervical and the descending branch of the occipital; the vertebral artery substitutes for the internal carotid in the cranium. Nevertheless symptoms of cerebral disturbance supervene in about 25%.

After interruption of the *external* carotid, circulation is maintained by anastomoses between most of its large branches (facial, lingual, superior thyroid, occipital) and their fellows, by their anastomosis with branches of the *internal* carotid and of the occipital with branches of the subclavian, etc.

The Triangles of the Neck

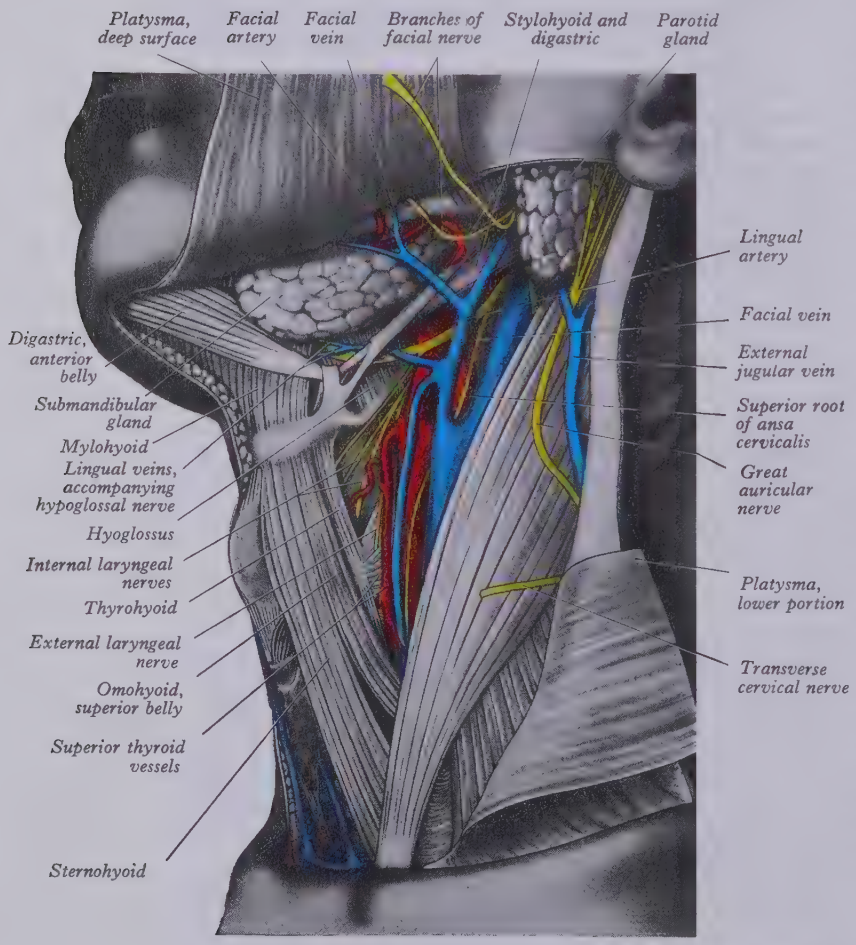
Anterolaterally the neck (6.75) presents a somewhat quadrilateral area, limited *above* by the base of the mandible and a line continued from its angle to the mastoid process, *below* by the clavicle's upper border, *in front* by the anterior median line, *behind* by the anterior margin of trapezius. This region is divided by the sternocleidomastoid, ascending obliquely from the sternum and clavicle to the mastoid process and occipital bone. The area anterior to this is the *anterior triangle* and that behind it the *posterior triangle*. While these and their subdivisions are emphasized by some as being purely arbitrary because many major structures (arteries, veins, lymphatics, nerves, some viscera) transgress their boundaries without interruption, nevertheless they have a topographical value in description. However, two further points should be made. Some of their subdivisions *are* easily identified by inspection and palpation and provide invaluable assistance in surface anatomical and clinical examination (vide infra). As the neck has a roughly cylindrical form, crossed obliquely by the sternocleidomastoid, the names anterior and

6.75 The triangles of the right side of the neck: a highly schematic two dimensional representation of what in reality are non-planar trigones distributed over a waisted column. Submandibular would be an alternative name for digastric.

posterior are not particularly apt; the triangles are not plane (and coplanar as represented in a two-dimensional diagram such as 6.75) but both are spiralized regions (trigones) on the surface of the column.

THE ANTERIOR CERVICAL TRIANGLE

This is bounded anteriorly by the median line and posteriorly by the anterior margin of the sternocleidomastoid, its base being the inferior mandibular border and its mastoid extension noted above; its apex is at the manubrium. It may be subdivided into muscular, carotid, digastric and submental triangles.



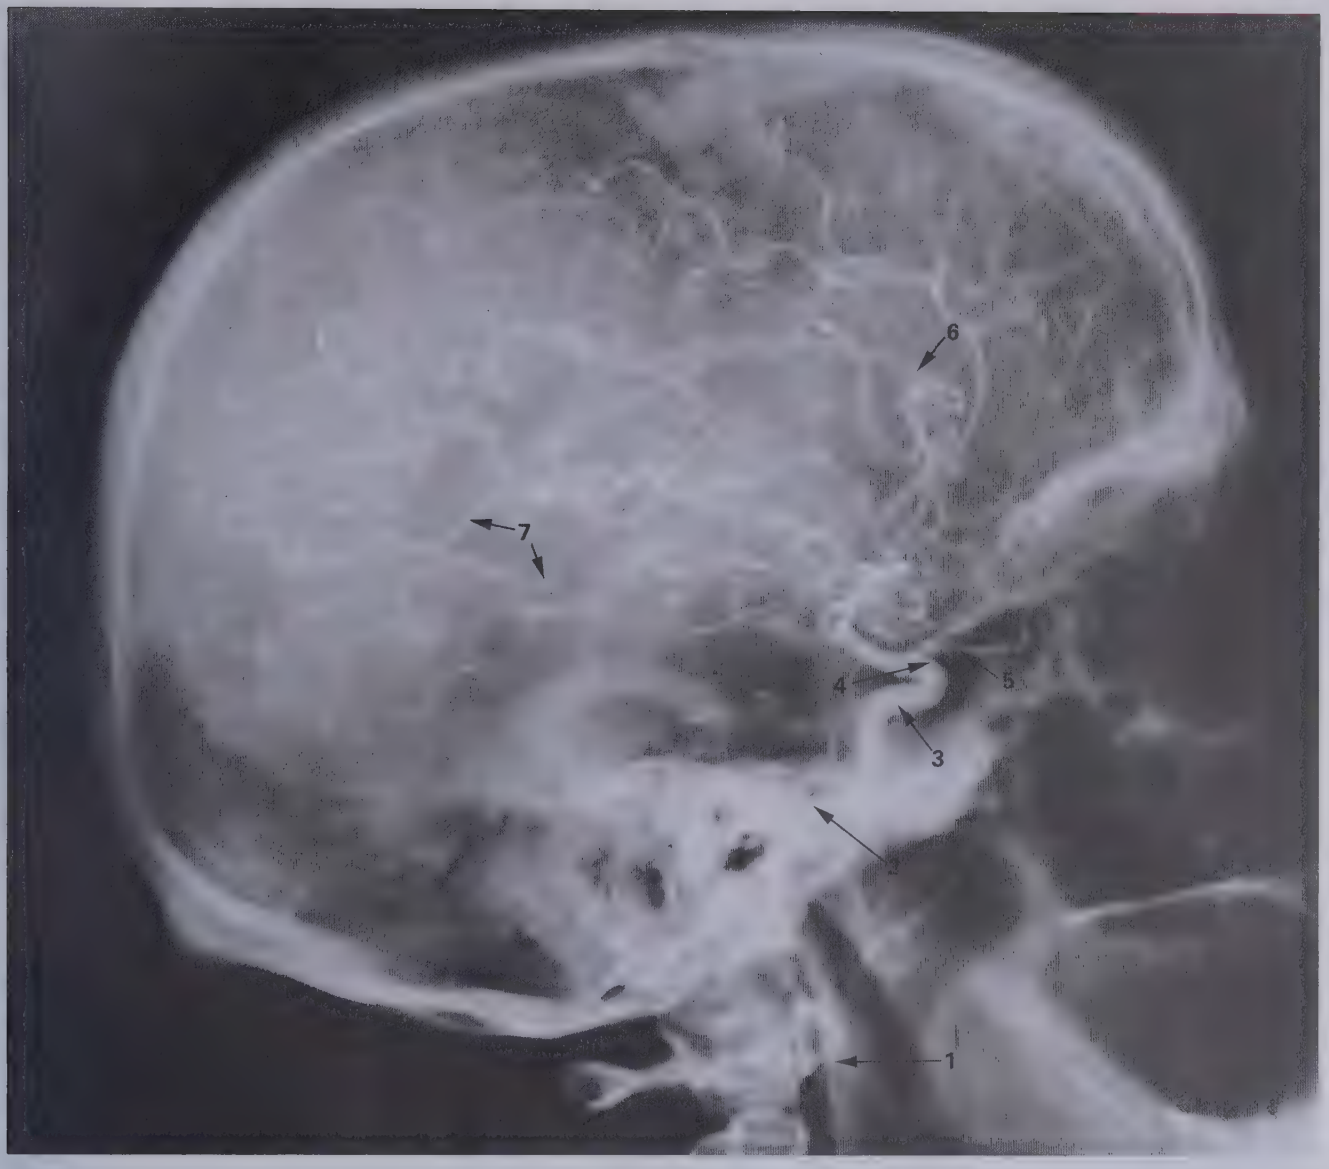
The muscular triangle is bounded by the median line from the hyoid bone to the sternum, inferoposteriorly by the anterior margin of the sternocleidomastoid and posterosuperiorly by the superior belly of the omohyoid.

The carotid triangle is limited posteriorly by the sternocleidomastoid, antero-inferiorly by the superior belly of the omohyoid and superiorly by the stylohyoid and posterior belly of the digastric. In the living, except the obese, the triangle is usually a small visible triangular depression, sometimes best seen with the head and cervical vertebral column slightly extended and the head contralaterally rotated. Often the latter position is quite unnecessary; judicious oblique lighting (window or lamp) throws the hollow into relief.

It is covered by the skin, superficial fascia, platysma and deep fascia containing branches of facial and cutaneous cervical nerves. The *hyoid bone* forms its *anterior angle* and adjacent floor; its position can be located immediately on simple inspection, verified by palpation. Parts of thyrohyoid, hyoglossus and inferior and middle pharyngeal constrictors form its floor. It contains the upper part of the common carotid and its division into external and internal carotid arteries, overlapped by the anterior margin of the sternocleidomastoid; the external carotid is first anteromedial, then anterior to the internal. Branches of the external carotid are also encountered: the superior thyroid runs antero-inferiorly, the lingual anteriorly with its upward loop, the facial anterosuperiorly, the occipital posterosuperiorly and the ascending pharyngeal medial to the internal carotid. Massive arterial pulsation greets the examining finger. The veins correspond to the branches of the external carotid artery: superior thyroid, lingual, facial, ascending pharyngeal and sometimes the occipital, all ending in the internal jugular vein. The hypoglossal nerve crosses both carotid arteries, curving round the origin of the lower sternocleidomastoid branch of the occipital, where the superior root of the ansa cervicalis leaves it, descending anteriorly in the carotid sheath. Medial to the external carotid, below the hyoid bone, is the internal laryngeal nerve and, below this, the external laryngeal. Many structures in this region, such as all or part of the internal jugular vein, associated deep cervical lymph nodes, vagus nerve, etc., may be variably obscured by the sternocleidomastoid and, pedantically, are thus 'outside the triangle'; much more importantly, their location is obvious during clinical examination.

The digastric triangle is bordered above by the base of the mandible (and its projection to the mastoid process), posteroinferiorly by the posterior belly of the digastric and stylohyoid and antero-inferiorly by the anterior belly of digastric. It is covered by the skin, superficial fascia, platysma and deep fascia, in which are branches of facial and transverse cutaneous cervical nerves. Its floor is formed by the mylohyoid and hyoglossus. Its anterior region contains the submandibular gland, superficial to which is the facial vein and deep to it the facial artery, crossing the lower border of the mandible at the anterior edge of the masseter; on the mylohyoid are the submental artery and mylohyoid artery and nerve. Variably related to the submandibular gland are the submandibular lymph nodes (p. 844). Its posterior region contains the lower part of the parotid gland; the external carotid, passing deep to the stylohyoid, curves above the muscle and overlaps its superficial surface where it ascends deep to the parotid gland to enter it. The external carotid, which is superficial to the internal carotid, crosses it posterolaterally; deeper and separated from the external carotid by styloglossus, stylopharyngeus and the glossopharyngeal nerve, are the internal carotid artery, internal jugular vein and vagus nerve.

The submental triangle, unpaired, is demarcated by both digastric muscles (anterior bellies); its apex is at the chin, its base the body of the hyoid and its floor the mylohyoid muscles. It contains lymph nodes and small veins uniting to form the anterior jugular.



6.76 Dissection of the left anterior triangle. The platysma has been divided transversely; its upper part has been turned upwards on to the face, its lower part turned backwards, exposing the lower part of the sternocleidomastoid. Dominating the centre of the illustration is the carotid triangle, with many of its contents and surrounding structures.

THE POSTERIOR CERVICAL TRIANGLE

The posterior triangle is delimited anteriorly by the sternocleidomastoid, posteriorly by the anterior edge of trapezius, inferiorly by the middle third of the clavicle; its apex is between the attachments of the sternocleidomastoid and trapezius to the occiput and is often blunted, the 'triangle' becoming quadrilateral. It is crossed, about 2.5 cm above the clavicle, by the inferior belly of the omohyoid, which divides it into occipital and supraclavicular triangles.

The occipital triangle, the upper, larger part of the posterior triangle, has the same borders, except below where its limit is the omohyoid. Its floor is, from above down: splenius capitis, levator scapulae, and scaleni medius and posterior. (Sometimes semispinalis capitis appears at the apex.) It is covered by the skin, superficial and deep fasciae and below by the platysma. The accessory nerve pierces the sternocleidomastoid and crosses on the levator scapulae obliquely down and back to the deep surface of the trapezius; cutaneous and muscular branches of the cervical plexus emerge at the posterior border of the sternocleidomastoid; below, supraclavicular nerves, transverse cervical vessels and the uppermost part of the *brachial plexus* cross the triangle. Lymph nodes are arranged along the posterior border of the cleidomastoid from the mastoid process to the root of the neck.

6.77 Internal carotid arteriogram (right): lateral view, in adult male of 33 years. The following can be identified: parts of the internal carotid artery (and individual vessels): 1. cervical. 2. intrapetrous. 3. cavernous. 4. terminal. 5. ophthalmic artery. 6. anterior cerebral artery. 7. branches of middle cerebral artery. Note the absence of radio-opaque injectant from the cerebellar vessels.
